W. W. Eberhardt: Mr. Evans has obviously made a misinterpretation of Tables III and IV of our paper in stating that "The Petersen coil installation increased interruptions in the remainder of the system apparently due to excess voltage causing bus flashover and transformer trouble." As pointed out in the explanation of the 1922 interruptions, the 343 minute interruption charged to transformers occurred during a short-circuit test when the Petersen coil was out of service; the interruptions charged to conductors were caused by trees falling on the line; and the interruptions charged to oil switches were caused by mechanical trouble in the switches. These interruptions were obviously, therefore, not caused by any action of the Petersen coil. The only interruptions strictly chargeable to the Petersen coil are the bus insulator flashovers of 79 and 62 minutes in Table IV. Eliminating the cases of trouble not chargeable to the Petersen coil, the total for 1922 would be 9 cases of trouble with a total outage of 155 minutes compared with 45 interruptions in 1921 with a total outage of 304 minutes.

In order to make the comparison between Tables III and IV complete, we wish to present the following tabulation of lightning storms occurring over the Lock 12-Vida line in the years 1921 and 1922.

	1921	1922
January.....	0	3
February.....	7	7
March.....	8	12
April.....	2	8
May.....	6	17
June.....	11	16
July.....	18	16
August.....	19	10
September.....	11	8
Total.....	82	97

From this tabulation it is seen that during the period when the Petersen coil was in service the lightning storms were more numerous than before the installation, thereby making the comparison even more favorable for the Petersen coil.

Mr. Trueblood in his discussion has pointed out that the Petersen coil has been operated with approximately 23 per cent excess reactance. The object in operating above the resonant point is to avoid the continuous flow of the neutral current of 6 amperes at the point of resonance. As pointed out by Mr. Trueblood, the same results could be obtained by operating below the resonant point, with the added advantage of perhaps eliminating the excessive voltages obtained in the past. Experiments will probably be carried out along this line.

Mr. Blume's suggestion of improving the operation of the Petersen coil by the introduction of more resistance, thereby preventing danger due to serious overvoltage and resonance is well taken. As pointed out in our paper, our experiments with the Petersen coil will be continued along the lines suggested, the results of which we hope to have available at some future date.

Frequency Conversion by Third Class Conductor and Mechanism of the Arcing Ground and other Cumulative Surges

BY CHARLES P. STEINMETZ

Fellow, A. I. E. E.
Chief Consulting Engineer, General Electric Co.

Review of the Subject.—In high-voltage power circuits, such as transmission lines and the high-voltage coils of large power transformers, not infrequently disturbances are observed of a frequency differing from, and usually very much higher than that of the power supply, and differing from the typical transient of energy readjustment, in that they do not gradually die out, but increase in intensity until either destruction occurs, or they finally limit themselves. Such cumulative oscillations or arcing grounds derive their energy from the machine power of the system, and so constitute a frequency transformation, of which the mechanism has been little understood.

Physically they may be derived from the typical condenser discharge by the conception of a **negative resistance**, in combination with a **source of power**, which supplies the energy given out by the negative resistance.

Attention is drawn to a class of conductors—to which arcs and gas discharges belong—the so-called “third-class conductors,” in which the voltage decreases with increase of current, and it is shown that these conductors can be considered as a combination of a negative resistance with a source of power, and as such are capable of transforming the low machine frequency into a high oscillation frequency of alternating currents, and their presence in an electric system thereby may produce cumulative oscillations.

The general equations are then derived of a system comprising a third-class conductor shunted by an inductive circuit containing

capacity, and supplied with voltage over an inductive circuit from an alternating low-frequency source, and it is shown that in such a system currents and voltages of two distinct frequencies may continuously exist, of which the one is the machine frequency, the other a high oscillation frequency. It is further shown that the voltage of the latter is limited only by the resistance of the oscillating circuit, and in low-resistance circuits may build up to very high values. Furthermore, the high oscillation frequency is essentially limited to the circuit shunting the third-class conductor and but little of it enters the supply circuit, while the supply frequency enters the shunt circuit to a limited extent only, and both frequencies are superimposed in the third-class conductor as the frequency converter.

A. Physical Explanation

I. THE THIRD CLASS CONDUCTOR

In a first class or metallic conductor, the voltage increases slightly more than proportional to the current, due to a positive temperature coefficient of resistance.

In a second class or electrolytic conductor, the voltage increases slightly less than proportional to the current, due to a slightly negative temperature coefficient of resistance.

As third class conductor may be defined a conductor in which, at least within a certain range of current, the voltage *decreases* with *increase* of current. Third class conductors comprise different types, such as

(a) Electronic or vacuum, gas or Geissler tube (spark) and vapor or arc conduction. In these the decrease of voltage with increase of current is due to the change of the conducting path by the current.

(b) Most of the so-called insulators probably are third class conductors. In these the decrease of voltage with increase of current is a temperature effect. That is, the negative temperature coefficient of resistance is so large that—at least in a certain range—the increase of the conductor temperature with increasing current decreases the resistance more than the current increases.

In Fig. 1, *I* gives the volt-ampere characteristic of a metallic conductor, *II* of an electrolytic conductor, and *III* of an arc as third class conductor. Fig. 2, gives the volt-ampere characteristic of a pyroelectric

FIG. 1—VOLT-AMPERE CHARACTERISTICS OF DIFFERENT CONDUCTOR TYPES

- 1. First class or metallic conductor
- 2. Second class or electrolytic conductor
- 3. Arc as third class conductor

conductor, a Nernst lamp glower, which in the range above 0.02×10^{-3} ampere is a third class conductor

(plotted for convenience with the fourth root of current and voltage as coordinates).

Such a volt-ampere characteristic of a third class conductor can be considered as a combination of a constant e. m. f. E_1 and an effective negative resistance r_1 :

$$e = E_1 - r_1 i$$

The effective negative resistance r_1 decreases with increase of current, as $r_1 i$ must always remain smaller than E_1 .

II. TIME LAG

If the current in the third class conductor varies periodically, between i_1 and i_2 , the voltage also will vary periodically, between e_1 and e_2 , and if the variation is slow enough so that at every value of current stationary condition is reached, the variation of voltage is inverse to that of current. That is, if i_1 is the minimum value of current, the corresponding value of voltage e_1 is the maximum value, and inversely. If however, the variation is sufficiently rapid, a lag of the voltage occurs

FIG. 2—VOLT-AMPERE CHARACTERISTIC OF NERNST LAMP GLOWER
As Third Class Conductor

behind the current, that is, the maximum value of voltage is not reached at the minimum value of current, but a little later, and so the minimum value of the voltage is reached a little later than the maximum value of current, and correspondingly, the amplitude of the variation is reduced, the more so, the more rapid the pulsation.

This time lag of the third class conductor, and the reduction of amplitude of variation resulting from it, depends on the nature of the conductor. It is extremely small in ionic conduction, but may be very considerable where the variation of the effective resistance of the third class conductor is a temperature effect.

As first approximation, the periodic variations of current and voltage in a third class conductor thus may be expressed by:

$$i = I_0 - I \sin 2\pi f t$$

$$e = E_0 + E \sin (2\pi f t - \varphi)$$

where the lag angle φ increases with increasing fre-

quency f of the pulsation. It is negligible for very low frequency, and becomes 90 deg., and the amplitude of the resistance variation therefore negligible, for very high frequency.

In ionic conduction, φ is still small at ratio frequencies; in the Nernst lamp glower (temperature effect) φ is already practically 90 deg. at 60 cycles.

The volt-ampere characteristic of the third class conductor under rapidly varying current (its "transient characteristic") thus differs more or less from its "permanent" characteristic as shown in Figs. 1 and 2.

III. THE CONDENSER DISCHARGE

If a condenser of capacity C discharges through an inductance L and (constant) ohmic resistance r , and the latter is below the critical value, the discharge current is oscillatory, that is, consists of successively alternating half waves of constant frequency and uniformly decreasing amplitude. The decrease of the current, or the "attenuation" is given by the exponential factor:

$$A = e^{-\frac{r}{2L}t}$$

If then the discharge circuit of the condenser contains, besides the ohmic resistance r , a third class conductor of the effective negative resistance r_1 , the attenuation of the condenser discharge is:

$$A = e^{-\frac{r-r_1}{2L}t}$$

Thus, if the effective negative resistance r_1 is greater than the ohmic resistance r , the exponent

$$-\frac{r-r_1}{2L}t$$

is positive, and A increases with the time t , thus is not an attenuation but an accumulation. The amplitudes of successive half waves of the condenser discharge current then progressively increase, that is, we get a cumulative surge.

As seen in I , the effective resistance r_1 of the third class conductor decreases with increase of current. In such a cumulative surge produced by the presence of a third class conductor in the inductive condenser discharge circuit, the successive half waves of current will progressively increase, until by the increase of current the effective negative resistance r_1 has decreased to equality with the ohmic resistance r , and the exponent of the exponential term A has become zero, $A = 1$, and the successive half waves of the condenser discharge current become equal, that is, an alternating current results.

Thus the final result of a condenser discharge through a third class conductor of sufficiently high effective negative resistance is an alternating current of a frequency determined by the circuit constants.

IV. ENERGY RELATIONS

A current i through the effective negative resistance $-r_1$ consumes a voltage $-r_1 i$ which is in phase with the current, thus represents electric power generation.

Hence an effective negative resistance can exist independently only in the presence of some other source of energy, supplying the power (mechanical drive for instance). Thus an electric generator may be considered as an effective negative resistance. The most typical negative resistance is the induction machine driven above synchronism, since (below saturation) it generates a voltage proportional to the current, thus is a constant negative resistance.

As seen in *I*, a third class conductor may be considered as the combination of a counter e. m. f. E_1 , and an effective negative resistance $-r_1$: $e = E_1 - r_1 i$. As $r_1 i$ must always remain smaller than E_1 , therefore the power generated by the effective negative resistance: $-r_1 i^2$ always is less than the power consumed by the counter e. m. f. E_1 : $E_1 i$ and the counter e. m. f. E_1 thus abstracts from the electric circuit the power which is returned by the effective negative resistance r_1 .

In the condenser discharge through a third class conductor, the current wave builds up cumulatively by the effective negative resistance r_1 , but the condenser voltage is lowered discontinuously by the counter e. m. f. E_1 , at every reversal of current, and with it the current wave is lowered, and as E_1 is greater than $r_1 i$, the discharge oscillation gradually dies out, (though by a different law than in the standard condenser discharge equation,) as discussed in a previous paper.¹

If however the counter e. m. f. E_1 of the third class conductor is supplied by some outside source of electric power, and therefore does not abstract energy from the condenser discharge, then the cumulative effect of the negative resistance of the third class conductor r_1 on the condenser discharge current i would continue until limited by the decrease of r_1 with increasing i , and an alternation results.

Now the importance of this phenomenon is, that the character of the supply voltage giving the counter e. m. f. E_1 has no necessary relation to the frequency of the condenser discharge; the latter is determined by the values of the capacity and inductance, and may be a high or very high frequency, while E_1 may be of machine frequency, 25 or 60 cycles, or even continuous voltage. The power supplied by the effective negative resistance to the high-frequency condenser discharge is derived from the counter e. m. f. E_1 and the latter is fed from the low-frequency machine power. We therefore have here a frequency transformation giving a steady power supply to the high-frequency oscillation, so that the latter are not any more limited energy transients, but unlimited power permanents, of corresponding destructiveness. As such they have been frequently observed in electric power systems, as arcing grounds in transmission lines, and as high-frequency cumulative surges in the high-voltage coils of large power transformers.

As the exact mechanism of this frequency transforma-

tion from the low machine power frequency to the high frequency of the cumulative surge is not generally familiar, the following may be of interest, though a similar problem has been studied in a different manner in radio engineering in the theory of the vacuum tube as oscillator.

V. FREQUENCY

Suppose a condenser of capacity C discharges through an inductance L , an ohmic resistance r and a third class conductor N , and upon this third class conductor, a constant alternating voltage e_0 is impressed through a supply circuit of resistance r_0 and inductance L_0 , as shown diagrammatically in Fig. 3. We can consider the arrangement as a divided circuit consisting of a third class conductor N in shunt to the circuit C, L, r , and energized over the circuit L_0, r_0 by voltage e_0 .

We can assume that r is sufficiently small to make the condenser discharge oscillatory, and that the frequency f of this oscillation is high compared with the frequency f_0 of the supply voltage e_0 .

FIG. 3—CIRCUIT DIAGRAM OF FREQUENCY TRANSFORMATION BY THIRD CLASS CONDUCTOR

N : Third class conductor

C = Capacity, L = inductance, r = resistance of shunt circuit

L_0 = Inductance, r_0 = resistance of supply circuit

e_0 = low-frequency supply voltage

Denoting then the currents in the two branch circuits by i and i_1 , the voltage by e_1 , the differential equations can be written as those of a circuit containing resistance, inductance and capacity.

As seen therefore, if the effective negative resistance of the third class conductor is sufficiently high, the oscillatory starting transient of the condenser C does not die out, but cumulatively increases in amplitude, until limited by the decreasing negative resistance, and so reaches an alternating sine wave as final value, i , i_1 and e_1 then must consist of sine waves.

The differential equations are therefore integrated by representing i , i_1 and e_1 by summation of sine waves.

$$\sum B \sin (q t - \beta)$$

substituting these into the differential equations, and from the identities thus produced, calculate the constants B , β etc.

One of the terms must be of the supply frequency $q = 2 \pi f_0$, and the amplitude and the phase angle of its currents and voltages are given by the terminal condition, that the supply voltage is e_0 .

This term merely gives the permanent low-frequency alternating current and voltage distribution in the divided circuit Fig. 3.

B. Mathematical Calculation

I. GENERAL EQUATION

Let a third class conductor be shunted by a circuit of capacity C , inductance L , and ohmic resistance r and supplied by a constant alternating e. m. f. of machine frequency, over a resistance r_0 and inductance L_0 .

We may assume that r is below the critical value, so that the current in C , L , r is oscillatory, and that the frequency of oscillation of this circuit is high compared with the machine frequency, and that L_0 is large compared with L .

Let the alternating supply e. m. f. be a sine wave:

$$e_0 = E_0 \sin (q_0 t - \alpha) \quad (1)$$

where:

$$q_0 = 2 \pi f_0 t,$$

and,

$$f_0 = \text{frequency of power supply.}$$

Let:

e_1 = voltage at the terminals of the third class conductor

i_1 = current in the third class conductor

i = current in the circuit C , L , r shunting the third class conductor

e' = voltage at the terminals of the condenser C .

e_0 , e_1 , i_1 , i and e' being counted in the direction as indicated by the arrows in Fig. 3.

It is then, at the condenser C :

$$i = C \frac{d e'}{d t} \quad (2)$$

It is, in the closed circuit between the third class conductor and the capacity inductance shunt:

$$e_1 = e' + r i + L \frac{d i}{d t} \quad (3)$$

Hence, differentiating (3) and substituting (2) therein, gives:

$$\frac{d e_1}{d t} = i/C + r \frac{d i}{d t} + L \frac{d^2 i}{d t^2} \quad (4)$$

It is, in the supply circuit:

$$e_0 = e_1 + r_0 (i_1 + i) + L_0 \frac{d (i_1 + i)}{d t} \quad (5)$$

and the voltage across the condenser terminal is, by (3):

$$e' = e_1 - r i - L \frac{d i}{d t}$$

Assuming that the circuits have been closed suf-

ficiently long to reach stationary conditions, that is, that the starting transient has passed and any cumulative oscillation which may occur has built up to its final value.

e_1 , i_1 and i then must be periodic functions, and as such may be represented by a sum of sine waves:

$$\left. \begin{aligned} e_1 &= \sum E_1 \sin (q t - \beta) \\ i_1 &= \sum I_1 \sin (q t - \gamma) \\ i &= \sum I \sin (q t - \omega) \end{aligned} \right\} \quad (7)$$

Substituting (7) into (3) then must give an identity, that is, the coefficient of $\cos q t$ and $\sin q t$ must individually disappear. This gives:

$$\left. \begin{aligned} E_1 \cos \beta &= I (r \cos \omega - R \sin \omega) \\ E_1 \sin \beta &= I (r \sin \omega + R \cos \omega) \end{aligned} \right\}$$

where

$$R = \frac{1}{q C} - q L \quad (8)$$

Herefrom follows:

$$E_1 = z I \quad (9)$$

and

$$\tan \omega = \frac{r \sin \beta - R \cos \beta}{r \cos \beta + R \sin \beta} \quad (10)$$

where:

$$z = \sqrt{R^2 + r^2} \quad (11)$$

Substituting (1) and (7) into (5) then gives:

$$\begin{aligned} E_0 \sin (q_0 t - \alpha) &= \sum E_1 \sin (q t - \beta) \\ &+ \sum z_0 \{ I_1 \cos (q t - \gamma - \zeta) + I \cos (q t \\ &\quad - \omega - \zeta) \} \end{aligned} \quad (12)$$

where:

$$z_0 = \sqrt{q^2 L_0^2 + r_0^2} \quad (13)$$

$$\tan \zeta = \frac{r_0}{q L_0} \quad (14)$$

II. LOW FREQUENCY TERMS

(12) also must be an identity. That is, the coefficients of $\cos q t$ and $\sin q t$ must individually vanish. This gives, for: $q = q_0$; denoting the terms by the index 0:

$$\left. \begin{aligned} E_0 \sin \alpha &= E_1 \sin \beta_0 - z_0 \{ I_1 \cos (\gamma_0 + \zeta_0) \\ &\quad + I \cos (\omega_0 + \zeta_0) \} \\ E_0 \cos \alpha &= E_1 \cos \beta_0 + z_0 \{ I_1 \sin (\gamma_0 + \zeta_0) \\ &\quad + I \cos (\omega_0 + \zeta_0) \} \end{aligned} \right\} \quad (15)$$

Let:

$$r_1 = E_1 / I_1 \quad (16)$$

= effective resistance of the third class conductor.

IV. AMPLITUDE

Combining the low and high-frequency terms then gives the total expressions of current and voltage:

$$\left. \begin{aligned} e_0 &= E_0 \sin(q_0 t + \alpha_0) \\ \tan \alpha_0 &= + \frac{x_0}{r_1} \\ e_1 &= \frac{E_0}{\sqrt{1 + \left(\frac{x_0}{r_1}\right)^2}} \sin q_0 t + E_1 \sin(q t - \delta) \\ q &= -\frac{r}{2L} \tan \delta + \sqrt{\frac{1}{LC}} + \frac{r^2}{4L^2} \tan^2 \delta \\ i_1 &= \frac{E_0}{\sqrt{r_1^2 + x_0^2}} \sin q_0 t - \frac{E_1 \cos \delta}{r} \sin q t \\ i &= \frac{E_0}{k \sqrt{1 + \left(\frac{x_0}{r_1}\right)^2}} \cos q_0 t + \frac{E_1 \cos \delta}{r} \sin q t \\ i_0 &= i_1 + i \\ &= \frac{E_0}{\sqrt{r_1^2 + x_0^2}} \{\sin q_0 t + r_1/k \cos q_0 t\} \end{aligned} \right\} \quad (35)$$

where:

$$\left. \begin{aligned} q_0 &= 2 \pi f_0 \\ x_0 &= q_0 L_0 \\ k &= \frac{1}{q_0 C} \end{aligned} \right\} \quad (36)$$

r_1 = resistance of third class conductor.

Substituting into equation (6), gives the terminal voltage e' of the condenser C .

$$e' = \frac{E_0}{\sqrt{1 + \frac{x_0^2}{r_1^2}}} \sin q_0 t = E_1 \left(\sin \delta + \frac{qL}{r} \cos \delta \right) \cos q t \quad (37)$$

As seen, the high-frequency term of e' indefinitely increases with decreasing r . That is, the cumulative oscillation builds up to the resonance voltage of L and C , or until limited by the ohmic resistance.

Thus, where r is small, as in the high-voltage coils of power transformers, very high voltages may be produced.

As discussed in A III the second term in i_1 and e_1 must always be smaller than the first term. That is, it must be, in i_1 :

$$\frac{E_1 \cos \delta}{r} < \frac{E_0}{\sqrt{r_1^2 + x_0^2}}$$

Thus we may substitute:

$$\frac{E_1 \cos \delta}{r} = p \frac{E_0}{\sqrt{r_1^2 + x_0^2}} \quad (38)$$

where:

$$p < 1$$

Equations (35) thus become:

$$\left. \begin{aligned} i_1 &= \frac{E_0}{\sqrt{r_1^2 + x_0^2}} \sin q_0 t \{1 - p \sin q t\} \\ \text{and:} \\ e_1 &= \frac{E_0}{\sqrt{1 + \frac{x_0^2}{r_1^2}}} \sin q_0 t \left\{ 1 + p \frac{r}{r_1 \cos \delta} \sin(q t - \delta) \right\} \end{aligned} \right\} \quad (40)$$

As the second term in e_1 must be less than the first, it must be:

$$\frac{p r}{r_1 \cos \delta} \leq 1$$

or:

$$r \leq \frac{r_0 \cos \delta}{p}$$

or:

$$r_1 \cos \delta \geq p r$$

Herefrom follows:

(1) With a given resistance r of the oscillating circuit, the oscillation increases, that is, current and voltage build up, until they reach the values, at which the transient effective negative resistance of the third class conductor, $r_1 \cos \delta$, has dropped down to equality with the resistance r , or rather slightly lower.

(2) When in the inductive condenser shunt to a third class conductor, the ohmic resistance r is increased, the cumulative high-frequency oscillation still occurs—though of an amplitude decreasing with increase of the resistance r —until the ohmic resistance becomes equal to the transient negative resistance of the third class conductor, $r_1 \cos \delta$, or rather slightly larger. Then the oscillation stops.

(3) The amplitude e' of the voltage oscillation produced by the third class conductor, is approximately inverse proportional to the resistance of the oscillating circuit. (As seen by equation (37)).

V. INSTANCES

(1) Spark discharge on high-voltage coil of 60,000 volt 3000-kw. 60-cycle power transformer.

Let the constants be:

r = 6 ohms, or about 0.5 per cent resistance of the coil

L = 0.1 h, or about 3 per cent reactance

C = 0.0001 mf.

L_0 = 0.6 h, or about 20 per cent reactance of supply circuit

r_0 = 40 ohms, or about $3\frac{1}{3}$ per cent resistance of supply circuit

f_0 = 60 cycles, thus $q_0 = 2 \pi f_0 = 377$

(39) E_0 = 60,000 $\sqrt{2}$ = 85,000 volts.

Assuming $\delta = 60$ deg. as time lag at the oscillation frequency.

It is then, by equations (35) to (37):

$$\begin{aligned} q &= 316,000 = 837 q_0 \\ f &= 50,300 \text{ cycles} \\ x_0 &= 226 \text{ ohms} \\ qL &= 31,600 \text{ ohms} \\ k &= 26,600,000 \text{ ohms} \end{aligned}$$

Assuming the effective resistance of the oscillating circuit increased to 10 times the ohmic resistance, by the energy losses in the insulation etc. at the high frequency, that is:

$$r = 60 \text{ ohms.}$$

and assuming stationary conditions reached by the transient effective resistance of the spark discharge having dropped to equality with the ohmic resistance, that is:

$$r_1 \cos \delta = 60, \text{ and } r_1 = 120 \text{ ohms}$$

this gives:

$$\alpha_0 = 62 \text{ deg.}$$

and, denoting:

$$\varphi = q_0 t, \text{ gives:}$$

$$\begin{aligned} e_0 &= 85,000 \sin(\varphi + 62.) \\ e_1 &= 47,000 \sin \varphi \{1 + \sin(837 \varphi - 60.)\} \\ i_1 &= 392 \sin \varphi \{1 - \sin 837 \varphi\} \\ i &= 392 \sin \varphi \sin 837 \varphi \\ i_0 &= 392 \sin \varphi \\ e' &= 47,000 \sin \varphi \{1 - 263 \cos 837 \varphi\} \end{aligned}$$

or a maximum value of the condenser voltage of over 12 million volts.

Obviously, no such voltage is reached, but the insulation destroyed before the cumulative oscillation is built up to full value.

(2) Arcing ground on 30 mile three phase transmission line supplied with 30,000 volts, 60 cycles from generator and step up transformer.

Let the constants be:

$$\begin{aligned} r &= 4 \text{ ohms} \\ L &= 12 \text{ mh.} \\ C &= 0.3 \mu\text{f} \\ L_0 &= 0.2 \text{ h.} \end{aligned}$$

$$r_0 = 6 \text{ ohms}$$

$$f_0 = 60 \text{ cycles, thus } q_0 = 377$$

$$E_0 = 30,000 \sqrt{2} = 42,500 \text{ volts.}$$

Assuming $\delta = 45$ deg. as time lag at the oscillation frequency.

It is by equations (35) to (37):

$$\begin{aligned} q &= 16,500 = 44 q_0 \\ f &= 2640 \text{ cycles} \\ x_0 &= q_0 L_0 = 75.4 \text{ ohms} \\ qL &= 198 \text{ ohms} \end{aligned}$$

$$k = \frac{1}{q_0 C} = 8800 \text{ ohms}$$

Assuming as effective resistance of the oscillating circuit at 2640 cycles, twice the ohmic value, or:

$$r = 8 \text{ ohms.}$$

gives as limiting value of the transient effective negative resistance.

$$r_1 \cos \delta = 8, \text{ and } r_1 = 11.3 \text{ ohms}$$

This gives:

$$\alpha_0 = 81.5 \text{ deg.}$$

and, denoting:

$$\begin{aligned} \varphi &= q_0 t; \text{ gives} \\ e_0 &= 42,500 \sin(\varphi + 81.5 \text{ deg.}) \\ e_1 &= 6300 \sin \varphi \{1 + \sin(44 \varphi - 45 \text{ deg.})\} \\ i_1 &= 560 \sin \varphi \{1 - \sin 44 \varphi\} \\ i &= 560 \sin \varphi \sin 44 \varphi \\ i_0 &= 560 \sin \varphi \\ e' &= 6300 \sin \varphi \{1 - 19.2 \cos 44 \varphi\} \end{aligned}$$

or approximately:

$$e' = 120,000 \sin \varphi \cos 44 \varphi$$

That is, the arcing ground in this case produces a continuous oscillation which builds up to nearly three times the normal line voltage.

It is interesting to note that the cumulative surge of the arcing ground in a transmission line does not reach such excessive values as that in the high-voltage coil of the power transformer, but may be of moderate intensity, of the magnitude of the normal line voltage.

Discussion

THE subject of arcing grounds in transmission systems is one of the greatest interest to operators of power systems of any extent. The almost universal grounding of the neutral in this country is done primarily to alleviate the destructive effects produced by arcing grounds. However, in spite of its great importance, a clear understanding of what happens in an arcing ground is not general. There is no agreement as to the magnitudes of voltages and surges produced, and the various theories proposed call for different properties of the arc. The authors therefore considered it well worth while to attempt in the laboratory to duplicate the conditions of an arcing ground on a transmission system and by spark gap determinations of voltages and by oscillograms to determine the maximum voltages developed and to discriminate between the various theories proposed.

TRANSIENT CONDITIONS IN ELECTRICAL SYSTEMS

Any sudden change in the constants in an electrical system in general produces transient oscillations which superimpose themselves upon the normal voltage and current distributions in the system. A simple example may be given in the closing of a switch in a circuit containing inductance and capacity in series, such as is indicated in Fig. 1A. Fig. 1B shows the manner in which the condenser acquires the voltage of the power supply, the battery. The voltage on the condenser does not at once come to that of the battery but there is a transient oscillation about this voltage provided the resistance in the circuit is not too great. The initial amplitude of the oscillation will be equal to the change in voltage which the condenser must undergo in passing from its initial condition to the final steady condition. Therefore, in Fig. 1B the maximum voltage which the condenser momentarily takes on is approximately twice the voltage of the supply.

In respect to the effect upon the insulation of electrical apparatus two factors must be considered in these transient oscillations. One is the absolute value of the potential reached in the oscillation and the other is the rapidity or steepness with which the potential changes during the transient condition. The latter factor plays an important part in determining the distribution of

potentials within the apparatus during the transient condition, whereas the former determines the stress upon the insulation to ground. In transmission systems rapidly changing or steep wave front surges are impressed upon the apparatus as a result of the distributed character of the inductance and capacity as will be explained in more detail later in the paper. The type of oscillation considered in the first part of the paper, which will deal entirely with lumped inductances and capacitances, will involve changes of potential which are so slow that practically only the absolute value to ground will be important.

It is obvious that an arc when it starts constitutes just such a sudden change in the constants of a circuit

FIG. 1—SIMPLE OSCILLATING CIRCUIT

as has just been described so that when it strikes, an arcing ground must necessarily set up oscillations similar to those set up by closing a switch. However, there is a consensus of opinion that an arcing ground has in it more elements of danger than would correspond merely to this effect. It is generally believed that short-circuiting a line permanently to ground will not produce nearly the same disastrous results as arcing grounds are known to do.

THEORIES OF THE ARCING GROUND

Three theories to explain the high voltages induced by arcing grounds have been proposed. To explain these three theories in a similar manner the authors prefer to describe the action going on in an arc by an artifice of properly manipulated switches. The resistance of an arc is not a constant quantity but may vary from a practically infinite value when the current through it is very small, to an almost zero value when the current

through it is very large. Thus when alternating or pulsating currents traverse the arc the resistance of the arc may undergo changes which may keep pace with these pulsations or alternations of current. A switch also may be made to vary the resistance in a circuit from very high to very low values. The three theories may be classified according to how the change of resistance of the arc from low to high values or vice versa or the equivalent switching is controlled.

THEORY I. SWITCHING CONTROLLED BY THE HIGH-FREQUENCY OSCILLATION

This is usually known as the theory of generation of high-frequency by the "negative resistance" of the arc. The Poulsen arc generator of radio frequency currents operates on this principle. The manner in which oscillations are built up when a switch is operated synchronously with the natural period of an oscillating circuit which it shunts may be seen from Fig. 2. Fig. 2A shows the circuit diagrammatically and Fig. 2B shows the building up of voltage on the condenser as the switch is operated. Beginning with the switch open, the condenser C is charged to the voltage of battery B with zero current flowing through the inductance L and resistance R . On closing the switch the condenser begins to discharge through the inductance giving an oscillation, such as has just been described, about the zero voltage value to which the condenser would ultimately come if the switch remained closed. However, suppose at the end of a half cycle of this oscillation at the moment the current from the condenser is zero, the switch is opened. At this moment the condenser has a nega-

FIG. 2—GENERATION OF OSCILLATIONS BY SYNCHRONOUS SWITCH

tive voltage equal in magnitude to the positive voltage which was first impressed upon it. An oscillation then begins in the circuit consisting of the condenser, inductance, resistance and battery. At the start of this oscillation the voltage of the condenser will add to the voltage of the battery in building up current through the inductance L and the resistance R . If the switch were left permanently open after the transient oscillation, the condenser would again come to have the volt-

age of the battery B . The amplitude of the oscillation will therefore, as Fig. 2B shows, be equal to twice the battery voltage so that the maximum potential which the condenser attains will be after the first half cycle of this oscillation equal to three times the battery voltage.

Now suppose at this moment the switch is again closed. The condenser, charged to three times battery voltage, again undergoes an oscillation and after a half cycle has a negative voltage three times that of the battery. We may again suppose the switch opened.

FIG. 3—SWITCHING CONTROLLED BY 60-CYCLE CONDITIONS IN SINGLE-PHASE CIRCUIT

The oscillation which then takes place in a half cycle will bring the condenser to a positive voltage of five times that of the battery. In this way the voltage on the condenser may build up to indefinitely large values.

Of course the resistance of an actual arc may not range from zero to infinite values. A closer approximation to the action of an arc building up oscillations, due to its "negative resistance" characteristic may be obtained by using one or more switches shunted by and in series with properly chosen resistances.

To apply this theory to an arcing ground on a transmission system, Fig. 3A will more nearly represent actual conditions. The oscillating circuit will then be the inductance and the capacitance of the grounded phase, L_1 and C_1 , or the inductance of the generating system and the inductances and capacitances, L_2 and C_2 , of the ungrounded phases, or both.

THEORY II. SWITCHING CONTROLLED BY 60-CYCLE CONDITIONS

Again using Fig. 3 we may follow the oscillations and the resultant development of potentials which ensue when the changes in the resistance of the arc or the opening and closing of the equivalent switch are controlled entirely by 60-cycle conditions. Let us suppose that the striking of the arc or closing of the switch takes at the moment when the 60-cycle voltage across it is a maximum and that the extinction of the arc or opening of the switch takes place when the 60-cycle current

through it is passing through zero. Assume that the two capacitances in Fig. 3A are equal or that a single-phase transmission line is being considered. Just before the first closing of the switch the voltages on the condensers will be as shown in portion 1-2, in Fig. 3B. Now, when the arc strikes or the switch closes at 2, $L_1 C_1$ undergoes a rapidly damped oscillation, damped because we are supposing that the resistance of the arc does not follow or synchronize with this high-frequency oscillation. $C_2 L_2$, together with the inductance of the supply system, will undergo a somewhat lower frequency oscillation, but also damped. The maximum potential reached by C_2 during this oscillation will be three times normal voltage while the maximum voltage reached by C_1 will be nearly equal to normal voltage. When the effects of these oscillations have completely disappeared the voltage on C_1 will remain zero, while the voltage on C_2 will be 60 cycles and double its former value and equal to that impressed by the generating system. This condition of affairs is shown in portion 2-3, in Fig. 3B.

The current through the arc or closed switch is now the charging current of the condenser C_2 . It will, therefore, be zero at the moment when the voltage on C_2 is a maximum. Let us suppose, then, that at such a moment the arc extinguishes or that the switch is opened. Opening the switch at this point evidently leaves a charge trapped on the condensers. From this point on the variation in supply voltage will again divide equally between the condensers. The course of of these voltages will then be as shown in portion 3-4, Fig. 3B; the charge which is retained upon the condensers causes their respective voltage waves to be displaced from the former zero line by an amount equal to their normal voltage.

If the leakage of the condensers is small this condition will persist until the arc strikes or the switch closes for its second time. Again we assume that this closing of

FIG. 4—CURVES OF FIG. 3 REFERRED TO COMMON ZERO

the switch takes place at the maximum of the voltage wave. Immediately after the striking of the arc transient oscillations take place, as shown at 4, in Fig. 3B, just as took place at 2. However, it is obvious that now the amplitude of oscillation of C_2 will be twice as great as that at 2 so that the maximum voltage reached will be four times normal voltage. The maximum voltage reached by C_1 will be twice normal voltage. Now if we suppose the switch stays closed so that these oscillations completely damp out we will again be back in

the condition shown in portion 2-3. Again, during the period 4-5, the voltage on C_1 will remain zero and that on C_2 will be 60-cycle and of double normal value. Again the arc will extinguish or the switch will open when the 60-cycle current through it is zero, which will be at a maximum of the voltage wave of C_2 , as shown at 5. When the switch does open we will then be exactly in the condition as shown at 3 so that should the arc strike again an oscillation will again take place exactly as shown at 4 with the development again of voltage four times normal on C_2 and twice normal on C_1 . Thus, however often the arc may restrike and re-

FIG. 5—SWITCHING CONTROLLED BY 60-CYCLE CONDITIONS IN THREE-PHASE CIRCUIT

extinguish, conditions will not become any worse than that shown at 4.

To follow conditions more clearly in the three-phase case, which will now be considered, it is desirable to combine the two curves of Fig. 3B upon a common zero line as shown in Fig. 4. Studying the curve of Fig. 4 we see that during the periods when the arc is extinguished, 1-2, 3-4, 5-6, the two curves preserve an invariable relation to each other but that after the extinction of the arc 3-4, 5-6 are displaced so that they become tangent to the normal zero line. During the periods that the arc is on 2-3, 4-5, one of the condensers, except for the transient oscillations, has a zero voltage. The amplitude of the oscillation which takes place upon each striking of the arc is equal to the change in voltage which the condensers must respectively undergo in passing from the steady condition before the striking of the arc to the steady condition after the striking of the arc.

Being guided by Fig. 4, we may now readily draw the course of voltages under this theory for the case of a three-phase transmission system. Fig. 5A is the diagram of the three-phase circuit and 5B shows the voltages on the condensers. Before the striking of the arc in the portion 1-2 of Fig. 5B the three voltage waves are in three-phase relation and symmetrical about the zero line. After the first striking of the arc and after the initial oscillations have died down, just as in Fig. 4, one of the voltages will be reduced to zero while the other two will take delta voltage symmetrical about

the zero line. This is shown in portion 2-3. When the arc extinguishes the three voltage waves will have the same position relative to each other as they had in the portion 1-2 but will now be displaced so that they are tangent to the zero line. After the arc extinction again at 4 and after the oscillations have damped out one of the voltages will again be zero and the other two will be delta voltages about the zero line. After the extinction of the arc at 5 the voltages will be relative to each other again as in portion 1-2, but again will be displaced so as to be tangent to the zero line as in 3-4. The steady conditions of voltage before and after the striking of the arc being known, the amplitudes of the oscillations are readily determined. The amplitude will, of course, be equal to the amount by which the voltage on any one condenser must change to get from the value it had in the steady state it was leaving to the value it will have in the steady state it is reaching.

At the moment 2 in Fig. 5, condensers C_2 and C_3 , just before the striking of the arc, have the voltage $\frac{1}{2} E$, where E is the normal voltage to neutral. After the arc has been on long enough for steady conditions to be reached the voltage will be $1\frac{1}{2}$ times normal voltage to neutral. The amplitude of the oscillation which takes place in going from the one condition to the other will therefore be equal to the difference of $1\frac{1}{2} E$ and $\frac{1}{2} E$, or equal to E . Hence, it is obvious that the maximum of voltage reached by the condensers C_2 and C_3 will be $2\frac{1}{2}$ times E .

Upon the second striking of the arc at 4, conditions are different because of the fact that the voltage waves are displaced in the portion 3-4. Here, before the striking of the arc, the voltage to ground of the condensers C_2 and C_3 will be $-\frac{1}{2} E$. After the arc has been on long enough for conditions to become steady the voltage of condensers C_2 and C_3 will have become $+1\frac{1}{2}$ times E . The amplitude of the intervening oscillation, therefore, will be equal to 2 times E , so that the maximum voltage reached by the condensers C_2 and C_3 will be $3\frac{1}{2} E$.

From this point on, conditions will repeat with the development of no higher voltages. Inspection of 5B shows that the maximum voltages reached by the short-circuited condenser C_1 will be equal to E on the first striking of the arc at 2, and $2E$ on subsequent strikings, as at 4.

THEORY III. SWITCH CLOSING CONTROLLED BY 60 CYCLES AND OPENING BY HIGH FREQUENCY

This is a theory which has been advanced and elaborated by Petersen¹ in recent years. This theory assumes that the arc strikes at or near the maximum of the 60-cycle voltage wave but that the arc extinguishes at a moment when the arc current passes through zero

1. E. T. Z. 38 Heft 47, Nov. 22, 1917, pp. 553-555.

E. T. Z. 38 Heft 48, Nov. 29, 1917, pp. 564-566.

as a result of that high-frequency oscillation which is of intermediate frequency.

Referring to Fig. 6, we may follow the development of voltages consequent upon this hypothesis. Again considering the equivalent of a single-phase line with equal condensers C_1 and C_2 , we have before the striking of the arc equal voltages symmetrical about the zero line in the portion 1-2 of Fig. 6B. The arc is then supposed to strike at 2 when the voltages are maximum. The short-circuited condenser undergoes a damped oscillation of high frequency. The other condenser begins an oscillation which will be of lower frequency because it includes the inductance of the generating system. The initial amplitude of this oscillation is evidently equal to E , the normal voltage to neutral. The current through the arc corresponding to this oscillation will be zero when the voltage of this oscillation reaches its maximum and at this point 3 the arc is assumed to extinguish or the switch to open.

Fig. 6—SWITCHING CONTROLLED BY HIGH-FREQUENCY CONDITIONS

The voltage on condenser C_2 at this moment is 3 times E , whereas that on condenser C_1 is zero. The supply voltage, however, can only maintain a difference of potential of $2E$ between the condensers C_1 and C_2 . There is, therefore, an equalization of charge between the condensers C_1 and C_2 until the voltages on C_1 and C_2 come to differ by $2E$. Thus there is at 3 a charge equalizing oscillation and after this is damped out the voltages of C_1 and C_2 are, respectively, $+\frac{1}{2}E$ and $+2\frac{1}{2}E$. The arc being extinguished, the course of voltage change of the two condensers C_1 and C_2 is as it was before in portion 1-2 except that they are displaced from the zero line.

We now suppose that the next striking of the arc or closing of the switch takes place when condenser C_1 reaches its maximum voltage to ground. This will be one-half cycle later at 4 in Fig. 6B when the voltage of C_1 will be $+2\frac{1}{2}E$ and that of C_2 , $+\frac{1}{2}E$. The arc strikes; condenser C_1 loses its charge completely in a rapidly damped high-frequency oscillation and condenser

TABLE I

	Iron and alum.	Copper and iron	Copper and copper	Copper and alum.	Brass and brass	Brass and iron	Remarks
Volts at <i>b</i>	10,000	10,300	9500	8500	9400	11,000	Without air blast

Volts at <i>b</i>	28,800	29,500	33,000	30,500	..	..	With air blast

During the above tests voltages were measured as follows:

E_{sec} with voltage transformer	= 12,960
E_b with gap <i>b</i>	= 7700
E_c with gap <i>c</i>	= 7050

trodes of the arc played any particular part in the magnitudes of the voltages developed.

Fig. 12 gives the diagram of the circuit and Table I gives the results obtained on these tests. In these tests the upper electrode of the arc gap was kept stationary and the gap drawn out by rotating the threaded lower electrode. The table clearly shows that the metals making up the arc electrodes had no great influence

FIG. 12—CONNECTIONS USED IN TESTING EFFECT OF DIFFERENT ELECTRODE MATERIALS

upon the voltages developed and therefor in the subsequent tests only copper electrodes were used.

EXPERIMENTS TO DETERMINE VOLTAGES DEVELOPED IN ARCING GROUND

The circuits used are shown in Fig. 13 and the results are given in Table II. During the progress of this work various oscillograms were taken of which characteristic ones will be given and described in the discussion of results following.

DISCUSSION OF EXPERIMENTAL RESULTS

The table of voltages observed under various conditions given above may be checked against the voltages which the three theories would require to be developed on the condensers.

Theory I permits the development of practically unlimited voltages upon the condenser in the oscillating circuits. Theory II, however, if the condensers are equal, limits the maximum voltage which can be obtained on the short-circuited condenser to twice its normal voltage and the maximum voltage which can be obtained on the other condenser to four times its normal voltage. When the short-circuited condenser is much smaller than the other, Theory II limits the voltage which can be developed in it to twice its normal

voltage, or, that is, twice the voltage of the supply and the voltage of the other condenser to three times the voltage of the supply. Theory III, for the case of equal condensers, will permit the development of four times normal voltage on the short-circuited condenser and six times normal voltage on the other condenser. If the short-circuited condenser is small compared to the other, then Theory III permits of practically unlimited voltages.

Examining Table II we find that the results are entirely in agreement with the predictions of Theory II.

In the case of equal condensers, as shown in tests 1-20 and 76-90, inclusive, with the exception of the first four tests, no voltages exceeding twice normal or 13,000 were observed on the short-circuited condenser; although voltages were observed exceeding this value, all the voltages were nearly equal to this value. For the voltage across the other condenser in no tests was more than three times normal voltage observed and in many cases this value three times voltage was nearly reached. The falling short of the maximum values predicted by the theory is to be expected because of the leakage from

FIG. 13—CONNECTIONS USED IN ARCING GROUND TESTS

the condensers during the relative long time between successive drawings of the arc.

Unequal condensers were used in tests 30-44 and 51-63. The unlimited voltages called for by Theories I and III were not observed at all and even the maximum voltage of three times the supply voltage required by Theory II was not observed. However, more than twice supply voltage was usually observed and the smallness of the condenser with the attended rapid leakage of charge between strikings of arc readily explains the inability to obtain higher voltages.

DISCUSSION OF OSCILLOGRAMS

With the results of Table II indicating the probable correctness of Theory II, it is interesting to study the various oscillograms for evidences of the action called for by each of the three theories. In the oscillograms the zero lines are shown which represent zero current through the oscillograph element but do not represent the zero lines of the voltage waves. This is due to the fact that when zero voltage is impressed upon the grid there is still the plate current flowing through the oscillograph element.

THEORY I

Theory I would require the appearance on the oscillogram oscillations of increasing amplitude during the periods that the arc was on. However, no oscillograms show this effect. Oscillograms 72,579-d, o and z, which are typical of those obtained with circuits A and C, show the oscillations through the inductance of the supply which were produced by the striking of the arc very clearly and these oscillations are clearly damped. An oscillation of the short-circuited condenser may be inferred by the slight breaks following each discharge in the curve for voltage across C₂. We may infer that these oscillations were highly damped because the curve becomes continuous again very shortly after. Oscillogram 72,579-r, taken with circuit B with a larger and lagging arc current, also shows only slight breaks in the curve for voltage across C₂.

THEORY III

Theory III requires the extinction of the arc to take place at the peak of the high-frequency voltage wave so that when the arc extinguishes a charge is left on the condenser in excess of the charge corresponding to the

(72579-O)

(72579-Z)

60-cycle voltage at that time. In no oscillogram was this observed. One would expect that the greatest chance for the Petersen theory to be valid would be when the short-circuited capacitance was small, for then the heating due to the dissipating of the energy of

the short-circuited condenser in the arc would be small, in fact, oscillogram 72-579-*o* does show the arc extinguish for a short time in nearly every half cycle. But even here the arc, after striking, held on long enough for the high frequency to damp out so that at the time of extinction the charge retained on the condenser did not exceed that corresponding to the instantaneous 60-cycle voltage. Thus, the displacement of the voltage waves was never in excess of the normal voltage to neutral as is required by this theory.

THEORY II

Theory II requires the striking of the arc at the peak of the 60-cycle voltage wave and its extinction also near the peak of a 60-cycle voltage wave. When the striking of the arc took place after the arc had been out for a little time, that is, more than a half cycle, the striking always did take place at the peak of the voltage but when an air blast was used so that the arc would be

(72579-a)

(72579-b)

blown out before the gap had become very long, reignition frequently occurred within the next half cycle before the peak of the voltage wave as shown at 1, oscillogram 72,579-*z*. Also when an air blast was used extinction sometimes occurred before the peak of the voltage, that is, before the 60-cycle charging current would normally pass through zero. However, these extinctions and reignitions give rise to voltages less than those called for by Theory II since the retained charge under these circumstances would be less than that corresponding to peak voltage and the amplitude of oscillation would be less because of the smaller total voltage to ground at the moment of striking. We may say then that the voltages called for by Theory II do not develop with each individual extinction and reignition of the arc, but we can say that usually when the arc extinguishes for a longer time it will do so at the peak of voltage with a retained charge equal to normal voltage to neutral and that the next striking of the arc will be at the peak voltage so that the maximum voltages

called for by this theory will nearly always be ultimately developed. The final extinction of the arc at the peak of the voltage wave and the displacement of the voltage waves from the zero line are clearly seen in oscillograms 72,579-*d* and *o*.

The spark gap voltages obtained and the oscillograms appear to substantiate Theory II as to the maximum voltages which may be developed by an arcing ground. However, it must be pointed out that the experimental work was limited to a 13,200-volt circuit and it is conceivable that for higher voltages with greater arc lengths in which heating of the electrodes might play a smaller part, Theory III calling for the extinction of the arc at zero of high-frequency current might find application. The authors' opinion is that this will seldom prove to be the case. As to Theory I calling for the development of high voltages due to the "negative resistance" of the arc they are even more strongly of the opinion that it will fail to be realized even with higher voltages.

GROUNDING VS. UNGROUNDED NEUTRAL SYSTEMS

In the experiments described above circuits *A* and *C* approximate conditions on a transmission system with an isolated neutral and circuit *B* approximates conditions on a grounded neutral system. The predictions of Theory II applied to circuit *C* were substantiated both by spark gap voltage determinations and by oscillograms. This theory applied to a three-phase system calls for displacement of neutral relative to ground and the development as a result of transient oscillations of maximum voltage of $3\frac{1}{2}$ times normal voltage to neutral on the sound phases and two times normal voltage to neutral on the grounded phase. In a grounded neutral system if the impedance between neutral and ground is not too large the charge left on the system after the extinction of the arc will be drained off before the next striking of the arc. Hence the maximum voltage which will be developed will be that corresponding to 2, Fig. 5, that is, $2\frac{1}{2}$ times normal voltage to neutral on the sound phases and 1 times normal voltage to neutral on the grounded phase.

Thus the maximum voltages to ground developed by arcing grounds on isolated neutral and grounded neutral systems, respectively, are in the ratio $3\frac{1}{2}$ to $2\frac{1}{2}$. However when the distribution of potentials within apparatus is considered, the magnitude of sudden changes in voltage becomes important and these sudden voltage changes are very much greater in the isolated neutral case than in the case of the grounded system. We must, therefore, consider the surges set up by arcing grounds which are propagated due to the distributed capacitance and inductance in transmission systems.

TRAVELING WAVES SET UP BY GROUNDING PHASE OF TRANSMISSION SYSTEM

The transient oscillations generated by grounding a phase in a transmission system were described above in terms of lumped capacitances and inductances. When

the capacitances and inductances are distributed, oscillations take place but are not simple sine waves as were described above. These oscillations are best pictured in terms of traveling waves. Referring to Fig. 14, when a ground suddenly occurs on a phase of the transmission line the capacity of the line is not discharged as a whole like a single condenser but those parts of the line nearest to the grounded point discharge first. Since the inductance to the grounded point is less for these nearest parts, they discharge almost at once while the farthest parts of the line still retain their charge. There are thus set up waves traveling in both directions from the point of ground. These traveling waves reduce the potential from V , the value just before the ground occurred to zero. When the traveling wave reaches the end of the line where a change of impedance is encountered, reflection occurs and at the point of reflection a sudden change of voltage

takes place amounting to $\frac{2 Z_2}{Z_1 + Z_2} V$, where Z_1 and

Z_2 are respectively the surge impedance of the line and the surge impedance of the apparatus at the end of the line. The mathematical derivation of this expression may be found in the appendix.

The oscillations of the ungrounded phases are also accompanied by traveling waves but owing to the inductance of the supply system which is in series, the wave fronts will be of much less steepness and therefore much less disastrous as regards voltage distribution within the apparatus at the ends of the line.

We may now compare the magnitudes of the traveling

FIG. 14—PROPAGATION AND REFLECTION OF TRAVELING WAVE

waves set up by an arcing ground in the two cases of the isolated neutral and the grounded neutral systems. For the isolated neutral system we have seen that the arc will usually strike at the maximum of the 60-cycle voltage wave and at that moment there will also be a retained charge on the system after the previous extinction which further displaces the voltage of the line from ground. The voltage of the line to ground is then two times the normal voltage to neutral. The magnitude

of the sudden change in voltage which occurs at the end of the line is therefore

$$\frac{2 Z_2}{Z_1 + Z_2} \times 2 E,$$

or nearly four times normal voltage to neutral. For the grounded neutral system there is no charge retained by the system at the moment the arc strikes and therefore we have $V = E$. Hence the sudden change in voltage due to reflection at the end of the line will be

FIG. 15—TRAVELING WAVE ON TRANSMISSION LINE

approximately $2 E$ or only one-half as great as that for the isolated neutral system. Most observations of abnormal voltages on isolated neutral systems due to arcing grounds have been not of voltages to ground but of voltages across parts of apparatus. The above discussion of the traveling waves set up by arcing grounds on isolated neutral systems show that this is what should be expected.

Appendix

REFLECTION OF TRAVELING WAVES

Consider a traveling wave started by any abrupt change in potential on a system containing distributed inductance and capacitance. The wave may start with an abrupt or sheer front such as results when closing a switch on a dead line or grounding an energized line or it may start with a tapered front such as may be induced by the release of an electrostatic charge on a cloud. As the traveling wave proceeds on its course it gives up energy in Joulian heat and radiation which causes a progressive tapering of its front. When this traveling wave strikes a point on the line where the impedance of the line makes an abrupt change the wave undergoes a reflection. The theory of such reflection follows. In Fig. 15 let A represent a traveling wave of voltage of any shape and let v be its potential at any point x .

Let L = inductance per unit length of line.

Let C = capacitance per unit length of line.

$$\text{Then} \quad \Delta v = -L \Delta x \frac{d i}{d t} \quad (1)$$

$$\Delta i = -C \Delta x \frac{d v}{d t} \quad (2)$$

$$\text{from (1)} \quad \frac{\partial v}{\partial x} = -L \frac{\partial i}{\partial t} \quad (3)$$

$$\text{from (2)} \quad \frac{\partial i}{\partial x} = -C \frac{\partial v}{\partial t} \quad (4)$$

$$\text{from (3)} \quad \frac{\partial^2 v}{\partial x^2} = -L \frac{\partial^2 i}{\partial t \partial x} \quad (5)$$

$$\text{from (4)} \quad \frac{\partial^2 i}{\partial t \partial x} = -C \frac{\partial^2 v}{\partial t^2} \quad (6)$$

$$\text{from (5) and (6)} \quad \frac{\partial^2 v}{\partial t^2} = \frac{1}{LC} \frac{\partial^2 v}{\partial x^2} \quad (7)$$

$$\text{also} \quad \frac{\partial^2 i}{\partial t^2} = \frac{1}{LC} \frac{\partial^2 i}{\partial x^2} \quad (8)$$

It is readily checked by substitution that

$$v = f(x + \alpha t) \text{ and}$$

$$v = g(x - \alpha t) \text{ are solutions of (8)}$$

f and g denoting arbitrary functions of $(x + \alpha t)$ and $(x - \alpha t)$, respectively, and

$$\alpha^2 = \frac{1}{LC}$$

For, substituting $v = f(x + \alpha t)$ in (7) we get

$$\alpha^2 f''(x + \alpha t) = \frac{1}{LC} f''(x + \alpha t)$$

$$\text{or} \quad \alpha^2 = \frac{1}{LC}$$

$v = f(x + \alpha t)$ evidently represents a voltage wave traveling with the velocity α in the direction of negative x ; for if we increase t by unity and at the same time decrease x by α the value of v is unchanged; but increasing t by unity and changing x by $-\alpha$ is equivalent to shifting the wave through the distance $-\alpha$ in unit time. Similarly, $v = g(x - \alpha t)$ represents a voltage wave traveling in the direction of positive x .

Let us now determine the traveling wave of current which accompanies the voltage wave $v = f(x + \alpha t)$, substituting, $v = f(x + \alpha t)$ in (3) and (4), we get

$$-L \frac{\partial i}{\partial t} = f'(x + \alpha t) \quad (9)$$

$$\frac{\partial i}{\partial x} = -C \alpha f'(x + \alpha t) \quad (10)$$

$$\text{Integrating (9)} \quad i = -\frac{1}{\alpha L} f(x + \alpha t) + F_1(x) \quad (11)$$

$$\text{Integrating (10)} \quad i = -C \alpha f(x + \alpha t) + F_2(t) \quad (12)$$

$$\text{since} \quad \frac{1}{\alpha L} = C \alpha, F_1(x) = F_2(t)$$

$F_1(x)$ and $F_2(t)$ therefore represent a constant current and can be neglected in considering the traveling wave. We have then, finally

$$i = -\frac{f(x + \alpha t)}{\alpha L} = -\frac{f(x + \alpha t)}{\sqrt{L/C}} = -v/Z \quad (13)$$

$$\text{where} \quad Z = \sqrt{L/C} = \text{surge impedance.}$$

In the same way we may determine the current wave corresponding to $v = g(x - \alpha t)$ and find

$$i = \frac{f(x - \alpha t)}{\alpha L} = v/Z$$

Consider now a traveling wave $v = f(x + \alpha t)$ reaching a point P at $x = 0$ where the line constants change from a surge impedance of Z_1 to surge impedance Z_2 . There will then appear a transmitted and reflected wave in addition to the oncoming wave. Before reaching P we have only the advancing wave

$$v = f(x + \alpha t) \quad (14)$$

$$i = -1/Z_1 f(x + \alpha t) \quad (15)$$

After reaching P we have on one side a transmitted wave.

$$v_2 = f_2(x + \alpha_2 t) \quad x < 0 \quad (16)$$

$$i_2 = -1/Z_2 f_2(x + \alpha_2 t) \quad x < 0 \quad (17)$$

And on the other side of P the oncoming plus reflected wave

$$v_1 = f(x + \alpha t) + g(x - \alpha t) \quad x > 0 \quad (18)$$

$$i_1 = -1/Z_1 f(x + \alpha t) + 1/Z_1 g(x - \alpha t) \quad x > 0 \quad (19)$$

At point P where $x = 0$ the voltage from either side must be the same and the current flowing to P on one side must equal the current flowing from P on the other side. Therefore from (16), (17), (18) and (19)

$$f_2(\alpha_2 t) = f(\alpha t) + g(-\alpha t) \quad (20)$$

$$-1/Z_2 f_2(\alpha_2 t) = -1/Z_1 f(\alpha t) + 1/Z_1 g(-\alpha t) \quad (21)$$

multiplying (21) by Z_1

$$-Z_1/Z_2 f_2(\alpha_2 t) = -f(\alpha t) + g(-\alpha t) \quad (22)$$

subtracting (22) from (20)

$$(1 + Z_1/Z_2) f_2(\alpha_2 t) = 2f(\alpha t)$$

$$f_2(\alpha_2 t) = \frac{2}{1 + Z_1/Z_2} f(\alpha t)$$

$$\text{or} \quad v_2 = \frac{2v}{1 + Z_1/Z_2} = \frac{2Z_1}{Z_1 + Z_2} v \quad (23)$$

Therefore the transmitted voltage and also the oncoming plus reflected voltage has a ratio to the oncoming

voltage of $\frac{2Z_2}{Z_1 + Z_2}$ irrespective of the nature or shape

of the wave.

Discussion

FREQUENCY CONVERSION BY THIRD CLASS CONDUCTOR AND MECHANISM OF THE ARCING GROUND AND OTHER CUMULATIVE SURGES

(STEINMETZ), and

VOLTAGES INDUCED BY ARCING GROUNDS

(SLEPIAN AND PETERS)

PITTSBURGH, PA., APRIL 24, 1923

H. R. Woodrow: In both papers, the maximum surge potentials have been given neglecting the absorption of our systems, and I believe experience would show that the actual potential rise is less than that given in either one of the two papers particularly on underground systems. This factor has been brought out in connection with some tests which have recently been conducted and which I hope someone will discuss later.

Our surges are not all due to arcing grounds, but some of them are due to switching operations, and on some tests which have recently been made on the Brooklyn Edison system, it appears that these surges may be as high as two and a half times normal voltage.

I have felt in a good many of our cases we say our trouble is due to arcing grounds and surges, and in many cases our deductions are simply the result of our inability to connect the trouble to anything else.

A particular case of this type has come to my attention recently and has caused a great deal of worry and annoyance as to the source of the trouble. We did find some surges of small magnitude and short duration, but none of them seemed to properly account for the trouble. However, after two or three months' study, and the loss of several 5000 kv-a. transformers, we found it due to nothing more than a little piece of iron placed in the wrong position and without ventilation.

J. Slepian: It is brought out very clearly in the first part of Dr. Steinmetz's paper that the generation of the high frequency is due to the properties of arcs. Some peculiar properties are necessary in arcs in order to produce high frequency. One would expect in a mathematical treatment, that somewhere in the treatment a definite statement would be made as to what is assumed about the arc. An equation or some definite statement should be made as to what is assumed as to the nature of the arc so that from it the currents and voltages can be calculated. However, you look in vain for any such statements in the mathematical work. You have to go through it carefully

FIG. 1

and look for points here and there. Sometimes it is a definite statement, and sometimes in a rather concealed way a property of the arc is assumed.

Now, of course, I was helped considerably going through the mathematical work by the previous discussion. The previous discussion gives some idea of the simplified characteristic that Dr. Steinmetz takes for the arc.

Taking on page 273, the first equation given, he assumes that the arc has a straight line characteristic, as given by the equation $e = E_1 - r_1 i$.

The equation given there would give a straight line as shown in accompanying Fig. 1, the slope r_1 , being the negative resistance. This applies only for the low frequency. When it comes to the high frequency, he brings in the idea of time lag between current

and volts. That is, the high-frequency volts and high-frequency amperes are not in phase. This is expressed in the equations at the bottom of the same column on page 273.

These equations plotted with volts and amperes as coordinates give an ellipse as shown in accompanying Fig. 2, so we guess that probably the characteristic that Dr. Steinmetz makes use of in his mathematic work is something of that nature.

Now, to find where he brings in quantitatively the magnitude of the negative resistance and axes of the ellipse, and so on, we have to hunt carefully. The first assumption we find is in equation 16 on page 276, which says, Let $r_1 = E_1/I_1 =$ effective resistance of the third class conductor.

In this section, however, he is dealing only with the low-frequency terms. In calling this resistance r_1 , he makes the assumption

FIG. 2

tion that volts and amperes of the low frequency are in the same ratio as for the high frequency. This means that the low-frequency volt-ampere curve is a straight line which has the same positive slope as the negative resistance with which he is going to work. As the low-frequency volts and amperes rise and fall, the high-frequency volts and amperes go round ellipses, and these ellipses come in and out, swell and retract, so that you get a curve of volts and current similar to that given on page 275 Fig. 4.

The high-frequency volts and amperes rise and fall with the low frequency but for some reason he has chosen to take the two in equal ratio. There is no reason why that should be the case.

The next assumption he makes as to the magnitudes in the arc is rather hard to illustrate in the mathematical work, so I will go to the first numerical case on pages 278 and 279. By assuming that delta equals sixty degrees as the time lag between high-frequency current and volts, an arbitrary assumption is made as to the shape of the ellipse. However, I don't quarrel with that. Some assumption must be made and that seems to be reasonable.

We next come to the assumption whereby a numerical value is given to the negative resistance, r_1 . Near the top of page 279, taking the high-frequency resistance of the oscillating circuit as $r = 60$ ohms, Dr. Steinmetz says, "and assuming stationary conditions reached by the transient negative resistance of the spark discharge having dropped to equality with the ohmic resistance, that is:

$$r_1 \cos \delta = 60, \text{ and } r_1 = 120 \text{ ohms,} \text{ etc.}$$

Thus, from the resistance of the oscillating circuit he has calculated the negative resistance of the arc.

Now, this is not always a correct procedure and may as in this example lead to absurd results. In the text of the paper itself, it is explained very clearly that we may not calculate the negative resistance in this way. In the last paragraph of Section III on page 273 we find, "Thus the final result of a condenser discharge through a third class conductor of *sufficiently high* effective negative resistance is an alternating current of a frequency determined by the circuit constants."

I have italicized the words *sufficiently high* because they indicate that there are two possibilities as to the steady state. If the negative resistance is *sufficiently high* there will be sustained oscillations with the negative resistance reduced to equality with

several hundred or several thousand amperes, will re-form, that is, strike again, if it is not interrupted for say one-fifth second. This minimum time seems to be dependent to some extent upon the length of the arc. This being the case, it appears that a power arc is a good conductor when thought of in half-cycle intervals, and that the resistance of the arc is low throughout the cycle. Otherwise, suppression of the voltage at the arc for so long a time as indicated would not be required to stop it.

Arising grounds on ungrounded systems certainly cause disastrous voltages. It has been my experience that if the neutral of a star-connected system is grounded through a resistance low enough to carry, say fifty amperes, the surges which are produced on delta or ungrounded systems do not occur to any dangerous degree. Accidental grounds produce no dangerously high-voltage effects on the ungrounded phases throughout the system, as indicated by the absence of lightning arrester discharges at various connected stations. For this reason, I do not consider that a high-resistance neutral is objectionable from the voltage standpoint; on the other hand, it is very desirable, from a current standpoint, since the flow of ground current is limited to a moderate amount.

Herman Halperin: Mr. Woodrow made some remarks about surges on underground cables, and I thought he was referring to some tests concerning which I was telling his committee which had taken place the last month in Chicago. I will show in brief, Fig. 5, what we did and what was found on some of these surge tests.

A kenotron set with one side grounded was used and the d-c. voltage charged a factory condenser. After that condenser was

FIG. 5

charged up in a few seconds or so, it went over the sphere gap into some three-phase paper-insulated lead-covered cables. In these three-phase cables we usually discharged into one conductor and the other two conductors were grounded; and at the end of the lines, the one conductor was grounded solidly or through a resistance. Then at various points we measured the voltages to ground by means of sphere gaps. In one case the first length was 350 feet and the remaining cable was about 15,000 feet long or more. These traveling waves that were put in at the sphere gap had a steep front and a gradually decreasing tail. The length of the main portion of the wave would be of the order of twenty micro seconds in time, which is a wave of very high frequency. In these tests we found that the voltage was decreased to somewhere around two-thirds of its initial value after it had gone through 350 feet of cable, and that it went down to a fifth or so at the end of the line, depending upon the cable and connections. Plotting the voltages against feet from the station the waves of this nature decreased in voltage rapidly at first and gradually towards the end. Of course when resorting to waves corresponding to very high frequency, the voltage decrease was very rapid at the beginning. The wave after it got down to the end of the cable was considerably flattened out.

It just indicates that traveling waves such as are shown in this second paper on page 791 will be considerably reduced in voltage after traveling a very short distance in underground cables, due to the damping qualities of the cable.

W. A. Hillebrand: Some of the largest of the high-power radio stations in the world utilize the negative temperature coefficient of the arc in order to transform the energy from a d-c. generator into the energy of a high-frequency oscillation. This is known as the Poulsen arc.

Dr. Steinmetz, in Fig. 3 sets up the circuits of the Poulsen arc and the equations thereof naturally follow. The identity between the fundamental relations that he derives and the Poulsen arc is rather striking.

With respect to some of the discussion on this subject, I would say that in order to generate oscillations by means of an arc, the magnetic field is not necessary, neither is it necessary to have a field of hydrogen. The magnetic field is used in the field with the Poulsen arc to get uniform arc conditions, so the conditions will repeat with a fair degree of uniformity. The hydrogen is used because of the high mobility of the hydrogen, and because of the high amount of radiation that is obtained. It is equivalent to a very large increase in the quantity minus R_1 that Dr. Steinmetz uses. In my opinion, in this discussion of the arcing ground, the matter of voltage is not of fundamental importance. One of the most important factors, it seems to me, has been overlooked and that is the matter of frequency. The moment you puncture the dielectric, you will get a streamer that will travel practically indefinite distance due to the high current that results from high frequency, and the high conductivity of the resulting arc. The relations between the strike distance of such an arc, once the dielectric is punctured, and those of, for instance, the normal 60-cycle variety, or rather, I would say the two bear no relation to one another whatsoever.

On one of the large high-voltage systems of the country, for example, one of the operating men told me he has actually observed in time of trouble streamers emanating from the conductor of a familiar type, such as you get from oscillators and such as you can only get under conditions of high frequency.

There is one form of arcing that can occur under one set of conditions, not referred to by Dr. Steinmetz in his paper, namely, between contacts of switch plane and clip where an imperfect contact is made.

That is of either an air break or oil type switch. I believe it is possible under such conditions for disturbances to be set up of the type that Dr. Steinmetz describes although obviously not of the same intensity.

C. L. Fortescue: There is evidently no doubt that arcing grounds do give trouble. We have had ample evidence from operating men today, that they do have trouble at times very high voltages are obtained by this cause on their systems.

Dr. Steinmetz has given a mathematical explanation and some figures showing that with certain assumptions the voltages that can be obtained reach very high values. Now, I think that Dr. Steinmetz' idea of the negative resistance might be carried out so as to give possibly more plausible values for the voltages reached.

I think that the principal thing these studies show is that our knowledge of these phenomena is very limited and that there is need for much further study.

Now, one of the difficulties of the study of these problems is that it is impossible to study them on a large scale because of the danger of causing damage. They have to be studied in the laboratory and in studying them in the laboratory we are so apt to get conditions that we do not get outside; it is so difficult to approximate conditions in the laboratory to those in actual service and theoretical analysis without corroborative experimental work is not very convincing when the problem is so complicated as in this case.

Charles P. Steinmetz: It is regrettable that Mr. J. Slepian rather misunderstood the bearing of my paper, as this led him to guess at assumptions made in the paper, and as I did not make these assumptions, his discussion, being based on these assumptions, becomes non-pertinent to the paper. For instance, I never made the assumption of a linear arc characteristic, which Mr. Slepian imputes by a misinterpretation of the equation on page 273, and his discussion based on this assumption does not apply. The purpose of the paper is not to prove that an arc produces high-frequency oscillations. It has been well known for

years, that an arc may produce undamped and cumulative high-frequency oscillations, or continual oscillations, or isolated damped wave trains—such as once more described in Messrs. Peters' and Slepian's present paper—depending on circuit conditions. For instance, in my book on "Theory and Calculation of Electric Circuits" which was published in 1917, an entire chapter of 40 pages is given to this subject. There for a number of different arcs, the stationary characteristics are given and the transient characteristics—called "dynamic characteristics" by Mr. Slepian—as derived by oscillogram, and discussion of the arc characteristics giving the various types of arc oscillations and their limitations, and oscillograms of undamped high-frequency waves produced by the arc. All this being well known, its rehash obviously has no proper place in the paper, especially as it has no direct bearing on it.

The purpose of my paper, as indicated by the title, is to show the mechanism by which a third class conductor—which may or may not be an arc—can act as frequency converter. None of the assumptions, which Mr. Slepian tries to find in the paper, are made, nor are they necessary, but the only assumption is that the circuit, Fig. 3, contains a third class conductor, as defined in the paper, that is, a conductor in which, over a certain range of current, the voltage decreases with increase of current. The argument of the mathematical part of the paper then is: Whatever may be the particular characteristic of the third class conductor, as univalent functions of time, current and voltage can be represented by a Fourier series with constant coefficients, equation (7). Integration of the differential equation then shows that only two terms can exist in this Fourier series, a low-frequency term, of the supply frequency, and a high-frequency term of resonance frequency. In the low-frequency term, the coefficients of current and voltage are found of the same sign, and their ratio r_1 therefore is positive, representing power consumption. In the high-frequency term, the coefficients of current and voltage are found of opposite signs, and their ratio (approximately r , the load resistance) therefore is negative, representing power production. The mechanism of frequency conversion consists in the low-frequency component acting as motor circuit, due to the positive r_1 , and the high-frequency component as generator circuit, due to the negative $-r$, as seen in the equations (35). To make oscillation possible, the power of the fundamental or motor component r_1 must be equal or greater than that of the high-frequency or generator component r . As r_1 is a function of the amplitude, the amplitude of the oscillation adjusts itself at that value of r_1 , where the motor and generator components are equal.

Here Mr. Slepian seems to have been badly mixed up, and to mistake for assumptions the mathematical conclusions derived

from the equations. There is no assumption whatever involved in the term r_1 , but r_1 is merely defined as the constant ratio of the two constant coefficients of the fundamental terms of the Fourier series of current and voltage respectively, equation (7). Being of the dimension of resistance it is called "effective resistance." As conclusion from the equations and not as assumption as Mr. Slepian seems to think, the relation between the load resistance r of the high-frequency component, and the effective resistance r_1 of the low-frequency term is derived.

As regards to the numerical values, and the probability of high power oscillating arcs in industrial circuits, I may best quote from my book of 1917.

"In transmission lines, usually the resistance is too high to produce a cumulative oscillation; in underground cables, usually the inductance is too low and thus no cumulative oscillation results,—in the high-potential windings of the large high-voltage power transformers, however, as circuits of distributed capacity, inductance and resistance, the resistance commonly is below the value through which a cumulative oscillation can be produced and maintained, and in high-potential transformers, destruction by high voltages resulting from the cumulative oscillation of some arc in the system, and building up to high stationary waves, have frequently been observed."

J. F. Peters: With reference to Mr. Woodrow's and Mr. Halperin's remarks, there is no doubt but what considerable absorption of surges occur, preventing the full value of possible surges neglecting absorption. This is particularly true for cable systems.

It is very interesting to note the large degree of absorption obtained by tests described by Mr. Halperin. Since energy varies with voltage squared after the surges have traveled 350 feet, the energy was reduced to less than one-half of its original value.

With reference to Mr. Hildebrand's discussion concerning an arc as generator of high frequency, he states that a gas is not necessary but is used on account of the large amount of radiation that it produces. The increased cooling of the arc is the big factor in making an arc generate high frequency. This is shown clearly by the difference in characteristics of an arc in air and in gas, as shown in Figs. 8A and 8B. With reference to the streamer following puncture of dielectric, mentioned by Mr. Hildebrand, I assume he means the gaseous vapors produced by the large current resulting from shorting the electrolytic charge. This, of course, may reach a considerable distance. High-frequency voltage of short duration, such as accompany surges, will not jump any further and when solid insulation is involved will not jump as far as low-frequency voltage.

To raise the temperature at this point we have to increase the input of energy. For constant current this is done by increasing the voltage, so that indirectly the distance between electrodes is a function of the voltage.

Based on the above conclusion, that the reactance per phase was a constant, independent of the load, the general equations of the three-phase furnace were developed.

To avoid any undue complications and obtain equations which could be easily discussed, the following assumptions were made:

The furnace is fed by three parallel and similar conductors situated in one plane and symmetrically disposed in relation to the middle one. Constant voltage across phases is impressed to these conductors by the transformers and their resistance is neglected, unless otherwise specified. As can be seen the impedance of the transformer is neglected also, unless otherwise specified.

GENERAL EQUATIONS

The voltage drop due to the inductance in three parallel conductors is:

$$\left. \begin{aligned} I_1 X_a &= -I_2 X_{1.2} - I_3 X_{1.3} \\ I_2 X_b &= -I_1 X_{2.1} - I_3 X_{2.3} \\ I_3 X_c &= -I_1 X_{3.1} - I_2 X_{3.2} \end{aligned} \right\} \text{ where } \quad (1)$$

$$\begin{aligned} X_{1.2} &= X_{2.1} \\ X_{2.3} &= X_{3.2} \\ X_{3.1} &= X_{1.3} \end{aligned}$$

and where I_1, I_2, I_3 designate the currents in phase 1, 2 and 3 respectively in amperes

$X_{1.2}$ is the effective reactance of phase 1 due to current I_2 in ohms

$X_{2.3}$ is the effective reactance of phase 2 due to current I_3

$X_{3.1}$ is the effective reactance of phase 3 due to current I_1

for reasons of symmetry $X_{12} = X_{23} = X$, X_{13} can be written αX where $\alpha > 1$. A dot above a quantity indicates that it must be taken as a vector. $\dot{I}_1, \dot{I}_2, \dot{I}_3$ being star currents must add up to 0.

$$\dot{I}_1 + \dot{I}_2 + \dot{I}_3 = 0 \quad (2)$$

Using the complex notation and taking I_2 as the origin we have

$$\left. \begin{aligned} \dot{I}_1 &= I(-\gamma - j\beta) \\ \dot{I}_2 &= I \\ \dot{I}_3 &= I(-\epsilon + j\beta) \end{aligned} \right\} \quad (3)$$

where $\gamma + \epsilon = 1$.

If we call R_a, R_b, R_c the resistance of the load in phase 1, 2 and 3 respectively. $I_1 R_a, I_2 R_b, I_3 R_c$ are the voltage drops due to load.

The total voltage drop in the three phases, from the point where the voltage is impressed to the neutral is:

$$\left. \begin{aligned} \dot{I}_1 Z_1 &= \dot{I}_1 (R_a - jX_a) = \dot{I}_1 R_a + j\dot{I}_2 X + j\dot{I}_3 \alpha X \\ \dot{I}_2 Z_2 &= \dot{I}_2 (R_b - jX_b) = \dot{I}_2 R_b + j\dot{I}_3 X + j\dot{I}_1 X \\ \dot{I}_3 Z_3 &= \dot{I}_3 (R_c - jX_c) = \dot{I}_3 R_c + j\dot{I}_1 \alpha X + j\dot{I}_2 X \end{aligned} \right\} \quad (4)$$

Combining (3) and (4):

$$\left. \begin{aligned} \dot{I}_1 Z_1 &= I \{ -(\gamma R_a + \beta \alpha X) - j[(\alpha \epsilon - 1)X + \beta R_a] \} = \dot{e}_1 \\ \dot{I}_2 Z_2 &= I [R_b - jX] = \dot{e}_2 \\ \dot{I}_3 Z_3 &= I \{ -(\epsilon R_c - \beta \alpha X) - j[(\gamma \alpha - 1)X - \beta R_c] \} = \dot{e}_3 \end{aligned} \right\} \quad (5)$$

The impedances of the three phases are:

$$\left. \begin{aligned} Z_1 &= R_a + \frac{(\alpha - 1)\beta X}{\beta^2 + \gamma^2} \\ &\quad - jX \left(\alpha - \frac{(\alpha - 1)\gamma}{\beta^2 + \gamma^2} \right) = R_1 - jX_1 \\ Z_2 &= R_b - jX = R_2 - jX_2 \\ Z_3 &= R_c - \frac{(\alpha - 1)\beta X}{\beta^2 + \epsilon^2} \\ &\quad - jX \left(\alpha - \frac{(\alpha - 1)\epsilon}{\beta^2 + \epsilon^2} \right) = R_3 - jX_3 \end{aligned} \right\} \quad (6)$$

We see that in phase 1 a resistance $\frac{\alpha - 1}{\beta^2 + \gamma^2} \beta X$ is added to the load resistance R_a , in phase 3 a resistance $\frac{\alpha - 1}{\beta^2 + \epsilon^2} \beta X$ is subtracted from R_c . Multiplying these two resistances by I_1^2 and I_3^2 respectively we have

$$P_{t_1} = I_1^2 \cdot \frac{\alpha - 1}{\beta^2 + \gamma^2} \beta X$$

$$P_{t_3} = I_3^2 \cdot \frac{\alpha - 1}{\beta^2 + \epsilon^2} \beta X$$

but $I_1^2 = I^2(\beta^2 + \gamma^2)$ and $I_3^2 = I^2(\beta^2 + \epsilon^2)$ so that

$$P_{t_1} = P_{t_3} = P_t = I^2(\alpha - 1)\beta X \text{ Watts} \quad (7)$$

P_t represents an amount of power which is subtracted from phase 1 and transmitted to phase 3 by a transformer action.

If E_1, E_2, E_3 are the voltages impressed across phase 2 and 3, phase 3 and 1 and phase 1 and 2 respectively, we have in combination with (5)

$$\left. \begin{aligned} \dot{E}_3 &= \dot{e}_1 - \dot{e}_2 = I [-(\gamma R_a + R_b + \beta \alpha X) - j[(\epsilon \alpha - 2)X + \beta R_a]] \\ \dot{E}_1 &= \dot{e}_2 - \dot{e}_3 = I [(R_b + \epsilon R_c - \beta \alpha X) - j[(2 - \alpha \gamma)X + \beta R_c]] \\ \dot{E}_2 &= \dot{e}_3 - \dot{e}_1 = I [-(\epsilon R_c - \gamma R_a - 2\beta \alpha X) - j[(\alpha \gamma - \alpha \epsilon)X - \beta R_a - \beta R_c]] \end{aligned} \right\} \quad (8)$$

$$\dot{E}_1 + \dot{E}_2 + \dot{E}_3 = 0$$

The total power consumed by phases 1, 2 and 3 respectively are:

$$\left. \begin{aligned} W_1 &= I_1^2 R_1 = I^2 [(\beta^2 + \gamma^2) R_a + (\alpha - 1)\beta X] \\ W_2 &= I_2^2 R_2 = I^2 R_b \\ W_3 &= I_3^2 R_3 = I^2 [(\beta^2 + \epsilon^2) R_c - (\alpha - 1)\beta X] \end{aligned} \right\} \quad (9)$$

The power delivered to the furnace by electrodes 1, 2 and 3 respectively are:

$$\left. \begin{aligned} W_a &= I_1^2 R_a = I^2 [(\beta^2 + \gamma^2) R_a] \\ W_b &= I_2^2 R_b = I^2 R_b \\ W_c &= I_3^2 R_c = I^2 [(\beta^2 + \epsilon^2) R_c] \end{aligned} \right\} \quad (10)$$

Equations (8) which include voltage, current, resistance and reactance are the desired general equations of the three phase furnace.

DISCUSSION

Taking first the general case where the three impressed voltages are equal, and the three currents are balanced: the conditions for balanced currents are,

$$\gamma = \epsilon = 1/2, \beta = 1/2 \sqrt{3}, \gamma^2 + \beta^2 = \epsilon^2 + \beta^2 = 1 \quad (11)$$

$$\left. \begin{aligned} \dot{I}_1 &= -I(1/2 + j1/2 \sqrt{3}) \\ \dot{I}_2 &= I \\ \dot{I}_3 &= -I(1/2 - j1/2 \sqrt{3}) \end{aligned} \right\} \quad (12)$$

if $\dot{E}_3 = E(\pi + j\zeta)$ the condition for equal voltage is

$$\left. \begin{aligned} \dot{E}_1 &= E(\pi + j\zeta) \left(-1/2 + j1/2 \sqrt{3} \right) \\ &= E \left[\left(-1/2 \pi - 1/2 \zeta \sqrt{3} \right) \right. \\ &\quad \left. - j \left(1/2 \zeta - 1/2 \pi \sqrt{3} \right) \right] \\ \dot{E}_2 &= E(\pi + j\zeta) \left(-1/2 - j1/2 \sqrt{3} \right) \\ &= E \left[\left(-1/2 \pi + 1/2 \zeta \sqrt{3} \right) \right. \\ &\quad \left. - j \left(1/2 \zeta + 1/2 \pi \sqrt{3} \right) \right] \\ \dot{E}_3 &= E(\pi + j\zeta) \end{aligned} \right\} \quad (13)$$

Combining (8), (11) and (13) we have:

$$\left. \begin{aligned} R_a &= \frac{R_a + R_b + R_c}{3} - 2/3 (\alpha - 1) X \sqrt{3} \\ &= R_{av} - 2/3 (\alpha - 1) X \sqrt{3} \\ R_b &= \frac{R_a + R_b + R_c}{3} = R_{av} \\ R_c &= \frac{R_a + R_b + R_c}{3} + 2/3 (\alpha - 1) X \sqrt{3} \\ &= R_{av} + 2/3 (\alpha - 1) X \sqrt{3} \end{aligned} \right\} \quad (14)$$

$$\text{if we call } \frac{R_a + R_b + R_c}{3} = R_{av}.$$

The three resistances of total power consumed by each phase are:

$$\left. \begin{aligned} R_1 &= R_{av} - 1/6 (\alpha - 1) X \sqrt{3} \\ R_2 &= R_{av} \\ R_3 &= R_{av} + 1/6 (\alpha - 1) X \sqrt{3} \end{aligned} \right\} \quad (15)$$

The total power input is $3 I^2 R_{av}$, but we see that the total power consumed by phase 1 is smaller than that consumed by phase 2 by an amount $I^2/6 (\alpha - 1) X \sqrt{3}$. The total power consumed by phase 3 is larger than that consumed by phase 2 by the same amount.

Subtracting from phase 1 and adding to phase 3

the transformation power $\frac{I^2 (\alpha - 1) X \sqrt{3}}{2}$ we have

finally for the power delivered to the furnace by phase 1, 2 and 3

$$\left. \begin{aligned} W_a &= I^2 (R_{av} - 2/3 (\alpha - 1) X \sqrt{3}) \\ W_b &= I^2 R_{av} \\ W_c &= I^2 (R_{av} + 2/3 (\alpha - 1) X \sqrt{3}) \end{aligned} \right\} \quad (16)$$

$$W_a + W_b + W_c = 3 I^2 R_{av}.$$

if $\dot{E}_3 = E(\pi + j\zeta)$ $\dot{E}_3^2 = E^2 (\pi^2 + \zeta^2)$

combining this last equation with (8) and (11) we have

$$\begin{aligned} E_3^2 &= E_2^2 = E_1^2 = 3 I^2 (R_{av}^2 + (\alpha + 2)^2 X^2/9) \\ &= 3 I^2 (R_{av}^2 + X_{av}^2) \end{aligned}$$

$$\text{where } X_{av} = X \frac{(\alpha + 2)}{3}$$

If we replace in (6) $R_1, R_2, R_3, X_1, X_2, X_3$ by their respective values we have

$$Z_1 = R_{av} - 1/6 (\alpha - 1) X \sqrt{3} - j \frac{(1 + \alpha)}{2} X$$

$$Z_2 = R_{av} - j X$$

$$Z_3 = R_{av} + 1/6 (\alpha - 1) X \sqrt{3} - j \frac{(1 + \alpha)}{2} X$$

X_{av} represents the average of the three reactances just as R_{av} represents the average of the three load resistances, and $3 I^2 X_{av}$ is the total reactive power as would be registered, for instance, by the reactance side of a double R A Max. demand meter.

If we are only interested in the total power without paying any attention to the unbalancing of the individual phases, the general equations are reduced to the equations of a three-phase balanced circuit. Since the currents are balanced we can introduce without error, the resistance of the conductors and if desired the impedance of the transformer.

In this case

$$\begin{aligned} R_{tot} &= \frac{R_a + R_b + R_c}{3} + R_{cond} + R_{transf.} \\ &= R_{av} + R_{losses} \end{aligned}$$

$$\text{and } X_{tot} = \frac{(\alpha + 2)}{3} X + X_{transf.}$$

$$Z_{tot} = \sqrt{R_{tot}^2 + X_{tot}^2}$$

Table I gives the values of the resistance per phase R_{tot} , the reactance X_{tot} , the power factor $\cos \varphi = R_{tot}/Z_{tot}$, the power input $W_{tot} = 3 I^2 R_{tot}$, the current I and the voltage E when three of these quantities are given. Multiplying W_{tot} by R_{av}/R_{tot} gives the power delivered into the furnace.

Numerical Example. A 3000-kv-a. transformer bank with taps for 75, 85 and 100 volts with 44,000 volts high-tension voltage feeds a three-phase electric furnace. The bus bars are connected delta, so that the transformer voltage, is also the voltage between phases. The transformer losses at full-load are 2 per cent, its reactance 6 per cent at the highest tap. We assume that the magnetizing current is negligible.

The following quantities have been measured by instruments:

High-tension line current: 40 amperes per phase

High-tension voltage: 44,000 volts between phases

The high tension is connected to give 100 volts on the low tension

Total power input high tension 2600 kw.

Using Case No. 3 of Table I, we find

$$R = \frac{2600 \times 10^3}{3 \times 40^2} = 542 \text{ ohms}$$

The resistance per phase on the secondary side is

$$R_{tot} = \frac{542 \times 100^2}{44000^2} = 0.00280 \text{ ohms}$$

The low-tension current is

$$\frac{40 \times 44000}{100} = 17600 \text{ amperes}$$

$$X_{tot} = \sqrt{\frac{100^2}{3 \times 17600^2} - \frac{2600^2 \times 10^6}{9 \times 17600^4}}$$

$$= 0.00171 \text{ ohms}$$

The full-load current of a 3000 kv-a. transformer

bank for 100 volts is 17,300 amperes in the furnace conductors, so that with 2 per cent resistance and 6 per cent reactance

$$R_{transf.} = \frac{3000 \times 10^2 \times 2}{3 \times 17,300^2 \times 100} = 0.000067 \text{ ohms}$$

$$X_{transf.} = \frac{3000 \times 10^3 \times 6}{3 \times 17,300^2 \times 100} = 0.0002 \text{ ohms}$$

assume that R_{cond} has been figured to be 0.000133 ohms so that $R_{transf.} + R_{cond} = 0.0002$ ohms.

$$R_{av} = 0.00280 - 0.0002 = 0.0026 \text{ ohms}$$

$$X_{av} = 0.00171 - 0.0002 = 0.00151 \text{ ohms}$$

$$\text{Efficiency} = \frac{0.0026}{0.0028} = 92.8 \text{ per cent}$$

$$\text{Aver. power factor} = \frac{2600 \times 10^3}{100 \times 17,600 \times \sqrt{3}} = 0.853$$

$$\text{Power input into furnace} = 2600 \times \frac{92.8}{100} = 2412 \text{ kw.}$$

After operating a while the furnace at 100 volts it is decided to change the taps to 85 volts. What will be the new conditions for the same high-tension current?

At 85 volts with 40 amperes high-tension current, the low-tension current will be $\frac{40 \times 44,000}{85} = 20,720$

amperes.

Using Case No. 1 of Table I:

$$E = 85 \text{ volts} \quad I = 20,720 \text{ a.} \quad X_{tot} = 0.00171 \text{ ohms}$$

$$R_{tot} = \sqrt{\frac{85^2}{3 \times 20,720^2} - 0.00171^2} = 0.001643 \text{ ohms}$$

$$R_{av} = 0.001443$$

$$W = 3 \times 20,720^2 \times 0.001643 = 2114 \text{ kw.}$$

$$\text{Power input into furnace} = \frac{2114 \times 0.001443}{0.001643} = 1856 \text{ kw.}$$

$$\text{Efficiency} = 87.9 \text{ per cent}$$

Power factor

$$= \sqrt{1 - 3 \cdot \frac{20,720^2 \times 0.00171^2}{85^2}} = 0.693$$

It can easily be shown that with increasing current the power input passes through a maximum for $R_{tot} = X_{tot}$. After this point any further increase in current means a decrease in power.

Taking, in case 5,

$$W = \frac{E^2 R}{X^2 + R^2},$$

where E and X are constant.

The condition for maximum power is

$$\frac{dW}{dR} = 0 = \frac{E^2 (X^2 + R^2 - 2R^2)}{(X^2 + R^2)^2}$$

$$0 = X^2 - R^2 \quad \begin{matrix} X^2 = R^2 \\ X = R \end{matrix}$$

$$\text{Power Factor} = \frac{R}{\sqrt{X^2 + R^2}} = \sqrt{2/2} = 0.707$$

$$I = \frac{E}{\sqrt{3(X^2 + R^2)}} = \frac{E}{X\sqrt{6}}$$

In our case, the power input is a maximum for $R = 0.00171$ ohms.

$$I = \frac{85}{0.00171 \cdot \sqrt{6}} = 20,310 \text{ amperes}$$

$$W = \frac{3 \times 0.00171 \times 20,310^2}{1000} = 2116 \text{ kw.}$$

$$\text{Efficiency} = \frac{0.00171 - 0.00020}{0.00171} = 88.3 \text{ per cent}$$

Power factor = 0.707. Power delivered to furnace = $2116 \times 0.883 = 1867$ kw.

The power delivered to the furnace passes also through a maximum but at a lower current as the total power input

$$W_{furn} = \frac{W \cdot R_{av}}{R_{tot}} = \frac{E^2 (R_{tot} - R_{losses})}{R_{tot}^2 + X_{tot}^2}$$

$$\frac{dW_{furn}}{dR_{tot}}$$

$$= E^2 \frac{R_{tot}^2 + X_{tot}^2 - 2(R_{tot} - R_{losses})R_{tot}}{(R_{tot}^2 + X_{tot}^2)^2} = 0$$

$$0 = X_{tot}^2 - R_{tot}^2 + 2R_{tot} \cdot R_{losses}$$

$$R_{tot} = R_{losses} + \sqrt{R_{losses}^2 + X_{tot}^2}$$

In our case:

$$R_{tot} = 0.0002 + \sqrt{0.0002^2 + 0.00171^2} = 0.0002 + 0.00172 = 0.00192 \text{ ohms}$$

$$I = \frac{85}{\sqrt{0.00192^2 + 0.00171^2} \cdot \sqrt{3}} = 19,120 \text{ amperes}$$

$$W_{input} = 3 \times 19,120^2 \times 0.00192 = 2104 \text{ kw.}$$

$$W_{furn} = 3 \times 19,120^2 \times 0.00172 = 1885$$

$$\text{Efficiency} = \frac{0.00172}{0.00192} = 89.6 \text{ per cent}$$

Power factor, (High-tension side) = 0.747.

It will therefore be more economical in our case to

$$\text{drop the high-tension current to } \frac{19,120 \times 85}{44,000} = 37$$

amperes when we change the voltage from 100 to 85 volts on the low-tension side. This current will give us maximum power into the furnace at that voltage.

Problems like the above can easily be solved by the analytical method; nevertheless it is generally simpler to prepare sets of curves giving for each available low-tension voltage the power input in transformer and

furnace, the power factor and if desired the low-tension resistance in functions of the low or high tension-current, depending on the manner in which the measuring instruments are connected, and whether high or low-tension current is mostly used for computations.

FIG. 1—CHARACTERISTICS OF ELECTRIC FURNACE FROM SIMPLIFIED CIRCLE DIAGRAM (SEE FIG. 2)

FIG. 2—COMPARISON BETWEEN SIMPLIFIED AND COMPLETE CIRCLE DIAGRAM

FIG. 3—CHARACTERISTICS OF ELECTRIC FURNACE FROM COMPLETE CIRCLE DIAGRAM

The two circle diagrams are so arranged that for 40 amperes high-tension current the kw. input and the power factor are the same. In comparing Figs. 1 and 3 one can see the error which is introduced by using a simplified diagram which neglects the magnetizing current.

Fig. 1 gives a set of curves for 100 volt low-tension voltage and $X = 0.00171$ ohms. One can naturally, if greater accuracy is desired, draw an exact circle

diagram similar to the one used for induction motors, but it will generally be quite sufficient for practical purposes to use curves as shown above.

Fig. 2 shows a comparison between the simplified circle diagram corresponding to the curves on Fig. 1 and the theoretical diagram which takes the magnetizing current of the transformer into account. This last circle has been drawn so as to give the same values as the simplified circle for 40 amperes high-tension current.

INFLUENCE OF UNBALANCING

As will be shown later the value of α , which is the ratio between X_{1-3} and X_{1-2} , can be taken as being between 1.2 and 1.3 according to the dimensions and arrangements of the leads. In the case of balanced current $\beta = 1/2 \sqrt{3}$.

The value of X_{av} will vary greatly, depending on the arrangement of the leads and the frequency. At 60 cycles, with well designed furnaces, values as low as 0.0015 were found, but in the same plant were furnaces with X_{av} as high as 0.0021. At 25 cycles these furnaces would have shown values of 0.000625 and 0.000875 ohms respectively.

In the previous example, we had found $X_{av} = 0.00151$

but $X_{av} = X \frac{(\alpha + 2)}{3}$, and if we take $\alpha = 1.25$

$$X = \frac{0.00151 \times 3}{3.25} = 0.001394 \text{ say } 0.00140 \text{ ohms}$$

introducing these values in the equation (7) we find that

$$P_i = I^2 (\alpha - 1) \beta X = I^2 (0.25 \times \sqrt{3}/2 \times 0.00140) = 0.000303 I^2$$

for $I = 17,600$.

$$P_i = \frac{17,600^2 \times 0.000303}{1000} = 94.5 \text{ kw.}$$

The total power consumed by each phase is

$$W_1 = I^2 (R_{av} + R_{losses} - 1/6 (\alpha - 1) X \sqrt{3}) = \frac{17,600^2}{1000} (0.0028 - 1/6 (1.25 - 1) 0.0014 \sqrt{3}) = 836 \text{ kw.}$$

$$W_2 = I^2 (R_{av} + R_{losses}) = \frac{17,600^2}{1000} \times 0.0028 = 867 \text{ kw.}$$

$$W_3 = I^2 (R_{av} + R_{losses}) + 1/6 (\alpha - 1) \times \sqrt{3} = \frac{17,600^2}{1000} (0.0028 + 1/6 (1.25 - 1) 0.0014 \sqrt{3}) = 898 \text{ kw.}$$

Total power input

2601 kw.

The losses per phase are

$$\frac{17,600^2}{1000} \times 0.0002 = 63 \text{ kw.}$$

The power delivered by each electrode to the furnace will be

Phase 1,

$$W_a = 836 - 63 - 94.5 = 678.5 \text{ kw. or } 28.1 \text{ per cent}$$

Phase 2,

$$W_b = 867 - 63 = 804 \text{ kw. or } 33.3 \text{ per cent}$$

Phase 3,

$$W_c = 898 - 63 + 94.5 = 929.5 \text{ kw. or } 38.6 \text{ per cent}$$

Total power delivered _____
to furnace 2412.0 kw.

The difference between the phases is therefore quite large, and would still be larger for furnaces with higher phase reactance.

Since it appears that the arc acts as a straight resistance, the arc voltage on each phase is easily calculated:

$$\text{Arc voltage phase 1 } \frac{678,500}{17,600} = 38.55 \text{ volts}$$

$$\text{phase 2 } \frac{804,000}{17,600} = 45.70 \text{ volts}$$

$$\text{phase 3 } \frac{929,500}{17,600} = 52.8 \text{ volts.}$$

Taking now the point where the power input on the high-tension side is a maximum, with the low-tension at 85 volts and the low-tension current 20,310 amperes, we have

	Total power consumed	Losses	Power due to transformer action	Power delivered to furnace	In per cent	Arc voltage
Phase 1.....	664	- 82.5	- 124.5	457	24.44	22.5 volts
Phase 2.....	705.5	- 82.5	= 623	623	33.33	30.7 volts
Phase 3.....	747	- 82.5	+ 124.5	789	42.23	38.9 volts
Total.....	2116.5 kw.			1869 kw.	100.00	

The lower the average power factor the larger are the differences between phases.

In the case studied above the value of X in equation (7) was 0.001394, this is rather low, and furnaces with larger values will be found, also α may be larger than 1.25. It follows that the values calculated above are rather favorable and that much larger differences between phases are possible.

This difference of voltage and power input between the phases is detrimental to the good operation of the furnace. The stock will move much more rapidly around electrode No. 3, and have a tendency to stick around No. 1.

The difference in voltage may affect the uniformity of the product. It is therefore necessary to design the furnace and arrange the leads in such manner as to make the difference between phases as small as possible.

SUGGESTIONS TO REDUCE UNBALANCING

Equation (7) gives the value of the power transmitted from phase 1 to phase 3.

$$P_i = I^2 (\alpha - 1) \beta X$$

For balanced currents $\beta = 1/2 \sqrt{3}$

$$\alpha = X_{1,3}/X \text{ where } X = X_{1,2} = X_{2,3}$$

For three parallel conductors, one of which carries the return current of the other two.

$$X_{1,2} = X_{2,3} = X = 2 \pi f \times 2 l \left(\log_e d/a + 1/4 - d/l \right) \times 10^{-9} \text{ in ohms}$$

If the three conductors are in the same plane, as assumed.

$$X_{1,3} = 2 \pi f \cdot 2 l \left(\log_e \frac{2d}{\alpha} + 1/4 - \frac{2d}{l} \right) \cdot 10^{-9} \text{ in ohms}$$

f is the frequency

l is the length of the circuit in cm.

d the distance between center lines of adjacent phases in cm.

a the geometrical radius of the conductor in cm.

This formula is only an approximation and assumes that d/l and a/d are small.

$$\alpha = X_{1,3}/X = \frac{\log_e \frac{2d}{a} + 1/4 - \frac{2d}{l}}{\log_e d/a + 1/4 - d/l} = 1 + \frac{\log_e 2 - d/l}{\log_e d/a + 1/4 - d/l}$$

$$\alpha = \text{approx. } 1.43 - 0.34 d/l - 0.016 d/a \text{ for } d/l < 0.25 \text{ and } 6 < d/a < 10$$

FIG. 4

P_i can be reduced by reducing X or α

(1) X being proportional to the frequency, the same furnace will be more satisfactory at 25 cycles than at 60.

(2) The closer the furnace is brought to the transformer the better, since X is proportional to the length of the leads. In case the distance is given, the bus bars should be carefully interlaced as close to the furnace as possible.

(3) The leads should be as close together as possible.

(4) The conductors should be of large dimensions.

The use of extra flexible cables will often permit to reduce l .

To reduce the distance between leads the method shown in Fig. 4 is suggested. The distance between the leads is smaller than the distance between electrodes.

Where two water-cooled pipes are used to carry the

current they should be placed in a vertical rather than in a horizontal plane (Fig. 5).

The use of hollow conductors will help to increase α . When using cables, they should form a hollow cylinder, each cable making a complete turn to avoid unequal current distribution (Fig. 6). The only way to reduce α without at the same time increasing X is to make l small.

If the conductors could be placed so as to form the 3 edges of an equilateral prism α would be equal to 1. Even if the ideal case cannot be attained, it would be possible to raise or lower conductor 2 out of the plane

FIG. 5

1.3, and it will often prove advisable to bring electrode 2 forward so as to make tapping easier.

It is interesting to study under which conditions the powers delivered by the three electrodes are balanced.

The condition for equal delivered power is:

$$I_1^2 R_a = I_2^2 R_b = I_3^2 R_c \quad (17)$$

1st Case. $I_1 = I_2 = I_3$ that is balanced currents. From equation (17) it follows that $R_a = R_b = R_c = R$, the three load resistances are equal

The conditions for balanced currents is

$$\gamma = 1/2 \quad \epsilon = 1/2 \quad \beta = 1/2 \sqrt{3} \quad \gamma^2 + \beta^2 = 1$$

Introducing these conditions in equation (8), we get

FIG. 6

$$\begin{aligned} E_3 = I \left[- \left(\frac{3R}{2} + \alpha/2 \times \sqrt{3} \right) \right. \\ \left. - j (R/2 \sqrt{3} - (2 - \alpha/2) X) \right] \end{aligned}$$

$$E_1 = I \left(\frac{3R}{2} - \alpha/2 \times \sqrt{3} \right)$$

$$- j \left(\frac{R \sqrt{3}}{2} + (2 - \alpha/2) X \right) \Bigg]$$

$$E_2 = I (\alpha \times \sqrt{3}) - j (-R \sqrt{3})$$

$$\begin{aligned} E_3^2 &= I^2 (3R^2 + X^2 (\alpha^2 - 2\alpha + 4) \\ &\quad + 2XR\sqrt{3}(\alpha - 1)) \\ E_1^2 &= I^2 (3R^2 + X^2 (\alpha^2 - 2\alpha + 4) \\ &\quad - 2XR\sqrt{3}(\alpha - 1)) \\ E_2^2 &= I^2 (3R^2 + X^2 (3\alpha^2)) \end{aligned}$$

$$\begin{aligned} E_3^2 &= I^2 X^2 (3R^2/X^2 + 3\alpha^2 \\ &\quad + 2(\alpha - 1)[R/X\sqrt{3} - (\alpha + 2)]) \\ E_1^2 &= I^2 X^2 (3R^2/X^2 + 3\alpha^2 \\ &\quad - 2(\alpha - 1)[R/X\sqrt{3} + (\alpha + 2)]) \\ E_2^2 &= I^2 X^2 (3R^2/X^2 + 3\alpha^2) \end{aligned}$$

Table II gives the value of the square root of the factor in parenthesis for different values of α and R/X . To obtain the respective voltage multiply by IX .

	E_1	100.0	99.9	99.8	99.7	99.6	
	E_2	100.0	100.0	100.0	100.0	100.0	

These factors multiplied by IX give the voltage to be applied between phases on the low tension, to get balanced loads in the furnace with balanced currents.

Since the currents are balanced R may include the resistance of the conductors.

Example:

Take $X = 0.00140$ ohms, $I = 19,000$ amperes, $\alpha = 1.3$ and $R/X = 2/\sqrt{3}$ we shall include in R the resistance of the leads which is taken as 0.000133 ohms.

In this case

$$E_3 = 2.8792 IX = 2.8792 \times 26.6 = 76.5 \text{ volts}$$

$$E_1 = 2.4269 IX = 2.4269 \times 26.6 = 64.5 \text{ volts}$$

$$E_2 = 3.0116 IX = 3.0116 \times 26.6 = 80.1 \text{ volts}$$

The power delivered by each electrode is

$$\begin{aligned} W_a = W_b = W_c &= \frac{19,000^2}{1000} (0.00140 \times 2/\sqrt{3} \\ &\quad - 0.000133) \text{ kw.} = 537 \text{ kw.} \end{aligned}$$

The losses in the leads are

$$= \frac{19,000^2}{1000} \times 0.000133 \text{ kw. per}$$

phase = 48 kw.

The power transmitted from phase 1 to phase 3 is

$$P_t = \frac{19,000^2}{1000} (\alpha - 1) \beta X \text{ kw.}$$

$$= \frac{19,000^2}{1000} (0.3 \times \sqrt{3}/2)$$

$$\times 0.0014 \text{ kw.} = 131 \text{ kw.}$$

So that the total power consumed by each phase will be

FIG. 7

	In	Per Cent	Voltage
$W_1 = 537 + 48 + 131 = 716 \text{ kw.}$	40.8	28.3	volts
$W_2 = 537 + 48 = 585$	33.3	28.3	volts
$W_3 = 537 + 48 - 131 = 454$	25.9	28.3	volts

1755 kw.

If the transformers were connected in delta on the low-tension, the voltages calculated above are the voltages which the three transformers should give at the chosen load. However since we assume balanced voltage on the high-tension, that is voltages which are 120 deg. apart, it is impossible to have 3 low-tension voltages which do not form an equilateral triangle. It follows that we cannot use the proposed method with a delta on the low tension.

If the transformers are connected in star on the low-tension one can always find three transformer voltages, 120 deg. apart, which will give the desired voltage across the star using special taps if necessary. The diagram in Fig. 7 will show how to find the three voltages.

Draw 3 equilateral triangles with E_1 , E_2 and E_3 as

bases. Join $A F$, $B D$, $C E$; these 3 lines meet in one and the same point O and the angles $A O B$, $B O C$, $C O A$ are equal to 120 deg.

$O A$, $O B$, $O C$ are the desired transformer voltages. The no-load voltage should be selected so as to give this voltage at the chosen load. The kv-a. on the high and low side of the transformers are equal if we neglect the magnetizing current; the three high-tension

FIG. 8—DISTRIBUTION OF CURRENTS AND VOLTAGES

voltages are equal and 120 deg. apart, while the three low-tension currents are equal and 120 deg. apart. It follows that in each transformer high-tension current and low-tension voltage are proportional. The three low-tension transformer voltages do not necessarily form a closed triangle so that the only possible connection on the high side must be a delta, where the currents do not necessarily form a closed triangle.

FIG. 9—DISTRIBUTION OF FURNACES TO KEEP HIGH TENSION BALANCED

We see therefore that the only combination which will permit us to use the proposed method of balancing the powers delivered to the furnace is star on the low side and delta on the high side.

The three line currents on the high side will be unbalanced, being proportional to the low-tension volts between phases. Fig. 8 gives a distribution of voltage and current in our case, assuming a high-tension voltage of 13,000 volts between phases. It is evident that any power company would object to any such unbalancing.

In a plant where there are several furnaces in operation this unbalancing can be corrected by connecting each high-tension line in succession to a different low-tension phase as shown in Fig. 9 being careful not to change the direction of phase rotation.

It may be objected that any change in load requires another value of the voltage. Since electric furnaces are mostly run at constant load, and changes are only of short duration, it would be quite satisfactory to keep the voltages unchanged.

If we plot in Fig. 7, the neutral point 0, in the furnace we see that it does not coincide with the neutral in the bus bars. There is a slight difference of voltage between these two neutrals. In all our investigations, we have assumed that the neutral in the bus bars is not grounded and that there is no connection between this point and the furnace bottom except through the regular leads.

Second Case. Instead of balancing the currents we can keep the three voltages balanced and arrange the currents so as to satisfy the condition for equal power on the three electrodes.

We have again $I_1^2 R_a = I_2^2 R_b = I_3^2 R_c$.

The conditions for balanced voltage is

$$\vec{E}_1 = \vec{E}_3 (-1/2 + j 1/2 \sqrt{3})$$

$$\vec{E}_2 = \vec{E}_3 (-1/2 - j 1/2 \sqrt{3})$$

introducing these conditions in (8), remembering that $I_1^2 = I^2 (\beta^2 + \gamma^2)$, $I_2^2 = I^2$ and $I_3^2 = I^2 (\beta^2 + \epsilon^2)$, and solving for β and γ , we get two equations of the third degree.

$$y^2 (4 - \alpha + 3 \alpha z) - 6 g y (z - 1) + (3 \alpha z - 4 + \alpha) (1 + 3 z^2) = 0$$

$$3 z^2 (\alpha y + g) - 2 z [(4 - \alpha) y + 3 g] + \alpha y - g y^2 - \alpha y + 3 g = 0$$

where $g = \frac{2 R \sqrt{3}}{3 X}$, $y = 1 - 2 \gamma$ and $z = -\frac{2 \beta}{\sqrt{3}}$

Solving for y and z leads to rather complicated expressions of the fifth degree.

Keeping α constant and varying g from 0 to ∞ gives one set only of continuous values for γ ranging from $\gamma = 1$ for $g = 0$ and tending towards $\gamma = 1/2$ for $g = \infty$, the corresponding values of β being 0 for $g = 0$ and $1/2 \sqrt{3}$ for $g = \infty$.

For the special case where $\alpha = 1$, that is when the three reactances are equal, there are three sets on values forming continuous curves from $g = 0$ to $g = \infty$; the general solution is $\gamma = \epsilon = 1/2$ and $\beta = 1/2 \sqrt{3}$ for every value of g , it is the case of balanced currents.

But it is interesting to know that for every value of g there are besides this general solution, two other solutions which give equal powers under the three electrodes, but with unbalanced currents. For certain values of g there are two more additional solutions but the curves on which they lie extend only over a small range of g . Similarly when $\alpha \neq 1$ there are values of g for which there are three and sometimes five solutions.

Of practical interest is only the one set of solutions which gives a continuous series of values from $g = 0$ to $g = \infty$.

Table III gives the values of β , γ and ϵ for different values of g , and for $\alpha = 1$ and $\alpha = 1.25$, while Table IV gives the corresponding values of $\sqrt{\beta^2 + \gamma^2}$ and $\sqrt{\beta^2 + \epsilon^2}$.

Take as an example, the case of $g = 2$, $\alpha = 1.25$ when $X = 0.00150$ ohms and $E = 110$ volts.

$$g = \frac{2 R \sqrt{3}}{3 X} R = \frac{3 g X}{2 \sqrt{3}} = \frac{2.3 \times 0.0015}{2 \times \sqrt{3}} = 0.0026 \text{ ohms}$$

From Table III we find $\beta = 0.513$, $\gamma = 1.0825$, $\epsilon = 0.9175$. Introducing these values in (8), we find

$$\vec{E}_3 = I (-0.005517 + j (0.0022245))$$

$$\vec{E}_1 = I (+0.000836 - j (0.0059205))$$

$$\vec{E}_2 = I (+0.004681 + j (0.0036960))$$

	I_3	0.750	1.0	0.859	1.686		
10	I_1	1.093	1.0	0.808	1.025	..	..
	I_2	1.0	1.0	1.0	1.0	..	..
	I_3	0.897	1.0	0.887	0.818	..	..
∞	I_1	1.0	1.0	1.0	1.0	..	..
	I_2	1.0	1.0	1.0	1.0	..	..
	I_3	1.0	1.0	1.0	1.0	..	..

Multiply by I to obtain I_1 , I_2 , and I_3 .

It follows that $E = I \times 0.00596$. Since we have assumed E to be 110 volts we have

$$I = \frac{110}{0.00596} = 18,470 \text{ amperes}$$

FIG. 10

from Table IV we find:

$$I_1 = 18,470 \times 1.198 = 22,140 \text{ amperes}$$

$$I_2 = 18,470 \times 1.0 = 18,470 \text{ amperes}$$

$$I_3 = 18,470 \times 0.519 = 9580 \text{ amperes}$$

Power delivered to furnace by each phase:

$$W_a = W_b = W_c = \frac{18,470^2}{1000} \times 0.0026 = 887 \text{ kw.}$$

$$P_t = I^2 (\alpha - 1) \beta X = \frac{18,470^2}{1000} (0.25) \times 0.513 \times 0.0015 = 65.6 \text{ kw.}$$

$$W_1 = W_a + P_t = 887 + 65.6 = 952.6$$

Power consumed by Phase 1

$$W_2 = 887.0$$

Power consumed by Phase 2

$$W_3 = W_c - P_t = 887 - 65.6 = 821.4$$

Power consumed by Phase 3 2661.0 kw.

The arc on electrode 1 will have a voltage of

$$\frac{887,000}{22,140} = 40.1 \text{ volts}$$

The arc on electrode 2 will have a voltage of

$$\frac{887,000}{18,470} = 48.0 \text{ volts}$$

The arc on electrode 3 will have a voltage of

$$\frac{887,000}{9580} = 92.5 \text{ volts}$$

As in the previous case, but in a larger degree the high tension currents will be unbalanced.

When the high tension, and the low tension are both in star or both in delta the high-tension line currents will be proportional to the correspondent low-tension currents.

If the high tension is in star and the low tension in delta, the high tension line currents can be found according to the diagram of Fig. 12, and in the case of high tension in delta and low in star according to Fig. 14.

In Fig. 12 the low-tension transformer currents I_a , I_b , I_c pass through the center of gravity of the triangle formed by the low-tension line currents. Dividing I_a , I_b , I_c by the voltage ratio of the transformers gives the high tension line currents.

In Fig. 14, i_1 , i_2 , i_3 are proportional to I_1 , I_2 , I_3 . The lengths AB , BC , CA represent I_a , I_b , I_c respectively.

FIG. 11

FIG. 12

Although this method of balancing the power delivered by the electrodes is easier to apply than the previous one,—balanced currents—it has two big disadvantages: First the currents on the high-tension side are very unbalanced, and secondly the 3 arc voltages are very different so that although the powers are the same, the conditions under the electrodes are different with their bad effect on the product.

Notwithstanding this rather negative result the investigation of this second case will show in which direction to go to correct partly for the unbalancing of

the loads. In a furnace under observation the difference in the loads was very large under balanced currents and showed badly on the electrode consumption, phase No. 3 using many more electrodes than 1 and 2. An increase of 10 per cent in the current of phase 1 and a somewhat larger decrease of 3 proved very successful.

INVESTIGATION OF OPEN DELTA CONNECTIONS

In order to study the distribution of currents in case the materials between electrodes should act as a resistor, and the energy should be consumed in that part of the furnace we can use equation (8)—setting $R_b = 0$. For reasons of symmetry $R_a = R_c = R$. Solving for γ and β we get:

$$\gamma = \frac{3R^2 + 3\alpha^2 X^2 + 2XR(2-\alpha)\sqrt{3}}{6(R^2 + \alpha^2 X^2)}$$

$$= 1/2 + \frac{2-\alpha}{3} \frac{R/X\sqrt{3}}{R^2/X^2 + \alpha^2}$$

FIG. 13

FIG. 14

$$\epsilon = \frac{3R^2 + 3\alpha^2 X^2 - 2XR(2-\alpha)\sqrt{3}}{6(R^2 + \alpha^2 X^2)}$$

$$= 1/2 - \frac{2-\alpha}{3} \frac{R/X\sqrt{3}}{R^2/X^2 + \alpha^2}$$

$$\beta = \frac{R^2 + X^2(4\alpha - \alpha^2)}{6(R^2 + \alpha^2 X^2)} \sqrt{3} = \sqrt{3}/6$$

$$+ \frac{2-\alpha}{3} \frac{\alpha R^2/X^2 \sqrt{3}}{R^2/X^2 + \alpha^2}$$

$$\gamma^2 + \beta^2 = 1/3 + \frac{2-\alpha}{3} \frac{2 + R/X\sqrt{3}}{R^2/X^2 + \alpha^2}$$

$$\epsilon^2 + \beta^2 = 1/3 + \frac{2-\alpha}{3} \frac{2 - R/X\sqrt{3}}{R^2/X^2 + \alpha^2}$$

$$I_1^2 = I^2(\gamma^2 + \beta^2)$$

$$I_2^2 = I^2$$

$$I_3^2 = I^2(\epsilon^2 + \beta^2)$$

$$I^2 = \frac{3E^2}{R^2 + X^2(4-\alpha)^2} \quad I = \frac{E\sqrt{3}}{\sqrt{R^2 + X^2(4-\alpha)^2}}$$

Table V, gives the values of $\sqrt{\gamma^2 + \beta^2}$ and $\sqrt{\epsilon^2 + \beta^2}$ for different values of R/X and α . The factors given in the table when multiplied by I give us I_1 , I_2 and I_3 .

	I_2	1.000	1.000	1.000	1.000	1.000	
	I_3	0.569	0.569	0.570	0.571	0.572	
∞	I_1	0.577	0.577	0.577	0.577	0.577	∞
	I_2	1.000	1.000	1.000	1.000	1.000	
	I_3	0.577	0.577	0.577	0.577	0.577	

Multiply by I to obtain I_1 , I_2 and I_3 .

The table shows that the currents are quite unbalanced, especially for large values of R . Such an unbalancing does not appear in a furnace under normal operation. The assumption that in alloy furnaces the current passes from one electrode to the nearest one through the charge is not correct.

CONCLUSIONS

The above study shows that the general performance of a three-phase electric furnace can easily be determined in advance with a large degree of accuracy by using the simple equations of a balanced three-phase system. The only thing that is necessary is to have previously determined X , or the low-tension reactance per phase, which is an important characteristic of the furnace.

On the other hand, due to the particular construction of the furnaces the individual phases show large differences which may affect the quality of the products. These differences can be calculated and once their cause and importance are well understood methods can be devised for their correction.

Discussion

For discussion of this paper see page 511.

Improvements in Ferro-Alloy Electric Furnaces of High Power Input

BY B. D. SAKLATWALLA and A. N. ANDERSON

Both of the Vanadium Corporation of America, Bridgeville, Pa.

Review of the Subject.—The paper deals with the subject of efficiency of power input in ferro-alloy furnaces and discusses the electrical factors to be considered in the design of the leads for achieving such efficiency. It also describes a new system of regulation, whereby the furnace temperature is kept constant by keeping

the energy input constant by means of true watt regulation. Also several factors in design and construction, are discussed, which help to keep the load-factor of the operation as close to 100 per cent as possible.

* * * * *

ALL metallurgical furnace operations can be divided into two general classes, the one consisting of reducing ores by means of a reducing agent, commonly carbon, and the other consisting of remelting and refining already reduced metals. The electric furnace has been adapted to both classes of operations. To the latter class belong the steel and brass, and to the former the ferro-alloy furnaces. As the heat energy required for reduction of ores is much greater than that required for the mere melting and refining of metals the ferro-alloy furnaces are fed by comparatively very much larger amounts of power. Consequently, the structure and arrangement of these furnaces have presented more interesting problems from the standpoint of the electrical engineer.

Since the classical experiments of Moissan more than thirty years ago to reduce metals in the electric furnace the application of electrical energy has constantly widened in this field. The furnaces have not only been constructed for a constantly increasing number of products but also have increased in their size and power input, so that today furnaces having a 12,000 or even more kv-a. capacity are commercially operating. Undoubtedly in the United States the Niagara district can be called the cradle of this industry. It was there that the carborundum, aluminum, graphite, carbide, and ferro-alloy furnaces had their inception and commercially established by the efforts of such men as Hall, Acheson and Price, and from there with the development of power projects spread to other industrial locations.

In the early days little was known of the electrical phenomena met with in alternating currents of higher than 25-cycle frequency and little attention was given to the purely electrical phases of the problem. Practically the only consideration given was to have sufficient conductor cross-section for a predetermined current. The pressure to be employed was arbitrarily chosen. It was considered dangerous to go over 100 volts on a furnace. The control of the arc and of the bath resistance, and the spacing of the electrodes were considered not practical with high voltages. Generally the pressure decided on was between 40 and 80 volts.

As the size of the furnaces and their power inputs increased it was found that the conductors heated up excessively in spite of the fact that the current density was no greater than in the smaller initial installations. Addition of extra copper was helpful but did not effect a cure. The conductors insisted on heating up with a density as low as 400 amperes per square inch. Undoubtedly other factors had to be taken into consideration, especially as frequencies higher than 25-cycle had to be encountered. As 60-cycle current became more and more standardized it appeared for a time that furnace energy input at this frequency had reached its limit at 3000 kv-a. Meanwhile alternating-current phenomena were being studied and investigated by such men as Steinmetz, Northrup, Carson, Dwight, Roland, Rosa, Grover, and others, especially in reference to skin effect, spacing and shape of leads for heavy duty conductors. The theoretical considerations of skin effect had been studied mainly with reference to currents of high frequency, though undoubtedly this effect is present in heavy conductors carrying large currents at low frequencies. W. C. Kennedy in a paper presented before the Association of Iron and Steel Electrical Engineers in 1917 stated that the resistance loss due to skin effect on a 3750-kv-a., three-phase, furnace, at 12,000 amperes per phase, was by actual measurements about 11 volts per lead, the drop without skin effect being 0.15 volt for 10,000 amperes.

Numerous suggestions for cutting down impedance by methods of distribution of current, by proper spacing and dimensioning of bars, looping the circuit, so-called interlacing, etc., were forthcoming and eagerly investigated. Putting them into actual practise had, however, been deferred. It was, therefore, the desire of the authors to practically carry out these theoretical considerations in the design of ferro-alloy furnaces they were responsible for.

It appears to have been common practise for some time to employ tubular conductors for high-tension bus structures. However, they do not seem to have found use as conductors for large currents.

It appears to be generally accepted that the skin effect resistance factor of flat strip conductors is less than that of equi-sectional solid round conductors. This holds good only under certain conditions at com

6. The farther apart the conductors the larger the inductance.

7. When inductive reactance expressed as per cent reactance drop amounts to 20 per cent or more, the actual volts drop in the line increases rapidly with decreased power factor.

Considering these factors, namely, the calculated voltage drop and line loss, the probable advantage of a progressively increasing voltage drop with decreasing power factor, and the fact that a bus structure of large copper tubing gave promise of a simple and rugged construction, it was decided to install 12 copper tubes of 3 in. diameter, interlaced and spaced 7 in. center to center, fixing the current density at approximately 800 amperes per square inch.

FIG. 1—POWER FACTOR—VOLTAGE LOSS CURVE FOR VARIOUS TYPES OF CONDUCTORS

Next in order was to find a transformer so constructed that its secondary terminals could be brought out to allow the installation of the tubes as planned. The one purchased is wound with two secondary coils per phase, making four terminals per phase and the adjacent leads are brought out plus and minus. In the 12 terminals thus brought out the alternate plus and minus arrangement is continued over the series.

The transformer delivers a 4000-kv-a. output at 40 deg. cent. temperature rise and 5000-kv-a. at a rise of 55 deg. cent. It is water cooled, 3-phase, 60-cycle. The high-tension voltage is 22,000, low-tension, 224 volts at no-load which drops to 220 volts at full-load with 100 per cent power factor and 209 volts at a power factor of 90 per cent. The actual transformer impedance is 11.3 per cent.

The nearest approach to the tubular form of con-

ductor for flexible leads for connecting the movable electrodes to the bus structure is the familiar asbestos cored extra flexible cable developed expressly for furnace operation. Consequently this type of cable of 1,000,000 circular mils diameter is used. There are 16 cables per phase, making 4 cables for each of the 3-in. tubes. The other end of the cable is connected to a 5-in. copper tube, about 8 feet long running across the furnace to the electrode holder. Directly underneath the terminals of the 3-in. tubes, which terminate at different lengths to allow placing of cables, are 3 slabs of slate each drilled with a hole just large enough to pass a cable. The 16 holes per phase thus drilled are in the form of a square, the spacing being such that each cable is 2 in. away from its neighbor. This spacing is maintained throughout the cable length by means of grooved blocks, one block clamping a row of 4 cables on both sides. These blocks also serve to prevent swaying motion of the cables without interfering with the up and down motion.

The general scheme of arrangement for adjacent tubes was applied to the cables. The "delta" connection is formed at the end of the 5-in. tube projecting over the back of the furnace and the cables are so placed that those carrying current of opposite sign are adjacent both with respect to cables in the same square and neighboring cables of adjacent squares.

This method of construction with respect to arrangement of the 3-in. transformer lead tubes and the flexible cables results in a very material reduction of impedance due to a-c. effects, as total resistance under full-load tests is increased but slightly over the measured d-c. resistance, the excess being less than 2 per cent with phases balanced. The absence of material reactive and inductive influences, and the absence of any iron forming magnetic fields in the circuit, naturally cause little if any disturbance in the phase relation between the impressed e.m.f. and the current, allowing the system to operate at a very high power factor.

Slight unbalancing of current values in the several leads does not materially affect the power factor. Heavy unbalancing however sets up impedances at which the power factor had been observed to drop below 0.6 and the voltage at the furnace, due to reactive inductance, drops approximately in accordance with the calculated power factor-voltage drop curve.

The phenomena of inductance and reactance are here utilized for the purpose of protecting the complete electrical equipment against heavy overloads, yet allowing it to operate at maximum efficiency when under control. It may be here pointed out that this effect could be further augmented by substituting for the 5-in. copper tubes over the furnace roof, a continuation of the interlacing system employed for the cables by extending the cables to the electrode holder, or by means of tubes or strips.

In order to control and keep up an electrical balance it is essential that the control mechanism employed be sensitive to slight changes in power and rapid restora-

trode which caused the trouble. Reversed condition reverses the operation of the magnets. Thus when one of the electrodes is out of balance this device throws the other two electrodes out of circuit and holds them in position while the unbalanced electrode finds its adjustment thereby restoring operating condition in much quicker time. By means of these regulations the period of contact of the arms and duration of circuit closing on the motors can be regulated to a great degree of nicety avoiding unnecessary movement of electrodes and wear and tear on the regulating equipment.

The general arrangement of the electrical equipment consists of two incoming 3-wire, 3-phase 22,000-volt feeder lines, equipped with lightning arresters and choke coils, automatic oil switches opening on overload and reverse current. A set of disconnecting switches are placed on each side of the oil switches. The lines feed parallel into a common set of busses. Each furnace transformer is connected to the bus through disconnecting switches and automatic overload and no-voltage release oil switch. All high-tension conductors within the building are of copper tubing. The secondary leads of the transformer are equipped with a set of disconnecting switches operated by hand or motor for "deadening" the portion of equipment situated in the furnace room, leaving the transformer alive to furnish power for motor drive, etc. The control room, containing all instruments, regulators, relays, etc., is a totally enclosed compartment. All instruments are placed on pedestals and the regulators in cabinets. This allows ready and easy access to all parts of the wiring and facilitates repairs. The low-tension disconnecting switches are operated from the control room. Switches of the same phase are levered to a common shaft and these shafts extend through the wall to the control room.

Each furnace is equipped, beside the regulators, with graphic recording watt meter, watt hour meter, voltmeter, ammeter for each phase and power factor meter. All of the instruments for the first unit installed are of the recording type to facilitate the study of the operation. The control room also contains a frequency meter. The furnaces may be regulated automatically or by hand — remote control. All switching, except high and low-tension disconnecting switching, is by means of remote control. An automatic change-over switch is located directly under the control room. This switch serves to connect the main factory feeder lines with a "live" transformer. It automatically shifts from a dead to a live line. It is operated, when desirable, by remote hand control from the control room. A spare set of regulator switches is provided that may be used on either furnace as may be required. A small auxiliary control room is located in the furnace building. This room contains switches for raising and lowering electrodes, ammeters and voltmeters. It is installed for the convenience of the furnace operators to enable them

to change electrodes quickly and other work connected with the operation. While using these switches the main control room is automatically cut out and the motor speed automatically doubled. All high-tension leads and equipment are contained in bus structure and partitioned off from the rest. One transformer is placed in a vault, the other is of the out-door type.

It is highly desirable that an electric furnace operation of this nature be made continuous with interruptions as few and short as possible. With this view in mind facilities for rapid change of furnaces and of electrodes have been provided. The furnaces are placed on a double set of rollers at right angles to each other, so that when the furnace needed relining it was rolled out of its position, then rolled aside and a spare one already lined rolled into its place. This method of change can be effected in less than two hours time.

For the same reason an electrode holder was designed

FIG. 3

to curtail the time of electrode changes. The holder used works on the friction-contact principle, eliminating all bolts, nuts or other tightening devices. It consists essentially of three members, (1) the outer casting of copper, forming a hollow water-cooled ring having a slight taper on the inside; (2) a copper ring fitting inside of the water-cooled ring and having its outside surface tapered to conform to the inside surface of the first member; (3) bronze wedges fitting between the second member and the electrode. In operation the second member is applied to the electrode by means of the wedges, this taking place on the furnace room floor and the electrode thus provided is lifted with the crane and simply dropped into the first member, making a friction contact by its own weight. The arrangement is shown in Fig. 3.

The advantage of this device, besides saving time, is that it obviates the necessity of loosening or tightening bolts or other devices on top of the furnace where working conditions are disagreeable. Further, should the holder get hot, as the water-cooled outer ring and electrode do not expand, the only material that can expand would be the second member ring and the wedges, which would produce a tighter contact, instead of a looser one, as in the case of a holder of the ordinary type. Also, as the electrodes are prepared for service between changes, under agreeable working conditions and at more leisure, it follows that, in preparing the wedges and ring they are properly cleaned and adjusted, insuring good contacts. This holder permits the change of an electrode in 1 to 2 minutes.

This furnace equipment operates at an average power factor of 99 per cent and an over-all electrical efficiency — for transformer and low-tension leads to electrode — of 98.5 per cent. Repeated tests in operation check well with calculated values.

The practical experience and data gathered from this installation indicates the advantage of application of the principles involved to large input furnaces for various metallurgical operations. Also they indicate the feasibility of larger installations probably with twice the power input operating with equal high efficiencies.

Discussion

SOME PROBLEMS IN ELECTRIC FURNACE OPERATION (ANDREAE);

IMPROVEMENTS IN FERRO-ALLOY ELECTRIC FURNACES OF HIGH POWER INPUT

(SAKLATWALLA AND ANDERSON);

PITTSBURGH PA., APRIL 25, 1923.

J. A. Seede: I remember distinctly a large smelting furnace making ferro-alloys in which the condition existed that Mr. Andreae points out, i.e., the charge surrounding the left hand electrode, looking at the furnace from the transformer, indicated that the temperature was too low to produce the required metallurgical action while the charge around the other electrodes indicated that the temperature was high and the metallurgical conditions satisfactory. Such unbalanced metallurgical conditions never produce satisfactory operation and no one had made, or has made to my knowledge, such a thorough analysis as the author has made in this paper.

One plausible reason has been suggested why the electrodes in electric furnaces do not operate equally and that has to do with the manner in which the furnace is charged. It is evident that if the furnace is not charged properly and an excessive amount of coke happens to be thrown around one of the electrodes the result is equivalent to inserting a resistance between the electrode and the charge which prevents the power being concentrated around the end of the electrode and while the same amount of energy may appear as heat around that electrode it will be diffused over a large area and the temperature gradient will be so low that no metallurgical action may result.

I am quite sure we are all much interested to read his analysis of the conditions in the electric furnace and it is astonishing to note the difference, where in a furnace taking a total of 2600 kw. there was a difference of 620 kw. between the input to electrodes No. 1 and No. 3. The suggestions for balancing the power input

to the furnace are very interesting but it is not quite evident how a practicable arrangement can be developed as is shown in Fig. 6.

Edward T. Moore: With reference to the second paper by Mr. Saklatwalla the means of regulation by the watt meter principle on the furnaces upon which he is working, I think are necessary, but I would not want it inferred, when it comes to steel furnaces in general, that this is necessary or even desirable. The regulation by the current method seems to be working out very satisfactorily; in fact, experiments conducted by using a Kelvin Balance alongside of the common regulator does not show any particularly improved results.

F. V. Andreae: I am aware that some of my suggestions for balancing the loads of the three electrodes are rather unsatisfactory from the point of view of the power companies.

My aim was to put the whole problem on a solid mathematical basis, and to show how the equations could be interpreted. Once the operator has a clearer view of his difficulties he is better able to attack them.

I wish to point out that the unbalancing of which I am speaking is not momentary but continuous, and is due to the disposition of the bus bars. In a ferro-alloy furnace of low power factor, say around 75 or 80, the operator has to choose between two evils. If he tries to keep his high-tension circuit balanced to please the power company his furnace will be quite unbalanced. If, on the other hand, he tries to balance his load in the furnace by equalizing the power under the three electrodes he unbalances his high-tension circuit. He will therefore have to compromise and if he has several furnaces he can easily connect them in such a way that the disturbance of the power company's line will be kept within satisfactory limits.

B. D. Saklatwalla: In the discussion the matter of uneven balance of the electrodes in a three-phase furnace has been brought out. The conditions of the bath at the electrodes can be kept uniform, avoiding an unbalance, by proper feeding of raw materials. In the case of the ferro-vanadium furnace this is achieved by a continuous feeding of the material between the electrodes at a rate commensurate with the electrical load.

Another point brought out by the discussion is the possibility of the use of the induction furnace in competition with the arc furnace. Besides circulation of the bath and other mechanical, or rather hydro-dynamical, effects, the passage of current through the molten metal may have effects of a molecular or even electronic nature depending on the electro-magnetic forces set up within the fluid metal. A study of such electromagnetic influences may prove some superiority of induction furnaces over that of the arc type, achieving a more perfect refinement of the metal.

A. N. Anderson: The regulation of the power input in an electric furnace by means of a true watt control offers several advantages over current regulators as there are several factors entering the problem. Some of these factors lie outside of actual furnace operations but are nevertheless worthy of consideration as they form very important factors in the problem as a whole.

The use of a control mechanism in which the current alone is kept constant can not govern or regulate other than the current consumption.

The parties interested in the power consumption of an electric furnace may be divided into three groups:

1. The manufacturer, selling the product of the furnace, who wants maximum production at minimum expense.
2. The operator responsible for the product.
3. The central station furnishing the power and interested in a high power factor, balanced load and freedom from excessive fluctuations.

The control of the energy input is therefore a factor of prime importance.

Because of the prevailing methods of transmitting power a large majority of electric furnaces now in operation are of the three-phase three-electrode type whether used for the smelting of ores or the production and refining of steel.

It is not possible to control and keep constant with any degree of accuracy the effective power input in these furnaces by means of current regulation alone or the combination of current and voltage regulation, where the voltage regulation consists of keeping a balanced potential between the electrodes and furnace charge.

All that a central station can do to deliver reliable power is to guard against overloaded lines and to keep the voltage constant at the station. It cannot materially regulate the load factor.

On lines supplying power to customers using electric furnaces of various types and of more or less intermittent energy consumption it is very difficult, if not impossible, to keep up a steady voltage and power factor. There are often variations in voltage between phases of the same line and the power factor in phases may also vary.

These conditions are not noticeable where power is supplied to motors or apparatus having balanced circuits, but is noticeable where devices such as electric furnaces are used.

It is highly desirable both from a technical as well as commercial standpoint to be well supplied with measuring instruments to keep a check on the various fluctuating factors.

A properly metered electric furnace installation, employing current regulators, will often show an erratic behavior of the furnace and irregular power consumption in spite of the control indicating a steady amperage flowing, as in addition to the com-

paratively small fluctuations in the incoming power lines those of the transformer secondary vary to a much greater degree, and it is not at all surprising to find such conditions as Mr. Andreae has investigated.

On the other hand, a furnace installation operating on a true watt control principle automatically corrects fluctuations due to variations in voltage and power factor so that the actual predetermined energy is controlled, measured and delivered to the furnace, and conditions such as Mr. Andreae describes cannot exist.

Assuming that volts times amperes times power factor are the factors that produce the heat and temperature required for the successful operation of an electric furnace of the type under consideration, it is apparent that the control of but one of these is insufficient unless one assumes that the others are constant, which unfortunately is very seldom the case. Often a heat gone wrong, a tap or power "off" on analysis, has been blamed on the operator or laid to some other cause when the real culprits were the current regulators.

To the manufacturer who pays the bill from the control station and collects from his customers for his product, the watt regulator serves to prevent peaks much more efficiently than a current regulator, thereby keeping costs at a minimum; it regulates the actual power input into the furnace and thereby maintains the predetermined energy at which the furnace is set to operate, thus helping to produce the desired product uniformly and at maximum efficiency.

The watt regulator benefits the central station insofar as it has a tendency to more effectively balance the load on the feeder lines and to prevent prolonged duration of peaks.

factory operation to such load and may cause complete interruption. It was therefore decided, since most failures on the 66 kv. system would undoubtedly be grounds, that the neutral of the system should be grounded through a high resistance to minimize disturbance resulting from such failures.

FIG. 3—TYPICAL 66 KV. LINE TOWER

The conditions imposed introduced certain problems in the relaying as follows:

1. On account of the high-resistance ground, relaying must be provided which would trip out a line on ground current less than full-load current.

2. On account of the heavy industrial motor and synchronous railway load, faults must be eliminated in a minimum time, thus barring out selective time systems.

3. Single line operation must be possible, preferably without additional relays over the number required for parallel line operation.

4. It must be possible to take care of future growth by the addition of parallel lines between any existing stations, or to add radial lines from any ring station, or to introduce additional sectionalizing stations to the present loop, without destroying the existing protection, either schematically or materially.

A study of all of the above factors showed conclusively that the general principle of balanced protection must be used. Such protection always possesses the inherent advantage that it is absolutely unaffected by conditions outside of its own section. This was a fundamental requisite in the problem at hand, which when viewed with the proper perspective, consisted of the proper selective relaying of a basic system framework. The next problem presented was to choose

FIG. 4—COMPARISON OF SCHEMES OF BALANCED LINE PROTECTION

ADVANTAGES

1. Simplicity of wiring and equipment.
2. Directional single-line protection afforded.
3. No additional relays required for ground protection.
4. Requires dead grounded neutral.

DISADVANTAGES

1. Imposes severe voltage unbalance on line which will effect synchronous machines.
2. Severe damage may result as heavy ground current must pass to operator relays.

ADVANTAGES

1. Satisfied all conditions for short-circuit protection for both parallel and single-line operation.
2. Small ground current may be used which ensures the elimination of voltage disturbances.

DISADVANTAGES

1. Additional relays necessary for ground protection, at least one per circuit being required.
2. Wiring is complicated.
3. Extra grounding potential transformer required for one scheme using the watt ground relay.
4. Another scheme used three double contacting watt relays per pair of lines but this scheme does not have a dependable selectivity.

ADVANTAGES

1. Wiring and equipment simple, only one set of relays being required for ground protection of two parallel lines.
2. Satisfies all short-circuit conditions, for both parallel and single-line operation.
3. Small ground current required to operate ground relays.
4. Ground relays very positive in action.

DISADVANTAGES

1. Ground protection is inoperative when ring is open.
2. Ground relays are non-directional for single-line operation.

ADVANTAGES

1. Simple wiring and equipment.
2. Only one ground relay required for ground protection of two parallel lines.
3. No potential connections required.
4. Ground relays very positive in action.

DISADVANTAGES

1. Neither short circuit nor ground protection is operative if ring is open.
2. Single-line operation is not directionally selective.

the proper form of balanced protection. This matter was gone into to some length and Fig. 4, shows a comparison of the schemes considered.

After considerable deliberation Scheme 3 was finally decided upon as fulfilling the most important requirements; namely, the ability to give complete short-circuit protection for both double and single line operation, with the ring either open or closed, with the use of but one set of short-circuit relays; the ability under normal conditions to selectively disconnect grounded sections of line with a minimum of disturbance to the system itself.

The relay equipment as installed at the various stations is shown diagrammatically in Fig. 5 and a typical station relay panel is shown in Fig. 6. The short-circuit relays are standard Westinghouse single-contact, type *CR*, 4-12 ampere, reverse power relays, and the ground relays are single-contact 1-3 ampere, selective differen-

FIG 5

tial current relays. Interlocking relays are installed in the trip circuits of both lines to render the good line non-automatic for a few seconds after the relays have tripped out one end of the defective line. This locks out the trip circuit of the good line until the relays at the opposite end of the section have had time to clear the defective line, thereby preventing the balanced relays from improperly disconnecting the good line of the pair on the end which clears first. On standard line sections the short-circuit relays are set to operate at 0.4 second definite minimum. The 7-ampere current tap is being used on the *C. R.* relays, and the 1-ampere tap on the *C. D.* relays. One 63-ohm grounding resistor is installed at each of the two generating plants. It is possible that this value of resistance may be increased at some later date.

A graphical representation of a typical relay operation on a ground fault is shown in Fig. 7. Sketch No. 7A shows the division of ground currents for a ground

fault on line 2 at a point just outside station *M*. With a ground resistance of 63 ohms at each generating station and a neutral voltage of 38,100 volts, this will give between 500 and 600 amperes ground current supplied by each generating station depending upon the

FIG. 6—TYPICAL RELAY PANEL AT RING STATIONS

location of the fault. Using the value of 600 amperes for convenience, it will be noted as shown in Fig. 7A that these currents divide equally until the faulty section is reached, where the shortest section of grounded line will add the fault currents from three lines and pass

FIG. 7—LOAD TIME CURVES OF *C R* AND *C D* RELAYS

900 amperes to ground, the remaining portion of the grounded line supplying 300 amperes into the fault. This will supply the line relays at the fault with a total of 1200 amperes, since the cross connection of the *C. R.* relays accumulates the currents in the two lines as

shown in Fig. 7B. The ground relays will receive a differential current of $900 - 300 = 600$ amperes. Thus both sets of relays will start to close contacts but it will be noted that the line relays receive only sufficient current to cause them to operate on the inverse portion of their time curves, requiring approximately 0.6 second to close contacts. The ground relays, however, operate on the definite minimum portion of their time curves and close contacts in 0.3 second. Assuming 0.4 second for the breaker to open, this makes a total

FIG. 7c—CHART SHOWING SEQUENCE OF EVENTS IN CLEARING GROUND LINE

time of 0.7 second to clear one end of the defective line. The opposite end of the grounded line will then start to clear on a similar cycle of operation and thus after 1.4 seconds the grounded line will be entirely disconnected from the remainder of the system. See Fig. 7c.

If for any reason the ground relays fail to respond to the ground fault, provision has been made that the grounding resistors will be short-circuited after a period of approximately 10 seconds following the occurrence of the ground on the system. This places a dead ground on the system which will draw short-circuit current through the line C. R. relays and cause them to operate on the definite minimum part of their time curves.

If the fault had been between phase wires instead of to ground, the C. D. relays would not have operated but the C. R. relays would receive the short-circuit current. For the minimum fault current these relays would operate at a point *P* Fig. 7 on the definite minimum part of the time curve and would close contacts, in 0.4 second. Adding to this the time of opening of the circuit breaker, the defective line would be cleared at one end in 0.8 second. Thus a maximum of 1.6 seconds would isolate the defective line from the system in case of short circuit.

Before putting this relay equipment into operation and in order to prove the effectiveness of the relay scheme, as well as to detect any defects that might exist in the apparatus which would jeopardize service,

it was decided to give service tests to the entire installation. The following procedure was accordingly carried out:

One pole of an out-door type G-11 circuit breaker was mounted portably and placed as near as possible to the point where it was proposed to apply the ground to the system. The point chosen because of its convenience was just outside the station and a connection was made to the line between the line breaker and the last disconnection point on the line side of the station. Control cables were brought into the station where the grounding apparatus could be manipulated safely and the relay operations observed simultaneously. The ground connection to the grounding breaker was made by two different methods:

1. A connection directly to the grounded side of the 11,000-volt ground resistor, which ground consisted of five interconnected copper plates 2 ft. 6 in. by 3 ft. 4 in. buried five feet under ground and surrounded by charcoal, located at various points around the station.

2. The ground presented by a fallen line wire was simulated by stretching 800 feet of 4/0 bare copper wire over the surface of the ground and this connected to the ground side of the test breaker. The particular point chosen happened to be a plowed field, in the case where it was tried, and a good ground connection was obtained.

To observe the effects of the through fault currents at the other stations on the system, meters were placed

FIG. 8—SYSTEM CONNECTIONS FOR TESTS

in the ground and relay circuits of those stations. Thus when the ground was applied, the readings on these meters would give evidence of the ability of these stations to balance out the through fault currents in the cross connection of the current transformers. Prior to the tests the relays were checked for proper operation by means of phantom loads.

In order to test all of the relays on the system with a minimum of test apparatus and connections the tests were made in the following manner:

A grounding breaker was installed at Wilmerding

Ground Selector for Ungrounded Three-Phase Distribution Systems

P. ACKERMAN

Associate, A. I. E. E.
Shawinigan Water and Power Co., Montreal, Que.

Review of the Subject.—Ever since three-phase distribution has been known, a controversy has been going on with respect to the relative merits of grounded and ungrounded neutral. The inability of locating and isolating a ground fault is the chief disadvantage of the ungrounded neutral system, this being the reason why lately the grounded neutral has been given preference.

The purpose of the so-called ground selector is to provide means to permit the selective clearance of a ground fault in an ungrounded neutral system. The device thus eliminates the mentioned disadvantage and raises the ungrounded neutral system to the same oper-

ating standard as the grounded neutral system, retaining at the same time the many other advantages inherent to the ungrounded system.

The paper describes the functioning of the ground selector and compares in detail the two systems. Two ground selector installations on largely different systems are described and the practical operating results are reported and discussed.

The conclusion is reached that the ungrounded neutral system equipped with a ground selector combines the advantages of the ungrounded and grounded neutral systems without being afflicted with their respective disadvantages.

INTRODUCTION

THE question of the advisability of operating three-phase distribution systems grounded or ungrounded has, within the past ten years, formed one of the liveliest subjects for discussion among transmission engineers. The reason for the greatly diversified opinion on this subject is chiefly due to the fact that either principle has its pronounced advantages and disadvantages.

In the early days of three-phase transmission the ungrounded system was used almost exclusively except where it was developed as a four-wire system.

With the increase in transmission and distribution voltages, insulation troubles started to multiply. Grounds started to develop quite frequently. It was then discovered that the ungrounded system was at an extreme disadvantage, particularly in case of extensive distributing systems, because there was no means available to detect and select the faulty feeder. Moreover the grounded phase produced a 73 per cent voltage rise between ground and the two sound phases. Such dynamic overvoltage, sometimes aggravated by resonance effects from an unstable arc at the point of fault, usually resulted in secondary breakdowns of weak insulation at entirely different parts of the system. Thus a short circuit developed disturbing the whole system and extending the damage unnecessarily to other parts of the system. A ground, left on the system for any appreciable time, was found to also have its weakening effect on the whole metallicly interconnected system and would thus prepare for future troubles. It was soon discovered, therefore, that continuing to operate on a ground fault was detrimental.

Improvements were suggested such as Creighton's

Presented at the Spring Convention of the A. I. E. E., Pittsburgh, Pa., April 24-26, 1923.

arc suppressor to render the ungrounded system safer. These improvements however failed chiefly in view of the fact that they aimed at the less vital disadvantage of the ungrounded system, namely the suppression of an arcing ground. They offered no solution, however, for detecting and selecting a faulty feeder.

As a result of this weakness of the ungrounded system the operating engineer's opinion gradually expressed in favor of the grounded system despite many disadvantages in regard to transformer connections. In the grounded system every ground meant a short circuit thus supplying the current necessary to operate relays and assure clearance of the faulty feeders. Thus the grounded system offered a natural solution for the most troublesome feature of the ungrounded system.

Today the stage has been reached where the general opinion is overwhelmingly in favor of the grounded system. Many operating companies, which have operated ungrounded in the past, have changed in recent years to grounded systems by devising various means of grounding.

The writer, being connected with a large distribution system with delta-connected transformers was, some years ago, confronted with the same problem of overcoming the serious conditions created by a ground on the ungrounded system as described above. Circumstances were such that grounding, either by changing to star-connected transformers or by providing an artificial grounding scheme, was not readily possible. He was forced therefore to the development of another scheme which is hereafter called "ground selector."

The purpose of this paper is to give a brief description of this scheme, to point out its advantages substantiated by actual operating records and to show how the ungrounded system equipped with a ground selector retains practically all inherent advantages of the ungrounded system and at the same time assures the same

effectiveness of clearing grounded lines as would be the case with the grounded system.

DESCRIPTION OF THE GROUND SELECTOR¹

A ground, occurring on a non-grounded distribution system, will be felt over the whole system. There is normally no means available to locate the faulty line except by disconnecting alternately individual sections of the system and observing whether the ground disappears. Such cut-and-try method is rather slow and always necessitates the momentary interruption of a larger part of the system than necessary, since many of the sound feeders may first be disconnected until the faulty feeder is located. The ground will cause a 73 per cent increase of voltage on the two sound phases to ground, and if left on for any length of time may cause the breakdown of another weak spot at an entirely different part of the system.

To reduce to a minimum the damaging effect of a ground, it is essential to provide means to have the grounded section cut out selectively and within the shortest possible time.

The ground selector has been developed to accomplish such selective and immediate clearance of a grounded feeder.

The fundamental idea of the ground selector is to produce intentionally a short circuit immediately after a ground develops on the system. This is accomplished by automatically grounding one of the sound phases at the main station bus by means of closing an oil switch, immediately upon the occurrence of a ground. Thus a complete phase-to-phase short circuit is produced and as a result overload current will flow into the faulty line, as if the line were on short circuit. Accordingly the ordinary overload protection will enter into action and disconnect the faulty line. As soon as the faulty feeder has cleared itself, the ground switch will open automatically and thus restore the system to normal condition.

Figure 1 shows schematically the principal features of the device. P_1 - P_2 - P_3 are single-phase potential transformers with their primary connected in star and with the star point grounded. The secondary of these transformers is connected to overvoltage relays R_1 , R_2 and R_3 , which latter, two in joint action, close the ground switches. The so-called transfer relays T_1 and T_2 are provided to assure an automatic clearance of the ground switch after the faulty line has cleared, as will be explained later.

Normally the three phases of the system will be balanced to ground, and as a result the potential on the transformer P_1 , P_2 and P_3 will be the same and equal 58 per cent of the voltage between wires. A ground on one phase will tend to lower the voltage on the

transformer, which corresponds with the grounded phase, and at the time the voltage on the other two phases will tend to rise toward a value equal to line voltage, that is 1.73 times normal voltage to ground. This overvoltage on the two sound phases is made use of to trip the two corresponding overvoltage relays and thus cause, by their joint closure, the automatic closing of one of the ground switches.

For instance a ground on phase (1) will cause a high voltage on phases (2) and (3). The joint trip of relays R_2 and R_3 will close the ground switch phase (3) thus causing a complete short-circuit between phases (1) and (3) and causing the faulty line to clear on overload. After the faulty feeder is cleared from the system a ground would remain due to the ground switch still being in closed position. In our particular example the ground would remain on phase (3) due to ground switch (3) remaining closed. The overvoltage relays

FIG. 1

of phase (1) and (2) would therefore trip and close ground switch (1) thus causing a bus bar short circuit if no special provision were made as by the installation of a transfer relay, to prevent such action.

The transfer relay blocks the closing circuit of the second ground switch immediately upon the closing of the first ground switch, and at same time prepares for the tripping of the ground switch which has been closed. When ground switch (3) closes, it energizes the coil of the transfer relay (T_2) throwing the lever over into the other contact position. In this position of the lever high voltage on phase (1) and (2) due to ground switch (3) being in closed position, will trip the ground switch (3) and thus re-establish normal conditions instead of closing wrongly the ground switch (1). Transfer relay (1) will in a similar manner prevent the closing of ground switch (3) and assure the opening of ground switch (1) when overvoltage relays R_2 and R_3 will

1. Original description in "Relay Protective Features of the Toronto Power Co.'s. Transmission and Distribution System" by P. Ackerman, *Journal, Engineering Institute of Canada*, April, 1921.

trip after a ground on phases (2) or (3) has been cleared, leaving ground switch (1) closed.

The above is a description of the essential features of the ground selector.

Various other features had to be embodied to make the device practical. These additional features are not shown in the schematic diagram but may be briefly discussed in the following:

The sketch shows three overvoltage relays only, and no provision to prevent these relays tripping on three-phase overvoltages, as may occur from various reasons. Such action would not be harmful in itself, since none of the ground switches would be able to close. The closing circuits would be ruptured instantly by the transfer relays upon the initial energizing of the circuits. However, their action would unnecessarily alarm the operator and necessitate the re-setting of the device. For this reason a balance potential relay has been introduced which only responds to an unbalance of potential to ground.

This relay keeps the actuation of the phase overvoltage relays blocked so long as it is not actuated itself. It therefore prevents the device from getting into action during three-phase overvoltage.

As a precautionary measure for any unexpected action on the part of the ground selector, the ground switches are equipped with overload relays, set sufficiently high for the line protection to clear before the ground switch opens.

As a further precaution, each ground switch is provided with complete electric control which enables the operator to actuate the ground switches by hand, if necessity arises.

A hand blocking switch is also provided by means of which the automatic features of the device can be stopped without, however, interfering with the hand control of the ground switches.

A ground resistance is provided in series with the ground switches. This resistance is purposely made low so as to influence only slightly the magnitude of distant short circuits, but having a tendency to hold up the bus voltage for grounds very close to the station.

The ground selector will operate once only and will have to be reset by hand by moving the transfer relay into the original position before it is ready for new action. This, however, does not cause any inconvenience, and has been found preferable to an automatic resetting which latter might cause trouble should a ground develop into a short circuit and clear the feeder before the ground switch has been closed completely.

From this description it will be noticed that the name "ground selector" is not quite correct, since it is actually the relay protection that selects the ground, whereas the device is a means only to create the condition which will enable the relays to act and select the grounded line. Nevertheless the name was adopted as being the most descriptive.

COMPARISON OF UNGROUNDED AND GROUNDED SYSTEMS

To fully appreciate the problem involved and the advantage derived from the ground selector it will be desirable to compare the characteristic features of grounded and ungrounded system under various operating conditions.

The following table tries to cover in a concise form, the behavior of the various possible operating methods, showing in the last column for each operating condition the scheme which is considered advantageous.

In going over Table I, it will be noticed that most of the items indicate that the ungrounded system equipped with ground selector proves in practically every respect advantageous or equal to the grounded system.

One item only may prove pronouncedly advantageous for the grounded system that is cost of grounding where $Y =$ connected transformers are in existence (see item 26). In this respect it may be pointed out however, that in many instances this saving compared with the cost of a ground selector may be more than offset by other inconveniences such as ineffective relay protection or loss of flexibility in the use of different transformer connections.

Some other items indicate that the grounded system appears to offer some advantage over the ungrounded system equipped with the ground selector.

It will be worth while to further analyze these items.

Item 7 points out the possibility of line switching causing a momentary shifting of the neutral should the three phases not close simultaneously. It is well realized today that damage to insulation is a function of magnitude of voltage and its duration; in other words, it does not only require high voltage, but the voltage must also last a certain time before it actually is able to do damage. A switching surge is of such brief duration and of rather limited voltage magnitude, so that the possibility of serious voltage stresses from switching surges is more problematic than real. Practical experience also plainly shows that troubles are hardly ever experienced at times of switching except in cases of very depreciated insulation which may barely be able to stand normal voltage.

Item 8 points out the fact that solidly grounded systems can have much more sensitivity set arresters than ungrounded systems. This is no doubt an advantage, but in view of the fact of the standard practice of a test voltage of two times line voltage for one minute on all equipment, the general improvement in design of transformer windings to withstand steep wave front impulses and the possibility of sensitive adjustment of arresters close to line voltage, this drawback of the ungrounded system should not be so serious.

Item 12 shows how, in case of the ground selector on the ungrounded system, the overvoltage on two phases created by a ground on the third phase cannot be avoided. The duration of this overvoltage is, however, so short and the overvoltage of such limited nature that any

Reference No.	Operating Condition	A Grounded System	B Ungrounded System with Ground Selector	Advantageous Scheme
14	Short between phases without touching ground.	Inductive interference will be small because of the neutralizing effect of feed and return wire.	Same condition as on grounded system.	
15	Shorts of two phases through ground.	Will constitute two single phase shorts 120° out of phase with resultant current passing back through ground to grounded neutral. Will result in heavy electro-magnetic interference.	Will constitute a single-phase short with metallic return so that inductive interference becomes neutralized.	B
	(d) Permissible emergency conditions.			
16	Disabled single phase transformer.	Y/Δ Transformers can be operated with one trf. disconnected, if step-up and step-down transformers have grounded neutral. This condition, however, will create serious electrostatic and electro-magnetic interference.	Δ/Δ Transformers, if using single-phase units, will permit operation on open delta, with one single-phase transformer disconnected.	B
17	Disabled line wire.	Y Permits operation with two wires only, provided step-up and step-down transformers have grounded neutral. Creates, however, serious electro-static and electro-magnetic interference.	Δ Could be operated with two wires if ground was used as third wire. Voltage between wires and ground would be increased by 73 per cent. Arrangement would create serious electrostatic and electro-magnetic interference.	A Advantage in exceptional cases only.
18	(e) Danger of secondary breakdowns in case of a ground.	No such danger because of fixed voltage to ground.	Hazard of cross short circuit very small because of ground condition lasting only for a very brief period.	A (apparently)
19	(f) High-resistance ground.	Occasionally high resistance grounds develop. Only 58 per cent of normal line voltage will be across the fault causing danger of insufficient current to actuate relays.	Ground selector when closing will throw full 100 per cent line voltage across fault, so that current will be 1.73 times greater, under similar conditions than in case of grounded neutral. As result more definite relay action is assured.	B
20	(g) No. of troubles.	Larger number of voltage disturbances and partial interruptions is to be expected since every ground represents a short circuit.	Smaller number of voltage disturbances and partial interruptions is to be expected since momentary self-clearing grounds not affecting system.	B
21	(h) Adaptability to existing systems.	Y-Connected transformers permit easily grounding of neutral point.	Ground selector can be easily installed on bus-bar of one of main stations irrespective of existing transformer connections.	
22		Δ Systems require special kind of grounding scheme, which will be particularly expensive if to be of low impedance to assure sufficient current for relay action.	Ground selector can be easily installed on bus-bar of one of main stations irrespective of existing transformer connections.	B
23	(i) Limiting effect on system in case of ground.	Disturbance can be limited by ground resistance or high impedance of grounding transformer as far as relay protection will permit.	Disturbance can be limited at liberty by ground resistance in circuit with the ground selector switches.	
24	(k) Short circuit stresses on equipment.	In case of all transformer neutrals of parallel operated transformers being grounded, the short-circuit stress will be equally distributed between all the transformers.	Ground selector providing a direct short circuit across phases of the system will divide the short-circuit stress equally among parallel operated transformer and generator equipment.	
25		Where only one generator or one transformer is grounded or where special grounding transformer is used, the total short-circuit stress will have to be taken up by the respective unit.	Ground selector providing a direct short circuit across phases of the system will divide the short-circuit stress equally among parallel operated transformer and generator equipment.	B
26	(l) Cost.	Where transformers are star-connected so that system can be grounded by grounding the transformer neutral, the expense will be very small.	The ground selector will require oil switches, potential transformers, ground resistances and some relay equipment which will involve a smaller or larger expenditure depending on the operating voltage.	A
27		Where a special grounding equipment must be provided, the expense may become considerable.	The ground selector will require oil switches, potential transformers, ground resistances and some relay equipment which will involve a smaller or larger expenditure depending on the operating voltage.	

cleared immediately upon indication of a permanent ground, and then the system was started again by closing one feeder at a time, leaving out the feeder, which made the ground reappear. With this procedure secondary breakdowns could usually be avoided although it meant a complete shutdown of the system.

It was realized that something had to be done to improve this situation and it was then that the idea of the ground selector developed. This was as far back as 1916. It was realized, however, that the scheme would only be beneficial if the overload protection of the distribution were effective and dependable. In an endeavor of putting first the short-circuit protection of the distribution into shape, the installation of the ground selector was delayed until September, 1918.

The main reasons in this particular case for adopting the ground selector in preference to some permanent grounding scheme were as follows:

1. The ground selector was cheaper and simpler to install, since existing spare feeder switches could be used for the purpose and since the ground current could be adjusted to any desired value to suit relay requirements.

A grounding scheme would have involved either a costly grounding transformer of very low impedance to ensure sufficient current to actuate the ordinary overload protection, or a less costly grounding transformer of higher impedance, in which case however the ground current would have been so limited that a special ground protection would have been required which in itself would have offered serious difficulties and expense if the same selectiveness and effectiveness was to be obtained for grounds as for shorts circuit.

2. The ground selector promised, for reason of the time lag, of closing the ground switch, to allow self clearing grounds to clear without disturbance to the system.

It was originally intended to provide dead artificial grounds, so as to obtain identical current conditions for grounds and short circuits to assure effective relay action under all conditions. However, it was finally decided to introduce a very low ground resistance in form of a large water rheostat which hardly affected the magnitude of the fault current under most limited current conditions in case of distant grounds, but which offered the great advantage of keeping up the bus-bar voltage for grounds close to the terminal station, thus helping to keep the synchronous load in step.

The ground selector was put in service in 1918 and has proved very effective and beneficial as following operating records will indicate:

Table II shows an operating record of the ground selector, showing the number and kind of troubles it had to clear.

Table III shows a summary of troubles experienced on the 12,000-volt distribution. This table indicates particularly the large number of self-clearing grounds without disturbance to the system, which shows a

decided advantage over a permanently grounded system.

It may be pointed out that since the installation of the ground selector not a single secondary breakdown, causing a cross short circuit to some other point of the system, has been experienced.

In all cases the trouble and partial interruption remained confined to the faulty feeder.

With the exception of one case the nature of the ground was always of sufficiently low resistance to produce sufficient ground current to effectively trip the relays. In the case which did not clear the feeder the ground current was sufficient to be distinctly noticed as overload on the respective line ammeter, enabling the

Considering however the character of the system, it must be realized that the results are rather better than expected.

The momentary self-clearing grounds are of a smaller percentage than in case of Table III of the 12,000-volt system, so that the advantage compared with a permanently grounded system is not so pronounced.

High-resistance grounds, where the ground selector was unable to produce sufficient current to operate relays are also somewhat more numerous than in case of

the Toronto system. There were however only three cases of this nature compared with forty-eight cases where sufficient ground current was developed to actuate relays, which means only 6 per cent ineffectiveness. In view of the uncertain ground condition along the line this must be considered an unexpectedly good result.

The number of secondary breakdowns, causing a cross short circuit to some other part of the system is, as seen from Table V, still undesirably large. It is to the credit of the ground selector, however, that only one of these cross short circuits actually caused a permanent insulation damage. All other cross short circuits were harmless flashovers traceable to asbestos mining districts caused by insulators whose flashover had been reduced by a combination of broken skirts from blasting and asbestos dust coating having become moist from fog or slight rain. Considerable trouble from flashovers in this district is experienced under normal voltage conditions and it is well known that sometimes insulators may be on the system unobserved which may barely be able to resist the normal operating voltage;

so that the least voltage disturbance will cause the insulators to flashover.

The large number of cross short circuits is therefore less an indication of a weakness of the ground selector in that respect than a weakness in the insulation of the system at these points and has to be remedied by increasing the local safety factor of flashover even under conditions of broken skirts.

The operating results of this system indicate, similar to the Toronto system, the ability of the ground selector to avoid secondary breakdowns, as long as the system has only fair insulation, and to provide sufficient current to effectively clear faulty lines.

CONCLUSION

The operating results show conclusively that the ground selector will improve the ungrounded system to the same state of perfection as claimed for the grounded system without having to resort to an artificial grounding method.

The operating results show that the ground selector prevents permanent secondary breakdowns and permits clearance of grounded lines as effectively as the grounded system. Besides this, the ungrounded system retains the advantage of less numerous voltage disturbances and partial interruptions and the flexibility of permissible transformer connections.

The ungrounded system, combined with ground selector and equipped with an effective relay protection should prove therefore advantageous compared with the grounded system, at least as far as large distributing systems are concerned and for voltages, not exceeding 60,000-volts.

This conclusion does not necessarily apply to parallel trunk lines where grounded neutral at both ends may prove cheapest and best.

It also does not apply to any system exceeding 60,000-volts since the complication and cost may become excessive.

Each individual case, of course, will have to be studied on its own merits to arrive at a conclusion of the most desirable arrangement.

Discussion

For discussion of this paper see page 532.

The Distance Relay for Automatically Sectionalizing Electrical Net Works

BY LESLIE N. CRICHTON

Member, A. I. E. E.
Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

Review of the Subject.—This paper describes a new relay for automatically sectionalizing transmission lines, similar to existing relays in many respects, but equipped with "brains" so that it can determine the location of the trouble and govern its operation accordingly. For dead short circuit its time of operation is proportional to the distance from the short circuit so that when it is used the circuit breaker nearest to the trouble always trips out first. When applied to any system it is adjusted to fit the particular length of line which it controls and no change in this setting need ever be made due to operating conditions on the remainder of the system.

Its discrimination is obtained by a time limit which varies directly as the voltage and inversely as the current existing during the trouble. It has the incidental advantage that since the circuit breaker nearest to the trouble is opened first, the final breaker to open is the one

having the longer section of line in series with it to limit the current and therefore decrease the duty required of the circuit breaker.

A RELAY WHICH DETERMINES ITS OWN TIME OF OPERATION

THIS is a new device, which when trouble occurs, makes a calculation to determine its location.

If the trouble is close to the switching point at which the relay is situated, the relay will operate quickly to disconnect the disabled section. If, however, the trouble is a long way off, the relay will operate slowly in order to allow any other relay which might be nearer to the trouble to act first.

Because this device adjusts its time of operation to suit the location of the trouble, it will operate on the most complicated sort of network; in fact, the more complicated the network, the more favorable are the conditions for its correct operation. In the past, reasonably satisfactory sectionalizing has been obtained by means of over-current and directional relays equipped with time limit features. The general scheme of operation has been to adjust the relays farthest from the power house with a short time limit and to increase this time limit on those relays which are located nearer to the power station. On a complicated system this is rather difficult and in some cases impossible, for instance, in the case of tie lines between two generating stations.

THE BASIS OF CALCULATION

In determining the distance, the relay makes use of Ohm's law and bases its calculation upon the value of the current and voltage existing at the time of the short circuit. A simple form of distance relay is shown in Fig. 1 wherein a current coil is shown arranged to close the relay contacts while a voltage coil is so arranged that, as long as voltage is applied, it will tend to overpower the current coil and prevent the contacts from

being closed. These two coils are proportionate so that on the particular section of line to which they are applied the current coil will just overpower the voltage coil when a short circuit occurs at the far end of the section. If a short circuit should occur in the next section, the voltage across the potential coil of the relay will be higher and will thus prevent it from operating, whereas, if the trouble is within that section of line and close to the relay, the voltage will be lower and the relay's action, therefore, more positive. With trouble

FIG. 1—PART OF A NETWORK SHOWING A SINGLE SECTION OF LINE AND AN ELEMENTARY DISTANCE RELAY

One defect is that it cannot distinguish between a short circuit at A and one at B.

immediately at the relay, the voltage will of course be zero and, therefore, the voltage coil will offer no opposition to the operation of the current coil. Another way of looking at this simple relay is to assume that the two coils are balanced against each other and that the circuit is divided into two branches, one branch going through the voltage coil having a fixed resistance and, therefore, taking a current which is proportional to the voltage, and the other branch consisting of the current coil in series with the section of line. This latter branch is of variable resistance depending upon the location of the short circuit and the coils are so designed that the current coil will just overbalance the voltage coil when

the resistance is its maximum. Therefore, when the short circuit is beyond that section of line, *i. e.*, when the resistance of that particular branch becomes greater than that required to balance the relay, the relay will not operate. On the other hand, when the resistance is less than that of the full section of line, *i. e.*, when the short circuit is closer to the relay, the unbalance will be still more pronounced and the relay action more positive.

The simple relay mentioned in the preceding paragraph has two obvious defects. First, it will not work properly if the short circuit should in itself have some resistance, which resistance, being an unknown factor, would be difficult to take into account. Second, it is unable to properly discriminate in case of trouble occurring close to the substation at the other end of the section, *i. e.*, the relay cannot tell whether the trouble occurs at A or B. This simple relay would furthermore be unable to clear trouble in a distant section which for some reason had not been cleared by the proper circuit breakers on that section.

The remedy for all these defects is simple; design the relay so that when the trouble is close, it will operate instantaneously, but when the trouble is some distance away it will operate slowly so as to allow any relay which is nearer to the trouble to act.

MECHANICAL PRINCIPLE

The principle of the time-limit distance relay is shown schematically in Fig. 2. This relay is of the induction type, the disk being rotated by the current coil whenever the current reaches sufficient magnitude, —the movement of the disk being damped by the

FIG. 2—SCHEMATIC DIAGRAM OF C Z DISTANCE RELAY

permanent magnet so that its speed is roughly proportional to the current. The movement of this disk does not directly close the contacts but instead it tightens a spiral spring. On the other end of this spring is fastened a lever which is pivoted at the center and which has the contacts on one end and the core of the voltage coil on the other. This voltage coil is so arranged that it opposes the closing of the contacts. When in the neutral position all parts of the relay are nicely balanced so that if there is no voltage on the voltage coil a very slight movement of the disk will close the contacts.

Similarly, if voltage is applied to the restraining coil, its pull will prevent the contacts from being closed until the spring has been tightened up sufficiently to overcome it and since the motion of the disk is damped, this will require some time.

MATHEMATICAL PRINCIPLE

It is evident that for a given voltage on the voltage coil the spring must be tightened to a certain definite point before the pull of the voltage coil can be overcome and, therefore, if the voltage is maintained constant the

FIG. 3—DISTANCE RELAY TYPE C Z

time required for the relay to close its contacts will vary inversely as the current, or stated mathematically:

$$T \text{ varies as } 1/I$$

Similarly if the current is maintained constant with a resulting constant speed of the disk, the time required for the contacts to close will vary directly as the voltage, or stated mathematically:

$$T \text{ varies as } E$$

Combining these two we have

$$T = E/I = Z = \text{distance}$$

IMPORTANT DETAILS OF DESIGN

The principle which has just been described is exceedingly simple but the actual design of the relay was quite difficult, principally because of the requirements that, during time of trouble, it must discriminate between different voltages of very small value, whereas, during normal operation, the voltage coil must be able to withstand full voltage continuously. Part of the method of overcoming this trouble has been to cast cooling ribs on the case containing the potential coil, as shown in the accompanying photograph and the schematic view, Fig. 3. This loss is only about 8 watts but it is generated in a coil no larger than an ordinary spool of thread. As a result of this design, the voltage coil will discriminate quite positively between zero voltage and 5 per cent of normal voltage. At first, difficulty was encountered due to the effect of residual magnetism when suddenly reducing the voltage from normal to a small value, but this has been overcome by using a core of a

9, trouble should occur at X the relay at A should operate in, say, 0.1 second. The circuit breaker will require about 0.25 second to open, the total time required to clear the short circuit being 0.35 second. Now the relay at B should have sufficient time delay so that it will not close its contacts before the breaker at A has had a chance to open (0.35 sec.). If we double this time in order to allow an ample margin of safety, we will then have a reasonable setting for the relay at B . Therefore, we have drawn the dash line across Fig. 8 to indicate the maximum time which should be required to operate any relay. This is the extreme case; the average short circuit will be cleared in considerably less time. This difference in time between adjacent stations is of course due to the difference in voltage between them. With the present design of relay the difference in voltage between two consecutive stations carrying the same trouble current must be at least 5 per cent in order to secure proper discrimination.

All of the preceding argument is based upon the assumption that trouble always consists of "dead" short circuits which the writer believes to be the case. If we

FIG. 9

assume that a high-resistance short circuit exists, it will increase the time of operation of the relay but this is not particularly serious because this resistance will also cut down the value of the current so that the shock to the system is not so great and can be withstood for a longer time.

ADJUSTMENTS

Consider curve B in Fig. 8 which has been plotted from the relay characteristics given in Fig. 7; and assume that the ampere turns on the current coil are reduced to one half. Therefore, with our assumed current, the disk will rotate at half speed which will allow the voltage to be reduced to half its value in order that the relay may operate in the same length of time. In other words by reducing the ampere turns on the current coil to one half we can reduce the distance by an equal amount, thus giving a curve D . Similarly by again halving the number of turns, curve E can be obtained. Similarly

the other curves in the group are obtained by means of taps on the current coil.

Suppose the section of line to which we wish to apply this relay is so long that the adjustment shown on curve B is unsatisfactory. We leave the current adjustment as it is and place sufficient resistance in series with the potential coil so that its current is cut to half its original value. Therefore, in order that the pull on the coil shall be the same with a consequent equal time of operation, it will be necessary to double the voltage, which can only be done by doubling the length of the section of line. Thus, we get curve B' and similarly by again doubling the resistance of the potential circuit we double the distance and obtain B'' . The other curves can be similarly extended so that adjustments can be made which are suitable to intermediate length of line section. It is thus seen that by two very simple adjustments the relay can be set to work properly on sections of lines whose length vary as much as 40 to 1.

METHOD OF SETTING RELAY

The unit of distance shown in Fig. 8 depends upon the size of the conductor, the spacing between them and the voltage of the system, all of which must be taken into account when setting the relay. It is also necessary to consider the ratio of the potential and current transformers, so that the total possible number of combinations is enormous, and in order to make the task of adjusting relays an easy one, it is important that the manufacturer of the device furnish curves or tables for systems of various voltages and various sizes of conductor showing the distances corresponding to the different relay settings. When the data are arranged in this way the problem of setting the relays is an easy one, it being necessary only to determine the distance between the switching stations to which the relay is to be applied and picking off the proper relay setting from the table. As a rule no calculations are necessary, although it may be occasionally advisable to make a rough check of the short-circuit current available in order to make sure that there will be sufficient current to operate the relay. Long and laborious calculations of the short-circuit currents available at all points of the system are certainly unnecessary. Likewise, it will not be necessary to determine the short-circuit current by means of calculating tables and similar devices.

ITS USE ON GROUNDED NEUTRAL SYSTEMS

When a short circuit occurs between two wires on a 3-phase system, the potential coil of the relay must, of course, be supplied with delta potential so that it can make its proper determination of the distance. On the other hand, it should be supplied with star voltage when a short circuit occurs between one wire and ground on a system having a dead grounded neutral. It, therefore, appears that two sets of relays should be used on such a system, one to clear short circuits between wires and

the other to clear grounds. On a system having its neutral grounded through a resistance, other relay schemes must be used to clear grounded conductors.

THE DIRECTIONAL ELEMENT

In addition to the distance determining element which has been described this relay will usually require a directional element in order to definitely locate the direction of the trouble as well as its distance away. For example in Fig. 9, which represents a rather simple distribution system, it is quite evident that if trouble should occur at *Y*, both relay *C* and relay *D* at substation *N* would have the same current and voltage actuating them so that they would both try to open their circuit breakers. In order to prevent such improper operation, each relay should be equipped with a directional element which has its contacts in series with the distance contacts and acts as a sort of "check valve" to prevent the relay from operating when power is flowing toward the bus bars. Therefore, in the figure relays *B* and *D* are each shown equipped with directional

FIG. 10—C Z RELAY ELEMENTARY DIAGRAM

element so connected that they will allow their respective relays to operate only when power is flowing away from the bus bars. Similarly the relays at substation *M* and in fact the relays on all the substations around the loop should be equipped with directional elements as shown. Of course directional elements are not necessary at the generating station and at other points where power can flow only in one direction.

This directional element is similar to the one which has been used so successfully for the past 8 or 10 years and consists of a very sensitive watt-indicating device without mechanical restraint of any nature and so sensitive that it will operate under the most extreme possible conditions of low voltages on the system. This directional element will easily discriminate on 1 per cent of normal voltage if the short-circuit current through the relay is, say, 5 or 6 times normal. This condition is easily obtained during short circuit; in fact it is unusual to have the voltage drop to as low a value as 1 per cent of normal.

In Fig. 10 is shown a complete diagram of internal connection of the distance relay including the directional element and the adjusting taps. It should be noted that during normal conditions on the system a large number of the directional elements will have their contacts closed, but this is a matter of no importance because the cooperation of the distance element is necessary before a circuit breaker can be tripped. Therefore, the question of normal direction of power flow has nothing whatever to do with the setting or adjustment of the relay.

METHOD OF CONNECTING RELAY IN THE CIRCUIT

The experimental work which has finally resulted in the production of this relay was begun quite a number of years ago and one of the earliest fruits of the work was the startling discovery that the directional element cannot be connected in the circuit as though it were an ordinary wattmeter intended to measure power consumption. Although the problem was quite baffling at first, it was found that there were several easy solutions, the best one being to connect the current coil of the directional element so that it utilizes the star current (the current in the line wire) and connect the potential coil so that it uses the delta voltage of the system having a phase relation 30 deg. behind the current. This scheme has been successfully used for a number of years on the present type of directional overcurrent time-limit relay and it is usually assumed that this lag in the voltage circuit is for the purpose of enabling the watt element to work under a little better power factor condition when the current lags due to the low power factor of a highly inductive short circuit. While this is, of course, an advantage, the principal reason for using the connection is that it prevents improper operation of the relays under badly unbalanced conditions such as will always occur when only two wires of a 3-phase circuit are short-circuited. For example if the two coils of the relay should make use of the star current and star voltage of the circuit, it would be theoretically possible to have short circuits of such a nature that the current in the relay would, in effect, lag 180 deg. behind the voltage so that the relay would operate in the opposite direction from what it should do.

In order to more thoroughly investigate this subject and check some of the theories, an elaborate 3-phase artificial transmission line was constructed. This part of the work is described in a paper on the artificial transmission line presented before the A. I. E. E., by Mr. George H. Gray, in 1917. The conditions which exist at numerous points of a large transmission system, during almost every conceivable kind of ground and short circuit were studied and classified in a number of diagrams and charts which makes the subject easily understood. It is, therefore, unnecessary to discuss the subject in this paper.

ADVANTAGE OF THE DISTANCE RELAY

All dead short circuits will be cleared within one second and the majority of them in considerably less time.

Trouble will be cleared with equal rapidity from all parts of the system.

The breaker furthest from the trouble opens last, thus insuring the insertion of considerable impedance in the path of the short circuit before finally interrupting it. This reduces the strain on the breaker, and, in effect, converts every breaker on the system into a "resistance type" breaker.

It does not require an excessive amount of mathematical calculations when applying it to the distribution systems.

CONCLUSION

Although the distance relay as described in this paper is a new idea, it can hardly be said to be entirely untried because its use does not involve a large number of new mechanical devices or new electrical connections. The induction type of protective relay has been thoroughly tried out and found to give excellent service. The directional element has given the same good service and likewise the method of connecting it into the circuit has been thoroughly approved by years of experience. In effect, the well known directional time-element over-current relay has been taken and been given sufficient "brains" to enable it to determine what time limits it should have in its particular location.

Discussion

SELECTIVE RELAY SYSTEM OF THE 66,000-VOLT RING OF THE DUQUESNE LIGHT COMPANY

(SLEEPER);

GROUND SELECTOR FOR UNGROUNDED THREE-PHASE DISTRIBUTION SYSTEMS

(ACKERMAN);

THE DISTANCE RELAY FOR AUTOMATICALLY SECTIONALIZING ELECTRICAL NET WORKS

(CRICHTON);

PITTSBURGH, PA., APRIL 25, 1923.

R. N. Conwell: Mr. Sleeper's paper gives an example of one of the methods of determining whether relays are correctly set for selective operation. There is another method, that of keeping accurate records of relay operations in service, which will give equally good results but these are not obtained as promptly as by applying actual short-circuit tests. The expense, however, is much less and it is the only method applicable to those systems in which the transmission cannot be taken out of service for tests. Both methods must be preceded and followed by the same careful analytical study which Mr. Sleeper has given to his problem.

I regret that Mr. Ackerman has brought into the subject of relay protection the item of interference to signal systems. The two are separate and distinct problems and I feel sure that any system of relay protection installed on a power supply line as a remedial measure in a case of inductive interference will be an entirely different relay system from that installed solely to isolate defective apparatus or transmission lines. The scale of fundamental limiting factors of time, current and voltage in the two problems are in the ratio of 10 or 100 to 1. Further-

more, Mr. Ackerman's paper brings up the old question of grounded versus ungrounded systems from both the system protection and interference points of view. From a purely power system point of view, I believe there is little doubt as to the desirability or even necessity of grounding. Inasmuch as Mr. Ackerman's device may be considered as a Creighton arrester with the high-tension phases crossed, the reduction in interference claimed for the device is not apparent, for the occurrence of a single-phase fault to ground in an ungrounded system results in the device operating to ground another phase and permitting the current required to operate the relays to flow through the ground between the fault and the ground established by the device. The condition therefore, is not unlike that found in a grounded neutral system when considered from the interference point of view.

The relay which Mr. Creighton has shown will fill a long felt need. The continual increase in the number of substations to be supplied from a transmission network has forced the use of long time settings, if arrangements could not be made for parallel line protection. The troubles and hazards incident to the use of long time settings in such cases will now be obviated by the use of the "Distance Relay."

P. Ackerman: I have been interested to hear the paper by Mr. Crichton, chiefly because I have been working on a similar principle, such scheme being in operation on one of the Shawinigan Water & Power Co.'s systems for about three years. My scheme has been described in a paper read before the Engineering Institute of Canada and published in the *Journal of the E. I. C.* in the December 1922 issue.

The only thing common to the distance relay of Mr. Crichton and the one used on the Shawinigan System is the underlying idea of using the potential for restraining the tripping tendency of the current unless the voltage is very low. With respect to the detail consideration of obtaining selective action of switches located in series to each other the two schemes are widely divergent. This is apparently due to the fact that the two schemes were developed with entirely different ends in view, probably because of the difference of the systems.

Mr. Crichton gave primary consideration to the desire of obtaining a relay which was not limited in its active distance range, so as to obtain a standby protection for switches located in series to each other. He thus conceived of the distance-time relay wherein the tripping time was an approximate function of the distance to the short-circuit point. He obtained this feature by cleverly combining the voltage restraining element with a time-limit overload relay.

I, on my part, was anxious to obtain primarily instantaneous protection over the largest possible portion of a line so as to reduce the damage to the line and the disturbance to the system, the latter consisting largely of synchronous motor load. I was also desirous of obtaining a protection which could be successfully applied to the generators. In view of the above, I found it desirable to keep the functions of the a-c. relay and the selective time-limit feature separate.

As shown in Fig. 1 I used a balanced beam with a current solenoid at one end and a potential solenoid at the other end. The balance between current and potential solenoids can be adjusted for any desired active distance range. Thus a relay can be adjusted to be effective to the end of a line, but not beyond. Such relay will not have to be selective with any other switch and in consequence can be made instantaneous. A second set of relays is adjusted to have an active distance range beyond the substation, thus obtaining a protection for substation shorts. If this latter set of relays was made instantaneous it would become non-selective with the protection of the feeder ahead. In order to assure time selective action, therefore, this latter set of relays is arranged to trip the oil switch through a definite time relay instead of directly.

Fig. 2 illustrates the difference in time curves obtained by the

I would not necessarily accept the conclusions as outlined here—that the ground selector system is a most advantageous one from the standpoint of inductive coordination—without having the theory developed and supported by something in the way of operating data.

E. A. Hester: Mr. Sleeper says that in order to get credit for effective relay operation it is necessary to get it when the relays are installed and before they are called upon to operate. That is to say, in effect, that the relays thereafter are usually blamed for any failure of lines or apparatus to clear, or for faulty sequence of operation. Unfortunately, that is true in a great many companies even at the present time, although there is a tendency toward a more thorough investigation of trouble, which in a great many cases absolves the relays from blame and attaches it to faulty application, or to the failure of other apparatus. In any case, it is the duty of the protection or relay engineer to draw the attention of his organization to successful relay operations. Attention is automatically drawn to unsuccessful operations, which quite often gives executives and others not so closely in touch with the actual operation a wrong impression. It is very interesting to note that a great many companies are establishing a bureau which takes care of protection alone. This is a very encouraging sign and it is to be hoped that these bureaus, by making careful analysis of relay operations and of interruption reports, will give the protective relays a reputation, which is rightfully theirs, of apparatus, which when correctly applied, is almost unequaled in precision of operation.

In this connection it may also be mentioned that the American Institute of Electrical Engineers and the National Electric Light Association both have Relay Subcommittees engaged in the preparation of a relay handbook. This should also do its share in preventing wrong applications with resultant faulty operation.

I should like to bring out one point with reference to Mr. Crichton's paper and Mr. Ackerman's discussion, *i.e.*, that this principle of "voltage restraint," as it was once called, has been successfully used by an operating company before the apparatus described in this paper and discussion was produced. Several years ago the West Penn Power Company tried out a scheme in which they locked the circuit breaker mechanism for voltages above a predetermined percentage. I believe Mr. Crichton was somewhat interested in this application. The scheme worked out very well for a while on this system, which had very long lines and relatively few stations scattered over a large territory. The scheme and its operation have been described in other papers presented before the Institute, both at Lake Placid, New York, in 1919 and in Niagara Falls, Ontario, in 1922.

H. A. P. Langstaff: Mr. Hester has referred to the voltage restraining relay on the West Penn System. This installation was made several years ago when the West Penn System was comprised mostly of radial feeders, and under this condition, operation was quite reliable. As the system grew and additional loops as well as generating stations were added, it was found advisable to install a more up-to-date type of relay, and as this installation was being made on part of the system, operation seemed to drift toward other sections of the system where the voltage restraining relay was still in service.

This feature brought out a very important point, which was brought quite forcibly to our attention, in connection with all switch operation analyses; *i.e.*, the re-equipping of a system as large as the West Penn with new relays. The work should be complete as soon as possible. In our particular case we found that the new relays, we might say, dammed up the operations in the new relayed section and diverted them to the remainder of the system.

In connection with the new impedance relay, we are wondering whether or not Mr. Crichton is going to allow us a royalty on the original idea.

We found the that time element of the West Penn voltage restraining relay was entirely too speedy, and we found that the addition of a time delay relay materially improved the selective operation. Twelve stations were equipped with this time element relay within one month's time, thereby enabling us to materially rearrange the operating scheme of dividing the system into three parts previous to storms, and remaining in parallel, which greatly reduced the number of interruptions.

There is one point which I would like to mention in connection with balance protection, which needs to be guarded against, and that is when one tie-line is out of service for repairs or in case of trouble, the remaining lines should have a sufficiently high setting to prevent an incorrect operation due to trouble on some foreign section. It is quite possible that a radial feeder out of a substation might have a considerably higher setting than the tie-line which is left in service.

Another point which has not been mentioned is that wherever more than one type of relay is used to control the one breaker, some form of indicator should be installed to show which relay was the cause of the switch operation. I believe this feature should be made standard equipment with all relays. This has a very important bearing on the setting of the relays, especially ground relays, which are more or less difficult to figure unless it is possible to carry out a schedule of experiments similar to those mentioned in Mr. Sleeper's paper. The writer has developed, and we now have in operation, about 25 indicators which give an audible as well as a visual alarm, and also has a Veeder counter which actually automatically records the total number of relay operations. This acts as a guide to the station attendant, and gives him a check on his switching equipment.

There is also another point which has not been mentioned in any of the papers or discussions, and that is the advisability of testing all relays in the laboratory. This question has been under consideration by us for some time, and we have not yet found this to be advisable. In the last two years we have installed approximately 600 relays and not more than 10 of these have been in our laboratory. All shipments are made direct from the factory to the job, installed on panels and given more or less of a laboratory test, and the settings made directly with the relays in position. Our percentage of failures has been exceptionally low.

Before starting on our relay program, the question of source of tripping current was very thoroughly investigated, and it was finally decided to use 12-volt storage batteries and vibrating rectifiers, adjusted to give a continuous trickling charge. We now have 15 of these installations in operation. Of course, all breakers are equipped with 12-volt, 5-ampere trip coils and the plunger in this is set approximately one-half its distance up in the coil in such a way that the coil will actually operate on six volts.

During the last two years I know of no failure which can be attributed to this low-voltage service. We have had one case of complete failure, due to the blowing of a main-line d-c. fuse, making all switches in this one station non-automatic, but this condition would have applied, regardless of the d-c. voltage.

Chas. McL. Moss: The difficulty of any system of balance relay protection is inherently the number of cross connections required between the current transformers of the two lines. I think you probably have not used them. Even in the diagrams we have had shown us, the connections are somewhat complicated and Mr. Sleeper admits that he left out some of them. The complications are further increased if there are more than two lines.

He has pointed out the necessity of operating lines in pairs, but has neglected to state that the Duquesne Light Company ran into some difficulties at some points where they had four lines, and if you try to pair four lines, and use all possible combinations the necessary complications cause it to fall down by its own weight, so they wisely abandoned it.

The meat of Mr. Crichton's paper was in his first few words, in which he stated that the distance relay was essentially a "self-setting" relay. We all know that we can set up any predetermined line conditions and can pack relays on that line and give the proper time setting, directional settings, current settings, to take care of any difficult conditions we can impose. Somebody comes along and puts on additional stations, involving more time settings. Instead of having normally multiple lines, we have single line operation and then in order to maintain our full protection we must reset the relays or limp along on a partially automatic protective scheme.

Mr. Ackerman, in pointing out the disadvantages of the grounded systems, brings out in a great many places in his tabulation the disadvantages of a grounded system due to transient grounds always interrupting the service. It appears to me that that difficulty should not be given so much importance because in any large system of today supplying any important service, we practically always maintain that over duplicate feeds because outside of normal maintenance we may get other faults besides grounds. With a grounded system with adequate relaying, we can clear a fault immediately, maintaining the service over the other lines. He also brings up in his tabulation the difficulty of grounded neutral system, due to the requirement of star-star transformers throughout, thus requiring tertiary windings. In a large number of systems where we have both the high and low-tension grounded, that is very simply and economically avoided by proper combinations of Y-delta transformers, making the tertiary unnecessary.

O. C. Traver: Mr. Sleeper makes a specification that single line operation must be possible, preferably without additional relays over the number required for parallel line operation. That is very laudable, but at the same time, there is one difficulty, in that without additional relays, it would take the same time to clear a short whether you have parallel line operation or single line operation. The single line must have enough time to allow others to clear. Therefore, the 1.2 seconds time mentioned by the author would be necessary to clear a fault in any case.

You have noticed in the moving pictures just shown that the arc developed first very small, and very rapidly swung across the screen out of the range of the picture. That is the sort of thing that makes trouble many times. It is the sort of thing I believe it is wise to steer clear of. Accordingly I think two sets of relays in most cases are more than justified, if you can prevent an arc from swinging into a phase-to-phase or three-phase fault. To secure the desired result you would use relays of the same general type as Mr. Sleeper has described, but two sets of them, the first set would be as nearly instantaneous as possible; the second coming into play automatically only after one line has gone. There is no material complication and the scheme works out very nicely.

I have seen a test similar to the one shown here on the screen, an arc started by a fuse, across a 110,000-volt circuit, with the full power of a large system back of it, and I was very much disappointed and greatly surprised because I expected to see some real honest-to-goodness fireworks and didn't get them. There was a ball of fire about the middle of the fuse and that ball never moved out of its tracks simply because the breaker was protected by an instantaneous relay. Although the wind was blowing at a good rate the arc had no time to move over and involve the other phases. For that reason, I am very much in favor of using as quick a time as can be had for parallel operation, and then automatically introducing a longer time for the remaining single-line operation. You usually secure an additional advantage through time grading making it possible to care for more than one line out of service at the same moment. It may not happen very often that you need to care for a condition like that, but it does happen sometimes, and this arrangement will give you entire control under all conditions.

Passing now to Mr. Ackerman's paper: He states at the

start that his particular circumstances were such that grounding, either by changing to star-connected transformers or by providing an artificial grounding scheme, was not readily possible. He, therefore, hit upon a very clever scheme of taking care of the situation which was apparently troublesome. He put on something and that something worked. I cannot quite agree, however, with his conclusions as applied to the general case.

Mr. Crichton has demonstrated a mighty interesting relay. The pioneer work of the West Penn Company and Mr. Ackerman's installation have already been referred to. The earliest reference to this principle, of which I am aware, is contained in a German patent issued about 16 years ago. Since this time the difficulty, as it appeared to some of us, has been that potential connections are required, and a double set at that, to care for both phase-to-phase faults and faults to ground. The usefulness of the scheme when properly applied cannot be doubted although any universal use is seriously questioned.

Some time ago the General Electric Company developed what was called an "overload-undervoltage relay" but due to the above mentioned difficulties the time was not considered ripe for exploitation. The characteristics are about the same as for the relay described by Mr. Crichton though the method of securing them was very different. This relay also consisted of two elements but instead of a direct mechanical connection, the two elements worked independently. One of these was a voltage element and the other was an induction over-current relay of standard construction. The net action of the combination was that the voltage element automatically varied the time setting of the over-current relay.

L. P. Ferris: Mr. Ackerman has referred in several places to the matter of inductive interference, as have also two of the previous speakers in discussing his paper. In a comparison of the grounded neutral system, and the isolated system, it is well to differentiate sharply between the situation under steady state or normal operating conditions and the situation under abnormal conditions as of short circuit.

In Mr. Ackerman's Table 1, reference No. 4, operating conditions normal, he brings out a recognized difference between the grounded neutral system and the system operated without ground connection. In the first we have a source of residual current and voltage which is not present in the isolated system, so I believe he is correct in stating that the isolated system has the advantage from that standpoint.

In reference 13, condition of a ground on one wire, Mr. Ackerman draws no conclusions as to which system is the more advantageous. He states in reference to the ungrounded system that the short-circuit will have the same serious effect as in the case of the grounded system. That, I think, should be qualified because with Mr. Ackerman's scheme he grounds a phase which is not normally grounded, producing a phase-to-phase short circuit through the ground. Now, if the two grounded points and line between them embrace the parallel, you have a phase-to-phase short circuit completed through the ground which may give a more severe condition than the grounded neutral system, but that will depend to some extent upon the amount of resistance which Mr. Ackerman uses. If that resistance is small I should expect the grounded neutral system to have the advantage.

In reference No. 14 I believe Mr. Ackerman's conclusion is that the two systems stand on a par, and this is substantially correct.

In reference No. 15, I think the statement that the ungrounded system gives a metallic short circuit and neutralizes interference should be made conditional on the grounds on the two phases occurring on the same side of the parallel. If the grounds are on opposite sides of the parallel, you will have the condition of a phase-to-phase short circuit embracing the parallel and, of course, you will get induced voltages.

In reference No. 19: Mr. Ackerman claims as an advantage

Lightning Disturbances on Distribution Circuits

BY MALCOLM MacLAREN

Associate A. I. E. E.
Professor of Electrical Engineering, Princeton University

Review of the Subject.—A general survey is presented of the nature and distribution of failures and interruptions due to lightning upon the circuits of a large city supply system. Recommendations are given for improving conditions without specifying particular makes of arresters, in recognition of the fact that a considerable number of different types is proving adequate to meet the conditions imposed upon them on the moderate voltage systems under consideration. The subject is treated under three principal divisions: 1st. Troubles on 115-230 volt distribution circuits. 2nd. The 2300 volt circuits, and 3rd. The 13,200 volt circuits. It is shown that line failures on the low-voltage circuits are so infrequent as to be practically negligible, and that the blowing of fuses and injuries to other parts of the equipment on customer's premises are infrequent except in the case of house meters. A considerable number of meter burn outs are recorded, and it is shown that trouble from this source increases with the length of the secondary circuit. To guard against future trouble, especially as secondary networks are developed, it is recommended that a simple spark gap or other equivalent type of arrester be installed at the customer's premises as a part of the equipment in his service box. For the 2300 volt circuits, it is found

that lines which run over high ground and open country are more exposed to transformer burn outs and the blowing of transformer fuses than lines in the built-up sections where buildings screen the circuit. Also, that the amount of damage to the exposed lines decreases as the number of arresters increases and that a transformer directly protected by an arrester is in a very large measure guaranteed against complete breakdown and to a less extent against the blowing of its fuses from lightning. Also, that the effectiveness of this protection is decreased with high resistance in the ground connection. Finally, for the 13,200-volt aerial circuits, it is shown that on lines at a considerable distance from generating points most of the damage from lightning is in insulator breakages and without interruption to service, but where line reactance is not sufficient to prevent flow of heavy dynamic current at the time of discharge, the conductor is often fused allowing the line to fall. To guard against these troubles, arresters should be distributed along the line at not more than two mile intervals and near generating stations the three arresters of a group should be mounted on successive poles and provided with independent ground connections.

* * * * *

THE investigations which form the basis for this paper were made upon the Philadelphia Electric Company's system during the summers of 1921 and 1922. As lightning disturbances show so many eccentricities and as each storm has its own individuality both as to its path over the system and as to the intensity of its activity, it is necessary, in a study of this nature, to consider a great mass of data and at the same time analyze many individual cases, before any generalizations can be made.

The work was classified under three main divisions:

I. The low-tension distribution system, mainly 115-230 volt, three-wire single-phase with neutral grounded.

II. The main primary distribution system, 2300 volts, three-wire two-phase ungrounded.

III. The high-tension system, 13,200 volts, three-phase with neutral grounded at the generating stations only.

I. FAILURES ON THE LOW TENSION SYSTEM

It will probably be rather generally conceded by distribution engineers that lightning troubles on the low-tension system are of comparatively infrequent occurrence and of a much less serious character than those on other parts of the system. It was thought best, however, in these investigations, to obtain some quantitative results from lightning failures on these low-voltage circuits; both for the lines themselves and for the apparatus upon the customer's premises. Considering first-line failures, records were obtained for the storms occurring upon June 3rd and 10th, and July 1st and 12th, 1922, which were found to be sufficiently

widespread and severe to be fairly typical. The line-men's reports upon circuit failures during these storms were, therefore, investigated, and it was found that they reported no insulator failures upon the low-voltage circuits and only three cases of low-voltage lines being down; one of these being due to a tree falling upon the circuit. On a system as extensive as the one under consideration this amount of injury could readily be passed over without further investigation.

At first sight the record of failures upon customers' premises did not offer a very encouraging field for analysis. The three classes of failures which might in some cases have been caused by lightning were the blowing of fuses, injuries to house fixtures and to meters. Monthly totals for each of these were recorded. If any considerable number of house fuses had been blown by lightning disturbances, this fact was completely masked by the large number blown by other causes. The totals ranged from 4000 to 5500 and were in some cases greater for winter months than during the lightning season. The number of injuries to house fixtures never reached 150 per month and they were quite irregularly distributed. There was, however, distinct evidence that a majority of the meter burn outs might have been due to lightning as there was a large increase in the number of such failures during the summer months. More specific information regarding these failures was therefore sought by obtaining a record of all meter repair orders issued on the days of the four storms referred to above, and upon the day following each storm. By this method a few meters might have been included which had not failed from lightning, but there could not have been enough of them to appreciably effect the results. Also, it was not possible to locate all of those which were

injured by lightning for it was necessary to rely upon the customer for reporting the trouble and if the house was closed at the time, or if the failure did not interrupt the service, the injury would not be detected until it was too late to determine with certainty the cause of the failure.

Consideration should first be given to the geographical distribution of these meter failures, especially in comparison with the disturbances which occurred on the primary circuits during the same storms, as shown from the record of the blowing of transformer fuses. Both of these classes of failures were located on a pin map, but the comparison shows up more distinctly in Fig. 1, which gives the number of failures in parallel strips of territory 2500 feet wide running across the city from east to west. The few failures which occurred in West Philadelphia are not included as they were too scattered to have any significance and by their omission a truer picture can be obtained of conditions in the central and southern portion of the city where underground distribution is largely employed.

The most striking feature of this diagram is the comparative immunity from lightning troubles that is

FIG. 1

shown for the secondary circuits in the northern sections of the system which comprise Tacony, Germantown, Chestnut Hill and the outlying territory. This is the more remarkable when it is known that in previous years the primary circuits in these sections had suffered so severely that it had been necessary to provide much more liberal lightning arrester protection there than in any other parts of the system. No such protection had been found necessary for the secondary circuits. It is evident, therefore, that mere geographical location within the area of maximum lightning disturbances is not the determining factor in causing failures in these low-tension circuits. A hint for the solution of this problem may be obtained from wireless practise where the design of the aerial controls so largely the ability of the station to pick up distant signals. Upon this basis the explanation for the absence of meter failures in the northern territory was sought by comparing the relative lengths of the secondaries. An inspection of the secondary circuit diagrams showed that throughout this territory a majority of the customers are served from separate transformers having short secondary taps, and

even where several services are run from one transformer the secondary circuits are shorter than those which prevail in the more congested districts. In order to check this theory further the meters which failed during the storms mentioned above were identified with the circuits which served them, and, except for two questionable cases where the addresses were not clearly given, all of the 105 failures were on circuits of approximately 1000 feet or more in length.

This investigation also brought out the fact that in only two cases were meters which failed connected to transformers on which the fuses were blown during the same storm, and in no cases were such meters connected to transformers which were burned out by lightning. Thus all the evidence points to the fact that the lightning disturbances in the secondary circuits are not transmitted from the primaries through the transformers, but originate in the secondaries themselves and are controlled largely by the length of these circuits.

The losses occurred indiscriminately upon meters connected to ungrounded circuits or circuits grounded outside the premises or directly at the meter. No true perspective upon the protective value of these methods of connection was obtained, however, as the relative number of meters using each type of connection was not known.

On a system containing over 240,000 meters a record of 105 failures during four of the most severe storms of the season does not appear very serious and yet, in view of the efforts that are constantly being made to minimize interruptions to service, it does seem as though these conditions might be improved. Possibly the correct solution is to provide heavier insulation for the meters, but it is questionable whether, if the meters cease to function as lightning arresters, more serious damage and even loss of life may not result from lightning reaching the house circuits. Furthermore, as the load density increases, the tendency is toward the use of longer secondaries which should ultimately lead to the development of an interconnected system similar to the Edison direct-current network. In that event, these records indicate that much more serious lightning trouble may be expected.

It is known that on other systems a good deal of trouble is being experienced from meter burn outs, but the writer has been unable to obtain any data upon the extent of such damage nor whether measures are being taken to correct it. On the large city systems, at least, it would seem desirable to introduce some form of lightning protection on the secondary circuits which could be gradually extended over the system. A spark gap, or one of the other types of low-voltage arresters, should prove adequate if properly distributed. The best place to locate the arrester is on the customer's premises and it could properly be included as part of the necessary equipment of his service box. A suitable ground connection is available at this point and very little additional expense would be entitled.

II. THE 2300 VOLT SYSTEM

The consideration of lightning troubles upon these circuits was confined to a study of transformer failures and the blowing of transformer fuses. A general survey of transformer burn outs was undertaken during the summer of 1921. It appeared necessary to cover as large a number of cases as practicable, in order to eliminate the effect of the irregular distribution of individual storms, so that the study was based upon the records of failures from January 1st, 1920 to August 1st, 1921. As these records did not specifically indicate the cause of the failure, it was assumed that all transformers removed from the line on the day of a storm or on the following day had failed from lightning. Eighty-six transformers were so removed from the aerial lines during 1920 and forty transformers up to August 1st in 1921. This represents about one third of the total number of transformers removed from these circuits for all causes during this period, and, while it may include a few transformers which were not injured by lightning, the number cannot be sufficient to alter the conclusions reached, although it may account for some of the eccentricities which appear in the records. A further

Fig. 2

check upon this method of selection was obtained for transformers which failed from lightning from August 1st, 1921 to August 1st, 1922, by having the linemen report such cases immediately after each electric storm. In this way questionable cases should be eliminated, but the results shown for failures during the later period are entirely in harmony with the conclusions reached from a study of the earlier records.

The one hundred twenty-six transformers which failed from lightning from January 1st, 1920 to August 1st, 1921, were located geographically and their distribution is shown in Fig. 2. The transformers were also identified with the circuits to which they were attached and it was found whether or not they were protected with lightning arresters. In order to obtain a proper perspective of this phase of the subject, the length of all the aerial circuits of the system was recorded, together with the number of arresters and transformers connected and the number of transformer failures. This information is given below.

In some respects the records appear erratic, as should be expected in a study of lightning disturbances,

though it is believed, as already noted, that some irregularities are due to errors in the records and some possibly to not having covered a sufficiently long period in the investigation. Nevertheless, the following facts are clearly brought out:

1. Circuits which have the greatest amount of lightning protection suffer less than circuits in the same district with less protection.

2. During 1920 and 1921, the Tacony District suffered more severely than any other section of the system, and the greatest losses occurred on the circuits which had the least protection.

3. Large sections in the central part of the city, which had very little arrester protection, experienced no transformer losses.

4. A large number of circuits in different parts of the system should have additional protection.

The following information is submitted in confirmation of the above statements:

1. The circuits which have the greatest number of arresters per unit length of circuit in order of their protection are *CH-1*, *CH-3*, *TAC 1 & 4*, *FIL-2*, *GTN-4*, *FIL-10* and *GTN-1*. These have from three to four arresters per mile of line. There are 437 transformers connected to these lines and only one loss was reported for each year for the entire group, although before the arresters were installed Chestnut Hill and Germantown suffered most severely from lightning. *CH-4* and *GTN-2* each are protected with about one arrester per mile and the former of these lost four transformers and the latter five, which is greater than any other circuit outside of Tacony. The exceptional feature in these records is that *GTN-3* and 5 with about the same protection suffered no losses.

2. At the other extreme *TAC-2*, which is a very long line feeding all the territory north and west of Tacony, is very much exposed to lightning and is protected with only one arrester per seven miles of line, which means that long sections have no protection. There are 222 transformers on this circuit and 13 of these failed in 1920 and 14 in 1921. *TAC-6* has no arrester protection, but in places is less exposed than *TAC-2*, and this has lost a total of seven transformers for the two years out of a total of 60 connected. *TAC-3*, with about the same arrester protection as *TAC-2*, but with much greater natural protection, lost three transformers out of 62. The other Tacony circuits have more arrester protection and pass through thickly settled sections. None of these have lost more than one transformer.

3. For the last year and a half no failures due to lightning have been recorded for any of the circuits out of Ludlow or Columbia substations and only two from Marshall. One of these was a 37½ kv-a. transformer which had been in service only a month and was replaced by a 50-kv-a. suggesting that the failure had been due to overload rather than lightning. There are twelve circuits from Susquehanna, eight from Ontario

really important phase of the problem is to consider how to minimize the blowing of fuses during electric storms.

As already indicated, this trouble cannot be due, except in rare instances, to lightning disturbances in the secondary circuits, for direct evidence shows that lightning surges on the secondaries, as indicated from the burning out of house meters, is not associated with primary failures, either with the blowing of fuses or the burning out of the transformers. The cause of the fuse failure must therefore be localized at the transformer itself. It is apparently due to a flashover across the transformer surfaces or in the primary coils, the insulation being reestablished, at least in part, after the blowing of the fuse has extinguished the arc.

Further information upon these fuse failures was obtained by definitely localizing with their circuits the 112 failures which occurred during the four storms in June and July, 1922, to which reference has already been made. For comparison with transformer burn outs the distribution of these failures is shown in Fig. 2. It is seen that they follow much the same course as the transformer burn outs as should be expected. The agreement would probably have been closer if the same lightning period had been considered in the two cases. The divergence which is shown for the northern territory for instance, may be explained by the large increase in the number of lightning arresters installed in this district between the periods covered by the two sets of records.

The records for these four days showed that in 17 cases fuses blew on the same transformer in two or more successive storms, and in several cases later records indicated that ultimately the transformer broke down permanently. It is evident, therefore, that the blowing of transformer fuses is serious, not only for the interruptions which they cause to the service, but also for the deterioration in transformer insulation which they indicate.

As the lightning disturbances which causes a fuse to blow comes in over the primary, the arrester protection which may be justified purely in saving the transformer from burn out, should also prove effective in reducing the trouble from the blowing of transformer fuses. Unfortunately, this investigation does not indicate that the same measure of protection may be expected in the two cases. The records collected during 1922 showed that in only five cases were transformers burned out which were protected by arresters and in one of these a very old type of arrester was employed which was probably not operative at the time. On the other hand, during the same period, 30 cases were recorded where arrester protection was not effective in preventing the transformer fuses from blowing. Apparently in all but very exceptional cases the arrester carries off a sufficient amount of the energy of the lightning surge to keep the transformer from complete failure, but in some cases it allows enough energy to pass to temporarily break

down the insulation until the blowing of the fuse clears the circuit. This points to the importance of obtaining low ground resistance for the arrester in order that it may deflect as much of the lightning discharge as possible. As already noted, it is very difficult to obtain this in certain of the outlying sections of the system. It is believed, however, that this investigation shows conclusively that with the present installation, transformer failures from lightning are being kept within remarkably low limits and the blowing of transformer fuses in being minimized.

III. THE 13,200-VOLT SYSTEM

The 13,200-volt circuits of this system are, in the majority of cases, underground, and serve as feeders from generating stations to substations. There are, however, a number of aerial circuits operating at this voltage which feed substations in the outlying districts, and others which supply large power customers. The latter are increasing in number and importance each year.

A group system of numbering has been adopted to indicate in general the geographical location of the circuit. Circuits No. 704 to 706 run on the same pole line from Tacony westward, eventually separating to feed railway substations in the northern territory. Circuit No. 708 follows the river from Tacony to Bristol. Circuit No. 1126 runs from Hunting Park substation to Manayunk. Circuits No. 1301 to 1305 interconnect the above mentioned railway substations and tie in with the Chestnut Hill substation. Circuits No. 2101 and 2102 run practically from the Schuylkill Generating Station to the extreme southern portions of the city. Circuit No. 2118 is located in Frankfort which is nearer the Delaware Generating Station than Tacony. Circuit No. 2301 serves a group of manufacturing plants north of Tacony. This completes the list of circuits in operation during 1921, which was the period covered by the investigation. The general practise has been to protect these circuits at the substations by electrolytic arresters and at customers' taps by spark gap arresters.

The company's records give definite information upon the number of interruptions of each of these circuits during electric storms, and in every case where it has been possible to locate the cause of the interruption, this has been given, together with the exact location of the trouble and the extent of the damage done. There is also very clear indication that lightning was responsible for many injuries to insulators, pins and cross arms, which did not interrupt the service. These injuries were detected by the linemen who patrol the circuits after each storm and at stated intervals throughout the year. It is unfortunately impossible from the nature of these reports to differentiate between failures from lightning and from other causes. It is found, however, that there are fully three times as many insulator failures on these circuits during the lightning season as in the

winter months. As most of the insulator breakages in winter are probably due to ice or high winds and failures from such causes must be less in summer, it appears conservative to assume that at least two thirds of the insulator breakages during the year are due to lightning. The reports give the number of repair jobs at each pole rather than the number of insulators replaced, so that the actual number of insulator failures will be greater than the figures given below. From the mass of data contained in these reports, the following information has been selected as it is believed that it is adequate to give a fairly clear representation of the character and extent of the damage done to these circuits by lightning during 1921:

Circuit	Length in miles	Interruptions during storms	Number of Repair Jobs		Interruptions per mile	Insulator repairs per mile
			On insulators	On cross arms and Pins		
704	8	3	28	2	0.37	3.5
705	6	1	6	1	0.13	1.0
706	7	3	21	6	0.43	3.0
708	9	1 intermittent	3	0	0.11	0.3
1126	4	1	1	0	0.25	0.25
1301	7	2	27	6	0.29	3.9
1302	3½	1	18	3	0.29	5.1
1303	5	0	9	5	0	1.8
1304	6	0	6	1	0	1.0
1305	4	0	10	8	0	2.5
2101	9	6	12	3	0.66	1.4
2102	8½	8	14	1	0.94	1.6
2118	1½	4	0	0	2.6	0
2301	1½	0	1	0	0	0.6

The records of failures on these circuits as given above show the customary freakishness of lightning and undoubtedly do not cover a sufficiently long period to bring out many of the peculiarities of the individual circuits. There are, however, certain features of the records which should be noted. In the first place, it appears that the circuits most distant from generating points, such as No. 1301-5, had a great many insulator failures but were remarkably free from interruptions during electric storms. Circuits somewhat nearer the center of the system such as No. 704 and 706 had much the same record of insulator failures, but experienced a greater number of interruptions. The circuits in South Philadelphia Nos. 2101-2102, which are still nearer large generators, had fewer insulator failures, but most of those which occurred during storms were accompanied with serious line trouble. It should furthermore be noted that the records of lightning trouble on 2300-volt circuits, which are much more complete than for 13,200-volt circuits, show that all through the territory north of the city, the injury from lightning to apparatus unprotected by arresters was much greater than in South Philadelphia. It is reasonable to suppose, therefore, that these 13,200-volt circuits in the Northern District had had many lightning surges induced in them which discharged themselves over insulators without

completely breaking these down, the high line reactance in such cases limiting the dynamic current to comparatively low values. However, when such surges occur on circuits where the line reactance is low as on No. 2101 and 2102, the dynamic current which accompanies a discharge generally destroys the insulation and the arc which follows burns off the conductor, allowing the circuit to fall. Short circuit conditions on No. 2118 are about as severe as on No. 2101 and 2102, though the latter has much better natural protection. Three of the four interruptions recorded for this circuit were accompanied with falling of the conductors. In these cases spark gap arresters near the points of trouble failed to protect. There were only three cases recorded in 1921 in which the circuits north of this point fell during electric storms. In one case there was a direct stroke on No. 705 outside the Oxford Substation, in another both No. 704 and 706 were down at the same pole, and in the third case, one span of No. 1301 fell near the Chestnut Hill Substation. It should be noted that in the two latter cases the failures occurred near the feeding end of the circuit where the dynamic current, which might develop on short circuit, would be a maximum.

Attention should be called to the relatively good records of Nos. 705 and 708. No explanation was found for this condition on No. 705 for it is just as much exposed as No. 704 and No. 706 being on the same pole line for most of the distance, and the circuits are transposed so that there should be no advantage of position. Circuit No. 708 had formerly been subjected to so many interruptions that it was completely re-insulated, 22,000-volt insulators being used in place of the lower voltage type employed on the other circuits and this undoubtedly accounts for the improved performance of this circuit.

Two general methods suggest themselves for reducing lightning troubles on these 13,200-volt circuits. Either to reconstruct the circuits with 22,000-volt insulators, as has been done with good results on circuit No. 708; or provide some form of lightning arrester protection on the lines themselves in addition to the arresters already in use at the terminals. The first method would involve considerable expense and while it might be employed advantageously at certain of the more exposed portions of the system, the more direct and satisfactory method would be to relieve insulation stresses by providing suitable discharge paths to ground through lightning arresters. This would in general require that the arrester should be suitable for pole mounting. On the circuits in the outlying districts at a considerable distance from the generating points there should be no difficulty in providing at reasonable expense, suitable protection by the use of spark gap or other compact form of arrester, distributed at about two mile intervals on the average.

The general opinion among operating engineers appears to be that the electrolytic or oxide film arresters

are the only types so far developed which can satisfactorily resist the tremendous dynamic discharge which may develop near large generating units.¹ The high first cost of such arresters and the difficulty in properly distributing them along the right of way, presents a serious problem in providing suitable protection for these high-voltage circuits leading out from generating points. An inspection of some of the spark gap arresters which had failed suggested that possibly this trouble might be caused by a short circuit between phases due to the simultaneous discharge of two or more of the arresters of the group. It was therefore proposed by Mr. H. S. Phelps of the Philadelphia Electric Company, to mount the three arresters of one group upon successive poles and provide independent grounds, thus introducing twice the ground resistance between phases at the time of discharge. Three groups of arresters arranged on this principle were installed on

July 1st of this year on the most exposed portions of circuits No. 2101 and 2102. The day after their installation a storm of unusual severity passed over these circuits. Lightning struck an oil tank within a few rods of the circuits, fuses were blown on a transformer connected to a 2300-volt circuit on the same pole line, and other damage was done in the neighborhood, but the arresters functioned satisfactorily and no damage was done to these circuits. The record for the rest of the summer has been equally satisfactory. The question still remains whether longer experience will justify the hope that this method will provide adequate protection for such circuits and there is the further question as to what is the minimum reactance which must be provided between such arresters and the generating units in order to insure proper performance.

Operating Experience with Current-Limiting Reactors

BY N. L. POLLARD

Fellow, A. I. E. E.
Public Service Production Company, Newark, N. J.

Review of the subject.—This paper describes the troubles experienced with different types of current-limiting reactors installed on the Public Service Electric Company's system. Many of these failures are attributed to poor mechanical construction.

The author states that the experience gained has resulted in much better designs. The conclusion is reached that if the present day

reactors are properly chosen with regard to thermal capacity they are very reliable.

Comparison of Different Types of Reactors. (1395 w.)
Conclusions. (225 w.)

THE purpose of this paper is to give an account of the operating experience with current-limiting reactors installed on the system of the Public Service Electric Company of New Jersey.

DESCRIPTION OF SYSTEM

The above-mentioned system is composed of two large sections: The Southern Division, which includes the territory between Camden and Trenton; and the Northern Division, which comprises the northeastern

ity. Since this system has reactors only on the generator leads in the Marion Station, and because all the apparatus will be replaced by 60-cycle machines within the next few years, no further mention will be made of it with the exception of a brief description of the reactors later.

The bulk of the 60-cycle current is generated at Marion and Essex Stations located about three and one-half miles apart and connected together by means of

FIG. 1

part of New Jersey. Since current-limiting reactors at the present time are used only in the Northern Division, merely this part of the system will be described.

The 13,200-volt, 25-cycle system is comparatively small, as it includes only 35,200 kw. generating capac-

ity. Since current-limiting reactors at the present time are used only in the Northern Division, merely this part of the system will be described. The 13,200-volt, 25-cycle system is comparatively small, as it includes only 35,200 kw. generating capac-

five 13,200-volt tie lines. The Marion capacity is 60,500 kv-a. and Essex 85,000 kv-a. In addition there are five other smaller stations with a combined capacity of 44,500 kv-a. feeding into the system at different points, giving this Division a total capacity of 190,000 kv-a.

Presented at the Spring Convention of the A. I. E. E., Pittsburgh, Pa., April 24-26, 1923.

Division consists of 580 miles of 13,200-volt lines and 121 miles of 26,400-volt lines. Of the 13,200-volt lines, 322 miles are overhead and 258 miles underground; of the 26,400-volt lines, 97 miles are overhead and 24 miles underground. Fig. 1 is a one-line diagram of the 60-cycle system in the north section of the Northern Division, and Fig. 2 shows the south section of this division.

FIG. 2

These two sections are tied together with a 26,400-volt line between Essex and Bayway, and with several 13,200-volt lines between Essex and Elizabeth.

NEED FOR REACTORS

The need for current-limiting reactors was first brought to our attention in 1912, when the oil circuit breakers commenced to fail on the 25-cycle system in

FIG. 3

the Marion Station. The reactance of these turbo-generators was only 3 per cent, so in order to relieve the excessive strains on the equipment, 3 per cent reactance coils were inserted in the generator leads of each machine. (Fig. 5 shows one of these reactors.) This relieved the 25-cycle system to a great extent from oil circuit breaker and other troubles.

In 1914 the 60-cycle system had grown to such an extent that the oil circuit breakers and other equipment were failing frequently. As a result of these failures we decided to install 5 per cent reactors on all radial 13,200-volt feeders, $2\frac{1}{2}$ per cent reactors on all tie feeders, and aluminum cell arresters on the feeder side

FIG. 4

of all reactors whether the feeder was overhead or underground. This required a total of 29 sets of reactors, all of which were purchased for 5 per cent reactance with a $2\frac{1}{2}$ per cent tap so that they could be used on either type of feeder. Essex Station was not built at

FIG. 5

this time. The seven tie feeders between Marion and City Dock Stations were equipped with $2\frac{1}{2}$ per cent reactors at each end. It was necessary to install reactors at both ends in order to allow selective action of the balanced relays which were installed on these feeders. Before purchasing the reactors we sent a man to the factory to witness tests, which included both high

voltage and high frequency, and we were assured by the manufacturer's engineers that these reactors were so well designed that they would stand up under any operating condition. The factory tests seemed to prove their statements.

FIG. 6

Fig. 3 shows the Marion and City Dock busses and tie lines at the time these 60-cycle reactors were installed. Fig. 6 illustrates a typical installation at Marion.

Contrary to expectation, we experienced considerable

FIG. 7

trouble with this first installation of 60-cycle reactors; therefore we decided to install an entirely different type in 1915 in the new Essex Station. These reactors are shown in Figs. 7 and 8. The first sixteen sets (Fig. 7) proved very satisfactory, but the second installment of

ten sets (Fig. 8) has been a constant source of trouble. Fig. 4 shows the Marion and Essex busses and tie lines after these reactors were installed.

From 1917 to the present time we have installed 18 sets of reactors of the types shown in Figs. 9, 10 and 11,

FIG. 8

and with two exceptions these have given very satisfactory service.

Table I gives the rating, type and number of reactors installed to date at Marion, Essex, and City Dock, including the twelve 25-cycle generator reactors at Marion.

part of the coil having the smaller diameter. After it was found that this second rebuilding produced very little, if any, improvement, we decided to rebuild six of these coils ourselves. Instead of porcelain brick we used cast concrete corners so as to obtain a tight fit

In addition to seventeen electrical failures, there have been several cases where the coils became noisy and had to be removed from service for mechanical repairs. At present, whenever a coil commences to become noisy, it is taken out of service and scrapped. It is needless to

FIG. 9

against both sets of pancakes. To secure ample insulation a 1/16-in. layer of sheet mica was placed between the coils and the concrete.

At first it seemed that this method of rebuilding was

FIG. 11

say that this design of reactor is not being perpetuated.

Group E, Figs. 9, 10, and 11. This group represents a total of 18 sets of reactors, part of which were built for 5 per cent with a $2\frac{1}{2}$ per cent tap, and the remainder

FIG. 10

FIG. 12

a success, but after a few months' service several of these coils became noisy again. On account of these reactors having windings of two different diameters, it is very difficult to make them strong enough mechanically to stand up under short-circuit conditions.

were $1\frac{1}{2}$ per cent coils for use on the generator tie bus. They were installed at different times between 1917 and 1920.

About one year after the first installation there were two instances of trouble: The first occurred on a tie

feeder and resulted in the short-circuiting of two reactors; the second occurred on another tie feeder and caused the concrete to crack on one of the coils. These demonstrations were sufficient to prove that the concrete supports were not close enough to prevent the conductors from pulling together and causing short-circuiting of the turns during times of trouble on the transmission lines.

After an investigation by the manufacturer it was decided to return part of these reactors to the factory for reinforcing, the decision applying only to those coils which were to be used on the $2\frac{1}{2}$ per cent tap. Fig. 10 illustrates one of the coils after it had been reinforced with additional concrete supports half way between the old ones.

The latest type of reactor which we have installed is shown in Fig. 11. This coil is supposed to have all of the necessary characteristics and none of the bad qualities of any of the types previously described. The few of this newer design that were installed have not as yet been in service long enough to demonstrate whether they will stand up under all conditions, but we hope that they will live up to our expectations.

Fig. 12 illustrates a generator tie bus reactor rated at 5 per cent, 545 amperes, 208 kv-a. We have purchased a number of these coils for future installation.

CONCLUSIONS

It has been the opinion among a number of central

station engineers that it was unnecessary to install aluminum cell arresters on the feeder side of reactors when the feeders consisted of underground cable. However, we have always felt that the arresters at times of system disturbances acted as relief valves, and since they have almost invariably discharged in cases of disturbances it would appear that they did relieve the system of at least a part of the strain.

As a word of caution it is well to point out the importance of adequate thermal capacity in reactors. From all indications a number of our failures were due to lack of thermal capacity. Since a reactor is essentially a protective device, it should be designed with a copper cross-section in excess of that of any part of the system which it protects, so that an extended period of severe duty will not cause it to fail because of lack of thermal capacity.

In spite of the troubles which we have experienced with reactors, the number of instances in which they functioned properly has far exceeded the cases of failure. Furthermore, the design of present-day reactors has been perfected to such an extent that, if properly chosen with regard to thermal capacity, the modern reactor may be considered as a very reliable piece of apparatus.

Discussion

Short-Circuit Forces on Reactor Supports—I

BY R. E. DOHERTY and F. H. KIERSTEAD

Associate, A. I. E. E.

Associate, A. I. E. E.

Both of the General Electric Company

Review of the Subject.—The mechanical stress in the supporting members of any structure or apparatus under steady state is determined by the dimensions of the member and the magnitude of the resultant applied force. Under accelerated motion, however, an additional factor enters, namely, the reaction of the mass; and if the supporting members in this case are resilient, that is, spring-like, then this becomes still another factor which enters the problem of determining the mechanical stress produced by a given impressed force.

The determination of the stress in the holding device (bolts, etc.) of reactors under short-circuit condition is just such a problem.

If any motion whatever is permitted under this condition, the factors of mass and resilience are active.

This paper gives a theoretical analysis of the problem, and shows that if any motion is permitted, thus allowing the factors of mass and resilience to become active, then the maximum stress may be significantly increased above that for no motion. Illustrative calculations show that this increase in practical cases may be of the order of 25 per cent. On the other hand, if motion of the reactors is prevented by sufficient initial bolt tension, or otherwise, then the maximum stress in the holding device obviously need be only as great as that corresponding to the maximum instantaneous peak of the electromagnetic force.

A NUMBER of papers¹ has appeared in which the problem of the electromagnetic force between electric conductors or between coils, has been analyzed. The stresses, however, which such forces create in the members on which they act, are not determined merely by the value of the electromagnetic force and the dimensions of the members, as would be the case with a steady applied force, but also depend in a large measure upon other factors. Hence the analysis of such stresses is a separate problem in which the electromagnetic force is only one of a number of factors.

SCOPE

The present paper investigates, in a theoretical way, the character of the force which is required to hold the reactor as a whole, against short-circuit forces. Unlike the problems covered by the foregoing papers, which were concerned with the character of the electromagnetic force itself, the present investigation assumes that this force is given, and inquires into the nature of the stresses it produces in the holding device, such as bolts, etc. In other words, the problem is of a purely mechanical nature.

As such, it is the same, in fundamental respects, as a number of other problems in engineering which involve the factors of mass, resilience and a periodic impressed force.

For instance: Fly wheels for synchronous machines mechanically connected to reciprocating apparatus²; torsional strain of a turbo-generator shaft during generator short circuit³; the behavior of bus bars

carrying short-circuit current⁴; the behavior of certain types of engine governors, etc. This class of phenomena is best illustrated by the simple case of the behavior of a weight, suspended by a spring, and acted upon by an alternating-current electromagnet.

Mathematically, the problem is identical with a much wider range of phenomena; that is, in addition to the above cases it involves the same form of differential equation⁵ as a number of familiar problems in electrical engineering. For instance: The electric circuit containing resistance, inductance and capacity in series⁶; the series circuit involving an exciter and alternator field.⁷

The present investigation, therefore, does not deal with a new phenomenon; it merely starts with certain assumptions, which appear reasonable, and which written down mathematically, give a well known differential equation, and then applies the solution to the physical conditions of the problem. This makes it possible, within specified limits, to answer a number of questions regarding the character of the force on the holding device.

In a later paper the authors expect to present some experimental data regarding these forces.

EQUATIONS

The equations are set up under the following assumptions:

Supporting floors rigid.

Single-phase short circuit.

Current wave completely off-set.

No transients; that is, damping neglected.

Reactor unit, including concrete, etc. rigid body.

Initial tension on holding bolts same on all bolts.

Reactors connected to give attraction.

Center lines of coils coincide, as in Fig. 1.

Displacement x sufficient to permit free movement of the reactor B , that is, no interference by supporting floor.

Magnetic force proportional to square of the current, other factors being constant.

Let

M = mass of reactor

i = current in reactor coils (amperes)

x = displacement of reactor B above floor (feet)

f_b = force due to bolts (lb.)

f_c = force due to currents (lb.)

W = weight of reactor = $g M$ (lb.)

g = gravity = 32.2 feet/sec.²

k = lb. force required to elongate bolts one foot

f_0 = total force due to initial tension in bolts at $x = 0$

e = modulus of elasticity of bolt material = 30×10^6 for steel

a = total cross section of bolts in sq. inches

l = free length (inches) of bolts under tension

t = time in seconds.

The sum of all forces acting on the mass must equal zero. That is,

$$\Sigma \text{ forces} = 0 \quad (1)$$

$$\text{Thus} \quad f_c - M \frac{d^2 x}{dt^2} + f_b - W = 0 \quad (2)$$

$$\text{But} \quad f_b = -(f_0 + kx) \quad (3)$$

$$\text{Where} \quad k = 12 e a / l \quad (3a)$$

$$\text{Therefore} \quad f_c - M \frac{d^2 x}{dt^2} - f_0 - kx - W = 0$$

$$\text{or} \quad \frac{d^2 x}{dt^2} + kx/M = f_c/M - \frac{(f_0 + W)}{M} \quad (4)$$

The force f_c is proportional to the square of the current. Thus, let⁸

$$f_c = K i^2 \quad (5)$$

The current i is of the form,

$$i = I_0 (1 - \cos \omega t) \quad (6)$$

as shown in Fig. 2.

where I_0 = maximum value of a. c. component of the current i

$$\omega = 2 \pi f$$

f = electrical frequency.

Substituting (6) in (5).

$$f_c = K I_0^2 (1.5 - 2 \cos \omega t + 0.5 \cos 2 \omega t) \quad (7)$$

Substituting this in (4),

$$\frac{d^2 x}{dt^2} + kx/M = -2 \frac{K I_0^2}{M} (\cos \omega t$$

8. The assumption is made that no deflection will be large enough to alter the value of K , that is, K = constant.

$$- 0.25 \cos 2 \omega t) + 1.5 \frac{K I_0^2}{M} - \frac{f_0 + W}{M}$$

$$\text{Let} \quad \frac{K I_0^2}{M} = D \quad (8)$$

$$k/M = \alpha^2 \quad (9)$$

$$\text{and} \quad 1.5 D - \frac{f_0 + W}{M} = E \quad (10)$$

Then the differential equation becomes,

$$\frac{d^2 x}{dt^2} + \alpha^2 x = -2 D \cos \omega t + 0.5 D \cos 2 \omega t + E \quad (11)$$

The solution of this equation will be in four parts as follows:

$$x = x_1 + x_2 + x_3 + x_4 \quad (12)$$

where, x_1 is given by the complementary function

$$\frac{d^2 x_1}{dt^2} + \alpha^2 x_1 = 0 \quad (13)$$

x_2 is given by the particular solution,

$$\frac{d^2 x_2}{dt^2} + \alpha^2 x_2 = -2 D \cos \omega t \quad (14)$$

x_3 , by the particular solution,

$$\frac{d^2 x_3}{dt^2} + \alpha^2 x_3 = 0.5 D \cos 2 \omega t \quad (15)$$

and x_4 , by

$$\frac{d^2 x_4}{dt^2} + \alpha^2 x_4 = E \quad (16)$$

Solution of (13) is

$$x_1 = C_1 \cos \alpha t + C_2 \sin \alpha t \quad (17)$$

Solution of (14) and (15) is obtained by temporarily using vectors and substituting

$$\left. \begin{aligned} \frac{d}{dt} x &= p x = j \omega x \\ \frac{d^2}{dt^2} x &= p^2 x = -\omega^2 x \end{aligned} \right\} \quad (18)$$

since a cosine function only is involved. Thus, in (14)

$$x_2 (-\omega^2 + \alpha^2) = -2 D$$

$$\text{and} \quad x_2 = \frac{2 D}{\omega^2 - \alpha^2}$$

$$\text{or} \quad x_2 = \frac{2 D \cos \omega t}{\omega^2 - \alpha^2} \quad (19)$$

$$\text{and similarly} \quad x_3 = -\frac{0.5 D \cos 2 \omega t}{4 \omega^2 - \alpha^2} \quad (20)$$

$$\text{Solution of (16) is } x_4 = E/\alpha^2 \quad (21)$$

Therefore by (12)

$$x = C_1 \cos \alpha t + C_2 \sin \alpha t + \frac{2 D \cos \omega t}{\omega^2 - \alpha^2} - \frac{0.5 D \cos 2 \omega t}{4 \omega^2 - \alpha^2} + E/\alpha^2 \quad (22)$$

Thus the solution involves two constants, C_1 and C_2 , which must be determined by the boundary conditions,

such as the value of x and of $\frac{dx}{dt}$ at some particular

value of t . In other words, with the constant value of displacement represented by the last term of (22) and with the definite functions of time represented by the 3rd and 4th terms, the constants C_1 and C_2 must be of such values that the sum of all terms must give the known boundary conditions. Or further, for instance, if $x = 0$ at $t = 0$, then the sum of the first two terms must be equal to minus the sum of the last three terms. It follows that if the boundary conditions happen to be such that they are given by the last three terms then C_1 and C_2 must be zero—that is, there would be no oscillation at the natural frequency

$$n = \frac{\alpha}{2\pi}$$

as discussed later.

To illustrate the application of equation (22) the following Cases will be considered.

FIG. 1

Case 1. Physical location of reactors as shown in Fig. 1. Hypothetical case in which the interference of the floor to the free movement of the reactor is neglected.

Case 2. Same as Case 1 except that the effect of the floor is considered.

Case 3. Same as Case 1 except that the frequency of the electrical force is doubled.

Case 4. Same as Case 2 except that the frequency of the electrical force is doubled.

Case 5. Reactors rigidly fastened to I-beams instead of being bolted to a rigid floor as in the foregoing Cases.

DATA

The following data are used in all Cases excepting Case 5;

$$W = 1000 \text{ lb.}$$

$$M = W/g = 1000/32.2 = 31$$

Average value of magnetic force is

$$1.5 K I_o^2 = 10 \times W = 10,000 \text{ lb.}$$

Thus, the peak value of the magnetic force, by equation 7,

$$= 4 K I_o^2 = 26,640 \text{ lb.}$$

and,

$$\frac{K I_o^2}{W} = \frac{K I_o^2}{g M} = 10/1.5 = 6.66$$

$$\frac{K I_o^2}{M} = 6.66 g = 214$$

Four steel bolts, each one square inch in cross-section and 10 inches free length

$$e = 30 \times 10^6 \text{ lb./sq. in. for steel}$$

Thus, by (3a)

$$k = 144 \times 10^6 \text{ lb./ft. elongation of bolts.}$$

By (25)

$$\alpha = \sqrt{\frac{144 \times 10^6}{31}} = 2160 \approx 2260 \text{ rad./sec.}^9$$

$$n \approx \frac{2260}{2\pi} = 360 \text{ cycles/sec.}$$

The above data may not be representative but they will serve for illustration of the application of the equations.

CASE 1

The physical relation of the reactors is shown in Fig. 1. The integration constants C_1 and C_2 are determined under the following hypothetical assumption: At $t = 0$, that is, at the moment the short circuit occurs, a shim between the reactor and the floor is suddenly withdrawn, thus permitting free motion of the reactor under the influence of all the forces assumed in the equation. This, of course, is far from a practical case, but it is of interest, and perhaps may be of importance to some readers, in helping to form an idea of the general character of the phenomenon, and in leading up to the second case, in which the effect of the floor is taken into account.

The integration constants are determined, therefore, from the boundary conditions that at

$$t = 0, x = 0 \text{ and } \frac{dx}{dt} = 0$$

Thus, from (22)

$$C_1 + \frac{2D}{\omega^2 - \alpha^2} - \frac{0.5D}{4\omega^2 - \alpha^2} + E/\alpha^2 = 0$$

and

$$C_2 \alpha = 0$$

Therefore

$$\left. \begin{aligned} C_1 &= -\frac{2D}{\omega^2 - \alpha^2} + \frac{0.5D}{4\omega^2 - \alpha^2} - E/\alpha^2 \\ C_2 &= 0 \end{aligned} \right\} \quad (23)$$

9. In order to have $n = 3f$, thus facilitating computations.

Substituting in (22)

$$x = \left[-\frac{2D}{\omega^2 - \alpha^2} + \frac{0.5D}{4\omega^2 - \alpha^2} - E/\alpha^2 \right] \cos \alpha t + \frac{2D}{\omega^2 - \alpha^2} \cos \omega t - \frac{0.5D}{4\omega^2 - \alpha^2} \cos 2\omega t + E/\alpha^2 \quad (24)$$

The angular velocity of the natural oscillations is, by (9) and (24)

$$\alpha = \sqrt{k/M} = 2\pi n \quad (25)$$

where n = oscillations per second

Also $\omega = 2\pi f$

Substituting these relations and also (8) (9) and (10) in (24), the final equation for x becomes,

$$x = \left[2 \frac{K I_o^2}{M \omega^2} \left\{ -\frac{1}{1 - (n/f)^2} + \frac{0.0625}{1 - \left(\frac{n}{2f}\right)^2} \right\} - \frac{1.5 K I_o^2 - (f_o + W)}{k} \right] \cos \alpha t + 2 \frac{K I_o^2}{M \omega^2} \left\{ \frac{\cos \omega t}{1 - (n/f)^2} - \frac{0.0625 \cos 2\omega t}{1 - \left(\frac{n}{2f}\right)^2} \right\} + \frac{1.5 K I_o^2 - (f_o + W)}{k} \quad (26)$$

Equation (26) is made up of two parts:

x_a = complex oscillation, given by the trigonometric terms, the average of which, over complete cycles, is zero.

and x_b = a constant deflection, determined by the difference between a constant force¹⁰ $1.5 K I_o^2$ and the sum of the weight W and initial bolt tension f_o .

The magnitudes of the different components of the complex oscillation are dependent upon the ratio of the frequency n of natural oscillations to the frequency f of the electrical system, and the second harmonic $2f$.

FIG. 2

The constant component x_b of the total deflection x is obviously

$$x_b = \frac{1.5 K I_o^2 - (f_o + W)}{k} \quad (27)$$

10. It is interesting to consider the value of current i , on which this force depends. By equation (5), force is $K i^2$

But here $i_1^2 = 1.5 I_o^2$, that is $i_1 = \sqrt{1.5 I_o}$. This is the root-mean-square of the total current during the first cycle. That is, the steady, or average, deflection is determined by the root-mean-square current.

This will evidently be zero when

$$f_o + W = 1.5 K I_o^2$$

or, when

$$f_o = 1.5 K I_o^2 - W \quad (28)$$

That is, x_b will be zero if the initial bolt tension f_o is the difference between the magnetic force $1.5 K I_o^2$ and the weight W .

Assuming the condition given by (28), then equation (26) becomes

FIG. 3—CASE I. HYPOTHETICAL CASE. ASSUMES OSCILLATION ABOUT FLOOR LINE AS AVERAGE POSITION

$x = 10^{-6} (61.5 \cos 2260 t - 85.5 \cos 377 t + 24 \cos 754 t)$
 $4 K I_o^2 = 26,640 \text{ lb.}$ $a = 1\text{st term, } b = 2\text{nd term, } c = 3\text{rd term}$
 $d = b + c, x = a + b + c$

$$x = 2 \frac{K I_o^2}{M \omega^2} \left[\left\{ -\frac{1}{1 - (n/f)^2} + \frac{0.0625}{1 - \left(\frac{n}{2f}\right)^2} \right\} \cos \alpha t + \left\{ \frac{\cos \omega t}{1 - (n/f)^2} - \frac{0.0625 \cos 2\omega t}{1 - \left(\frac{n}{2f}\right)^2} \right\} \right] \quad (29)$$

The electrical frequency is taken as 60 cycles. Thus,

$$\omega = 2\pi f = 377 \text{ rad./sec.}$$

Other data are given under "DATA" above.

Thus

$$n/f \approx 6.0$$

and

$$\frac{n}{2f} \approx 3.0$$

These values substituted in (29) give,

$$x = 2 \frac{6660}{31 \times 377^2} \left[\left\{ -\frac{1}{1 - (360/60)^2} + \frac{0.0625}{1 - (360/120)^2} \right\} \cos 2260 t + \left\{ \frac{\cos \omega t}{1 - (360/60)^2} - \frac{0.0625 \cos 2\omega t}{1 - (360/120)^2} \right\} \right]$$

Thus $x = (61.5 \cos 2260 t - 85.5 \cos 377 t + 24 \cos 754 t) \times 10^{-6}$

This is plotted as Case 1 in Fig. 3.

$$k = 144 \times 10^6$$

$$x = 106 \times 10^{-6} \text{ ft.}$$

Thus

$$f_s = -(9000 + 144 \times 10^6 \times 106 \times 10^{-6}) = -24,300 \text{ lb.}$$

That is, the maximum force on the bolts is 24,300 lb.

The peak force is by (7)

FIG. 5

$$f_m = 4 K I_o^2$$

But, in the particular problem, by assumption

$$K I_o^2 = 6.66 W = 6660 \text{ lb.}$$

Thus

$$f_m = 4 \times 6660 = 26,640 \text{ lb.}$$

FIG. 6—CASE 3. HYPOTHETICAL CASE. SAME CONDITIONS AS IN CASE 1, EXCEPT THAT THE ELECTRICAL FREQUENCY IS ASSUMED TO BE DOUBLED

$$x = 10^{-6} (56.2 \cos 2260 t - 93.7 \cos 754 t + 37.5 \cos 1508 t)$$

$a = 1\text{st term}, b = 2\text{nd term}, c = 3\text{rd term}, d = b + c, x = a + b + c$
 $4 K I_o^2 = 26,640 \text{ lb.}$

Thus the maximum force on the bolts is slightly less than the maximum magnetic force.

CASE 3

To study the effect of electrical frequency, assume all other data as in Case 1 except the electrical frequency, taking the latter as double, that is,

$$f = 120 \text{ cycles.}$$

Applying equation (29),

$$x = 2 \frac{6660}{31 \times 754^2} \left[\left\{ - \frac{1}{1 - (360/120)^2} + \frac{0.0625}{1 - (360/240)^2} \right\} \cos 2260 t + \left\{ \frac{\cos \omega t}{1 - (360/120)^2} - \frac{0.0625 \cos 2 \omega t}{1 - (360/240)^2} \right\} \right]$$

$$\text{Thus } x = (56.2 \cos 2260 t - 93.7 \cos 754 t + 37.5 \cos 1508 t) 10^{-6}$$

This is plotted in Fig. 6. It will be observed that the amplitudes of the different waves are of about the same magnitude as those in Case 1, but the phase relation of the different frequencies gives a different shape of resultant wave x . Thus the maximum value of x is approximately 170×10^{-6} feet in Case 1, and -120×10^{-6} in Case 3. These correspond respectively to 33,480 lb. and 8300 lb. on the bolts. In Case 3, if the positive peak of 106×10^{-6} in Fig. 6 is taken instead of -120×10^{-6} , the force on the bolts would be 24,300 lb. instead of 8300 lb. Thus the result of doubling the electrical frequency and keeping all other factors the same as in Case 1, is a decrease in the peak force on the bolts from 33,480 lb. to 24,300 lb.

CASE 4

Find the effect of the floor, other conditions being the same as in Case 3. Following the same procedure as in Case 2, new integration constants C_1 and C_2 are

FIG. 7—CASE 4. CURVE SIMILAR TO FIG. 4, CASE 2

All conditions being the same except that the electrical frequency is assumed to be doubled.

$$x = 10^{-6} (-24.3 \cos 2260 t - 35.9 \sin 2260 t - 93.7 \cos 754 t + 37.5 \cos 1508 t)$$

$$x = d + h + j \text{ for values of } d > \text{zero, } d = \text{same as in Fig. 6}$$

$$4 K I_o^2 = 26,040 \text{ lb.}$$

determined from the conditions that, at

$$\omega t = 103^\circ$$

$$x = 0$$

$$\frac{dx}{dt} = 0$$

That is, the reactor begins to leave the floor at the moment when the magnetic force becomes equal to $(f_0 + W)$ which occurs at $\omega t = 103^\circ$.

The forced oscillations, *i. e.* the ωt and $2\omega t$ terms, will be the same as in Case 3. Thus:

$$x = (C_1 \cos 2260 t + C_2 \sin 2260 t - 93.7 \cos 754 t + 37.5 \cos 1508 t) 10^{-6} = 0$$

$$\text{and } \frac{dx}{dt} = (-2260 C_1 \sin 2260 t + 2260 C_2 \cos 2260 t + 70,650 \sin 754 t - 56,600 \sin 1508 t) 10^{-6} = 0$$

Therefore

$$C_1 = -24.3$$

$$C_2 = -35.9$$

$$\text{and } x = (-24.3 \cos 2260 t - 35.9 \sin 2260 t - 93.7 \cos 754 t + 37.5 \cos 1508 t) 10^{-6}$$

This is plotted in Fig. 7. The maximum deflection is $x = 166 \times 10^{-6}$ feet, which corresponds to a force on the bolts of 32,900 lbs. The peak magnetic force is, as before, 26,640 lb. It is very interesting to compare Cases 1 and 2 with Cases 3 and 4, the conditions in the latter two cases being the same as in the former two except that the electrical frequency is doubled. In Case 2, the effect of interposing the floor was to decrease the maximum deflection below that in Case 1, where the reactor was free to oscillate. In Case 4, however, the effect of the floor is to *increase* the deflection above that in Case 3, where the reactor was free to oscillate. Moreover, although the maximum deflection in Case 3 (free oscillation) was less than that in Case 1 (free oscillation), nevertheless it was more in Case 4 than in Case 2.

CASE 5

Take the case where the reactors are *rigidly* bolted to and supported by I-beams, assuming one reactor mounted vertically above the other. Assume also that the resilience factor¹¹ k is the same as that used in Case 1, namely,

$$k = 144 \times 10^6 \text{ lb./ft.}$$

In this case f_0 is zero. Also at $t = 0$, the steady deflection x_1 is that which is caused by the weight W . Thus taking upward motion as positive

$$k x_1 = -W$$

and

$$x_1 = -W/k$$

Thus equation (26), modified for these boundary conditions, becomes

$$x = \left[2 \frac{K I_o^2}{M \omega^2} \left\{ -\frac{1}{1 - (n/f)^2} + \frac{0.0625}{1 - \left(\frac{n}{2f}\right)^2} \right\} - 1.5 \frac{K I_o^2}{k} \right] \cos \alpha t$$

11. Ratio of force exerted on the I-beam support to deflection it produces.

$$+ 2 \frac{K I_o^2}{M \omega^2} \left\{ \frac{\cos \omega t}{1 - (n/f)^2} - \frac{0.0625 \cos 2 \omega t}{1 - \left(\frac{n}{2f}\right)^2} \right\} + \frac{1.5 K I_o^2 - W}{k} \quad (30)$$

Substituting,

$$\begin{aligned} K I_o^2 &= 6660 & M &= 31.0 & \omega &= 377 & f &= 60 \\ n &= 360 & \alpha &= 2260 & W &= 1000 & k &= 144 \times 10^6 \\ x &= (-6.48 \cos 2260 t - 86.45 \cos 377 t + 23.6 \cos 754 t + 62.4) 10^{-6} \end{aligned}$$

This is plotted in Fig. 8. The maximum deflection is 166.5×10^{-6} feet, which corresponds to a force on the I-beam supports of

$$144 \times 10^6 \times 166.5 \times 10^{-6} = 24,000 \text{ lb.}$$

The peak or maximum magnetic force is, by assumption, 26,640 lb.

FIG. 8—CASE 5. REACTORS RIGIDLY BOLTED TO I-BEAM SUPPORTS INSTEAD OF RIGID FLOOR

Center lines of reactors in same vertical line, similar to Fig. 1. Resilience constant of I-Beam support same as for bolts in Case 1 (*i. e.* $k = 144 \times 10^6$)

$$x = 10^{-6} (-6.48 \cos 2260 t - 86.45 \cos 377 t + 23.6 \cos 754 t + 62.4)$$

$$a = \text{1st term, } b = \text{2nd term, } c = \text{3rd term, } d = \text{4th term, } e = b + c$$

$$x = a + b + c + d$$

$$4 K I_o^2 = 26,640 \text{ lb.}$$

The foregoing examples cover special cases of single-phase short circuit, with off-set current wave, and sine wave a-c. component, and with physical arrangement as shown in Fig. 1. For the case of reactors placed side by side, similar equations would apply, the main difference being that moments, instead of forces, would be involved provided the reactors were held by holding bolts in the floor, and no horizontal braces between them.

The case of three-phase remains. In this, as in the foregoing cases, the various factors enter in the same way, the difference being only in the character of the magnetic force. But whatever may be its character, it may be expressed as a function of time, and treated as in the case of single-phase. Thus the magnetic force on one of three reactors would be

$$f_{c1} = K_{12} i_1 i_2 + K_{13} i_1 i_3 \quad (31)$$

where K_{12} and K_{13} are constants.

in the frequency ratio might be such as to increase the amplitude.

To illustrate: if

$$n/f < 1.0$$

increasing the mass will decrease the amplitude,¹⁵ whereas if, for instance,

$$n/f = 2.0$$

then doubling the mass would obviously decrease the factor

$$2 \frac{K I_o^2}{M \omega^2}$$

by 50 per cent, but it would increase the factor

$$\frac{1}{1 - (n/f)^2}$$

from 0.333 to 1.0. Thus the net result would be an increase from 1.0 to 1.5, that is, a 50 per cent increase.

However, the full significance of the dependence of the amplitude upon the frequency ratio is not clear without consideration of the effect of the transients. There are two of them, namely, the transient of the short-circuit current, with consequent decrease in the magnetic force; and the transient of the free oscillation due to friction or damping. Both are neglected in the equations. The justification for this is two-fold: the natural frequency n as explained later, is usually enough greater than f to give the peak deflection in the first cycle of the electrical frequency, as in the Cases 1 to 5 inclusive, in which, neither transient, if they had been included in the equation, would have changed the oscillations significantly. Also, even if significant transients do exist, the calculated result is on the safe side, giving calculations slightly too high.

As resonance is approached, however, the transients are very important. For instance, by equation (26)¹⁶ it is evident that if $n = 0.9 f$, the amplitude of the ωt term will be approximately

$$10 \frac{K I_o^2}{M \omega^2}$$

while that of the $2 \omega t$ term will be only

$$0.156 \frac{K I_o^2}{M \omega^2}$$

thus, practically negligible. But while the ωt term is large, so is the αt term equally large and opposite. Hence, as shown in Fig. 5, the two waves, starting out in phase opposition, give practically zero resultant at first, which gradually builds up by successive phase shift due to slightly different frequencies, until ultimately, at 4.5 cycles of n and 5 cycles of f , the waves

15. Because an increase in M decreases both of the factors $2 \frac{K I_o^2}{M \omega^2}$ and $\frac{1}{1 - (n/f)^2}$, the latter being decreased since

$$n = \frac{1}{2\pi} \sqrt{K/M}.$$

16. Remembering that the amplitude of the free oscillation is just equal and opposite to the amplitude of the forced oscillation at $t = \text{zero}$. And hence if the frequencies are about equal, it will take considerable time for the two waves to gradually lift out of phase, thus building up the resultant wave. At resonance it would theoretically take an infinite time.

add in phase, giving a maximum equal to twice the amplitude of either wave. Then, for the same reason, it decreases again.

All this, provided there are no transients. But of course, there are transients. If the electrical damping were zero, then the free oscillation alone would die out due to mechanical damping, leaving only the forced oscillation, *i. e.* the ωt and $2 \omega t$ terms. Thus, as the former dies out, it leaves the latter, which it initially opposed and canceled. Hence if the transient of the free oscillation were rapid enough, the resultant oscillation would reach a maximum earlier than if that transient did not exist, but the maximum would be only half as great—namely, the forced oscillation alone. While there are very few data on the mechanical damping, it is probable that both transients—that is, the mechanical transient and the transient of the ωt term—are of about equal duration, say one-quarter second. In such a case, the maximum deflection would be the result of a race between the increase in magnitude due to phase shift of waves of different frequencies, on the one hand, and to a decrease due to transients, on the other. It is clear, therefore, that at near resonance the transient cannot be neglected.

To illustrate in a very rough quantitative way the effect of transients at near resonance, take Case 5, I -beam supports, assuming,

$$n = 0.9 f$$

$$f = 60 \text{ cycles}$$

neglect $2 \omega t$ term

neglect W

duration of transient of ωt term same as of mechanical transient = $1/4$ second.

transients of form $e^{-\gamma t}$

By assumption¹⁷

$$\gamma \approx 20$$

Applying equation (30)

$$x \approx e^{-20t} \left[- \left\{ \frac{10 K I_o^2}{M \omega^2} + 1.5 \frac{K I_o^2}{k} \right\} \cos \alpha t + \frac{10 K I_o^2}{M \omega^2} \cos \omega t + 1.5 \frac{K I_o^2}{k} \right]$$

Since

$$n = 0.9 f$$

$$\alpha = 0.9 \omega = \sqrt{k/M}$$

Hence

$$M \omega^2 \approx 1.25 k$$

$$\text{and } x \approx e^{-20t} \left[- \left\{ \frac{8 K I_o^2}{k} + \frac{1.5 K I_o^2}{k} \right\} \cos \alpha t + \frac{8 K I_o^2}{k} \cos \omega t + \frac{1.5 K I_o^2}{k} \right]$$

$$\text{Or } x \approx e^{-20t} \frac{K I_o^2}{k} [-9.5 \cos \alpha t + 8 \cos \omega t + 1.5]$$

This is plotted in Fig. 9. The maximum value of x occurs at about two cycles, and is

$$x_m = 6.5 \frac{K I_o^2}{k}$$

17. The transient term is assumed to apply to all terms in the equation. Strictly it applies to the αt and ωt terms, and to only a component of the constant term. But since the latter small, the assumption, for purpose of illustration, is justified

This corresponds, by equation (3), to a force on the support

$$f_s = k x_m = 6.5 K I_o^2$$

That is, about 60 per cent greater than

$$4 K I_o^2$$

which, by equation (7), is the maximum instantaneous magnetic force neglecting the transient.

If n is large compared to f the shape of the resultant deflection wave is that produced by the superposition of a high-frequency wave on one of lower frequency as shown in Fig. 3. Thus, the high-frequency wave a superposed on the lower frequency wave d produces the resultant curve x . If the ratio of the high-frequency n to the low-frequency f is an integer then the resultant wave repeats every cycle of the frequency f and therefore the maximum will occur in the first cycle of ωt . If the ratio is not an integer the resultant will not repeat and will, without transients, require a few cycles

(bolts, etc.) will depend in a decisive way upon the ratio of the frequency n of natural oscillation, to the electrical frequency f .

(2) If, however, the reactor is held rigidly, then the maximum force on the holding device will be independent of the frequency ratios, and need be only slightly in excess of the peak magnetic force. Or, conversely, if the initial tension in the holding device (plus weight of reactor) is equal to, or slightly greater than, the peak magnetic force, then no motion of the reactor can take place. It appears that this condition should always be sought.

(3) If the reactor is not held rigidly and n is large compared to f , say

$$n/f > 3$$

as is usually the case, then if motion is permitted, the maximum force on the holding device will occur in the first cycle of ωt , and will usually be as great or greater than the maximum magnetic force.

(4) If $n/f < 3$ and the reactor is not held rigidly, the maximum deflection may or may not occur in the first cycle of ωt . If it does, then the above conclusion applies. If it does not, then the transient cannot be neglected, and the equations do not apply. It is probable however, that in the latter, as in the former case, the maximum force on the holding device will be greater, than the maximum instantaneous magnetic force.

(5) The equations, which are based on definite assumptions given at the beginning of the paper, and discussed in foregoing pages, give results which indicate the general character of the phenomenon and magnitudes involved; and within limits specified,¹⁸ could probably be used as a guide in design calculations.

The authors wish to acknowledge the valuable suggestions of Mr. W. O. Dwyer and the assistance of Messrs. D. S. Snell and R. F. Franklin.

Discussion

For discussion of this paper see page 566.

18. Cases where $n > 3f$.

FIG. 9

$$x = e^{-20t} K I_o^2 / k [-9.5 \cos \alpha t + 8 \cos \omega t + 1.5]$$

a = 1st term, b = 2nd term + 3rd term, c = $a + b$, d = 3rd term

of f for the relative phase of the high-frequency wave to shift to the right position to give the maximum possible resultant. However, transients probably reduce the magnitude more rapidly than the phase shift builds it up. It thus appears reasonable to assume in this case also that the maximum occurs in the first cycle of ωt .

From the foregoing discussion of results, it appears that in cases where n is large compared to f the results are accurate enough to certainly indicate the general character of the phenomenon and magnitudes involved, and probably also close enough for guide in design calculations. In such cases, neglecting the transients would not involve serious error. However, it is clear from the numerical illustration just given, that where n approaches f , the transients can not be neglected. That is, the equations do not apply in such cases. But usually in problems of actual practise n is large compared with f .

CONCLUSIONS

(1) If the reactor is not held rigidly against all motion, the maximum force on the holding device

Report of 1922-23 Subcommittee (1863 w.)

AT the Pacific Coast Convention of the American Institute of Electrical Engineers, held in Portland, Oregon, July 1920, the following resolutions were passed:

WHEREAS, there exists at present a decided lack of uniformity in methods of testing and ratings adopted by the manufacturers of pin type insulators, affecting recommended line voltages and rated dry and wet flashover values; and

WHEREAS, the United States Bureau of Standards in the National Electric Code for overhead line construction has specified minimum values of flashover voltages on insulators used for transmission and distribution lines, but has not indicated the method of determining these values; therefore

BE IT RESOLVED: That the members of the A. I. E. E. in session of the Pacific Coast Convention recommend that steps be taken in the near future by the Standardization Committee of the Institute to properly standardize methods of testing and rating pin type insulators, in order to obtain uniform values of flashover voltages for similar types.

BE IT FURTHER RESOLVED: That a copy of this resolution be sent to the United States Bureau of Standards, Washington, D. C.

As a result of this action, the Standards Committee of the American Institute of Electrical Engineers in October 1920, appointed a subcommittee* to take up the work as outlined and advised it as follows:

It will be observed that the resolution of the Pacific Coast Convention refers more particularly to pin type insulators, but it is desirable for this subcommittee to give attention to the question of all types of insulators for transmission lines.

As a result of the work of this subcommittee certain specifications covering the usual design tests have been drawn up and recommended to the Standards Committee. It is considered desirable, however, to obtain as much criticism as may be possible from all insulator

users, before any final standardization is authorized, and it is with the desire of stimulating such criticism that the proposed specifications are presented herewith.

In undertaking to establish specified methods of conducting these tests, it was necessary to carry out investigations into the effect of test conditions. Such investigations were made at one of the insulator factories. It was found for instance that in the case of the test conductor for pin type insulators, laboratory tests demonstrated that on insulators having a dry flashover value ranging from 60 to 200 kv., with a test conductor less than 4 ft. (1.22 meter) long, the flashover voltage diminished with the conductor length, while for longer lengths the flashover voltage remained constant. A minimum length of 4 ft. (1.22) was therefore established. In general, where similar dimensions are given in these specifications they have been determined by the same sort of investigation.

In preparing these specifications a considerable lack of uniformity in definitions of accepted terms was encountered and, consequently, certain definitions have been proposed for standardization and these are published herewith. It should be remembered that these specifications are not intended to apply to routine factory tests. The Insulator Subcommittee is still giving consideration to this subject, and will welcome criticisms and suggestions leading to improvement in the form or subject matter of the specifications.

Pin Insulator Design Test Specifications as Tentatively Proposed

DEFINITIONS

The following terms are in common use and it is believed merit an exact definition or specification. The subcommittee therefore suggests the following:

A pin insulator is a complete insulator, consisting of one insulating member or an assembly of such members without tie wires, clamps, thimbles or other accessories, the whole being of such construction that when mounted on an insulator pin, it will afford insulation and mechanical support to a conductor.

A shell is a single insulating member without cement or other connecting devices.

Dry flashover voltage is the voltage at which the air surrounding a clean dry insulator or shell breaks down between electrodes, with the formation of a sustained

Presented at the Spring Convention of the A. I. E. E., Pittsburgh, Pa., April 24-26, 1923.

arc, the test being made as described under "Dry Flashover Test."

Wet flashover voltage is the voltage at which the air surrounding a clean wet insulator or shell breaks down between electrodes with the formation of a sustained arc, the test being made as described under "Wet Flashover Test."

Puncture voltage is the voltage at which an insulator or shell is electrically punctured when subjected to a gradually increasing voltage, the test being made as described under "Puncture Voltage Test."

The ultimate mechanical strength of a pin insulator is the load in pounds at which the insulator fails either electrically or mechanically, voltage and mechanical stress being applied simultaneously as described under "Ultimate Mechanical Strength Test."

DRY FLASHOVER TEST (DESIGN TEST)

Dry flashover test shall be performed with the pin insulator mounted in a vertical position on a steel pin of circular section 1 in. (2.54 cm.) in diameter mounted on a cross-arm, and of such length that the ratio of the shortest distance from the edge of the head around the insulator to the cross-arm, to the shortest distance from the edge of the head around the insulator to the pin, shall be 1.25. The cross-arm shall be of iron pipe, preferably grounded, not less than 3 in. (7.63 cm.) and not more than 5 in. (12.7 cm.) in diameter and shall extend at least 3 ft. (0.914 m.) on either side of the center line of the insulator pin. The head of the insulator shall be fitted with a straight, smooth metallic rod or tube not less than $\frac{1}{2}$ in. (1.27 cm.) in diameter extending in a direction at right angles to the cross-arm and at least 2 ft. (0.609 m.) in either direction from the center line of the insulator head. This rod shall be secured in the upper groove by means of at least one turn of wire not smaller than No. 8 A. w. g. placed in the side tie wire groove.

The character of the testing equipment and method of measuring voltage shall conform to the Standardization Rules of the A. I. E. E.

The test shall be performed by applying voltage between the rod fastened to the head and the steel pin, and raising it at a uniform rate of approximately five thousand (5000) volts per second to a value at which dry flashover occurs.

Records shall be made of barometric pressure, air temperature and humidity.

WET FLASHOVER TEST (DESIGN TEST)

The testing arrangement shall be the same as in the dry flashover test with the addition of equipment to provide a finely divided uniform spray at an angle of 45 deg. from the vertical and at a rate of 0.2 in. (5.07 mm.) per minute. The water shall have a resistance of from 3000 to 6000 ohms per in. cube (7620 to 15,250 ohms per cm. cube) and shall be delivered to the spray nozzle at a pressure of not less than 35 and not more than 50 pounds per sq. in. (2.46 to 3.51 kg. per sq.

cm.) measured at the nozzle. The vertical and horizontal dimensions of the vertical area sprayed shall be measured in a plane through the vertical axis of the insulator and shall be 1.75 times the corresponding over-all projected dimensions of the insulator. The precipitation shall be determined by measurements taken, with the insulator removed, at the location of the top, center and bottom of the vertical axis of the insulator when in its test position. Individual measurements shall show a variation of not more than 25 per cent from the mean of the three measurements.

Methods of applying and measuring voltage and of recording data, shall be the same as for the "Dry Flashover Test."

PUNCTURE TEST (DESIGN TEST)

In making this test the insulator shall be immersed in oil with the pin hole, line and tie wire grooves filled with conducting material, voltage being applied between the pin hole and tie wire.

Voltage shall be applied at not more than three-fourths of the dry flashover voltage and raised at a uniform rate of approximately 5000 volts per second for insulators having an average puncture of 200,000 volts or less, and at a uniform rate of 10,000 volts per second for insulators having an average puncture voltage of more than 200,000 volts, voltage being raised until puncture occurs.

Methods of applying and measuring voltage and of recording data shall be the same as in the "Dry Flashover Test."

CORONA FORMATION VOLTAGE (DESIGN TEST)

The testing arrangement shall be the same as for the dry flashover test, using a darkened room. A voltage sufficient to cause streamers shall be applied and slowly lowered until all brush discharges disappear. The point of disappearance shall be the corona voltage.

Methods applying and measuring voltage and of recording data shall be the same as in the "Dry Flashover Test."

ULTIMATE MECHANICAL STRENGTH TEST (DESIGN TEST)

This test shall be performed in a suitable insulated testing machine where mechanical loads up to the ultimate rupture point can be applied simultaneously with a potential 15 per cent below the dry flashover voltage at a frequency not greater than 60 cycles. During the test the mechanical load shall be increased at the rate of 2000 lb. (907.2 kg.) per minute until puncture takes place. For pin type insulators, the mechanical load shall be applied at right angles to the central axis, with a suitable metal supporting pin which will not materially deflect or bend under the maximum stress imposed. Attachment shall be made to the tie wire groove by means of a steel cable loop or bridle.

Methods of applying and measuring voltage and of

recording data shall be the same as in the "Dry Flashover Test."

Suspension Insulator Proposed Test Specification

DEFINITIONS

The following definitions are proposed:
A suspension insulator unit is a shell assembled with its necessary attaching members.
A string consists of two or more units connected in series.

DRY FLASHOVER TEST

Dry flashover test shall be performed with the insulator, unit or string, suspended vertically by the makers' standard cross-arm suspension hardware carried at the end of a grounded wire or suitable conductor suspended so that the vertical distance from the uppermost point of the insulator hardware to the supporting structure shall not be less than 3 ft. No other grounded structure shall be nearer than 3 ft. to any part of the unit or string. The insulator pin, or corresponding fitting, shall carry an inverted pipe tee made of 3/4-in. pipe, the head of the tee being not less than 6 ft. long, the stem of the tee being coupled at the middle point of the head and having such a length that the distance from the upper surface of the horizontal head to the lowest edge of the porcelain shall not exceed 0.7 of the diameter of the lowest unit.

Potential shall be applied between the stem of the pipe tee and the grounded suspension by raising the voltage at the rate of approximately 5000 volts per second to a value at which dry flashover occurs. Records shall be made of barometric pressure, air temperature and humidity.

The character of the testing equipment and method of measuring voltage shall conform to the Standards of the A. I. E. E.

WET FLASHOVER TEST

The wet flashover test shall be performed using the same general arrangement as in the dry flashover test with the addition of equipment to provide a finely divided and reasonably uniform spray at an angle of 45 deg. from the vertical and at the rate of 2/10 in. (5.07 mm.) per minute. The water shall have a resistance of from 3000 to 6000 ohms per inch cube (7620 to 15,250 ohms per cm. cube) and shall be delivered to the spray nozzle at a pressure of not less than 35 and not more than 50 lb. per square inch (2.46 to 3.51 kg. per sq. cm.) measured at the nozzle. The vertical and horizontal dimensions of the vertical area sprayed shall be measured in a plane through the vertical axis of the unit or string and shall be 1.75 times the corresponding over-all projected dimensions of the unit or string. Precipitation shall be determined by measurements, taken with the unit or string removed, at the location of the top, center and bottom of the vertical axis of the unit or string when in its test

position. Individual measurements shall show a variation of not more than 25 per cent from the mean of the three measurements.
Methods of applying and measuring voltage and of recording data shall be the same as for the dry flashover test.

PUNCTURE TEST

Puncture test shall be performed with the insulator or unit immersed in oil, voltage being applied between the cap and stud or corresponding metal fittings. Methods of applying voltage and recording data shall be the same as in the dry flashover test except that voltage application shall be begun at not more than 3/4 of the dry flashover voltage.

Report of Insulator Subcommittee of the Standard Committee, A. I. E. E. for 1922-1923

The Insulator Subcommittee, Working Committee No. 3, has held four meetings, as follows:
December 8, 1922 March 9, 1923
February 2, 1923 April 6, 1923
all at Institute Headquarters, New York, N. Y.

The subcommittee has continued the study, begun last year, of the factor of safety to be recommended between line voltage and dry flashover of the insulator.

It has tabulated the data received from 27 operating companies in reply to questionnaire sent out.

The subcommittee recommends that for the present this data be used in selecting pin insulators.

The subcommittee suggests that with steel supports or grounded pins it is desirable to use the higher factors of safety while with ungrounded pins on wood poles the lower factors of safety may be justified. At present the subcommittee is not prepared to recommend what this variation should be. A discussion of the entire situation is invited.

For convenience the following table gives flashover voltages corresponding to various line voltages, as taken from this data:

Line Kv.	Flashover Kv.		
	Minimum	Average	Maximum
11	68	88	110
13.2	..	91	..
22	90	110	121
33	109	124	142
44	163	172	180
60	186	192	222
66	179	185	198

The discrepancy between the tests for 60 kv. and 66 kv. is probably due to lack of sufficient data.
In this connection, the subcommittee wishes to submit as representing practise with suspension insulators the curve published by Mr. Peek in the *General Electric Review* of February, 1922. Attention is called to the difference in factor of safety between pin and sus-

pension insulators, particularly at operating voltages in the neighborhood of 60 kv.

ROUTINE TEST SPECIFICATIONS

The Subcommittee has given consideration to specifications covering routine factory tests on both pin and suspension units and suggests the following forms.

The Subcommittee does not take the position that these are necessarily the only tests which should be considered or, on the other hand, that all of the tests outlined must be made, but leaves this to the judgment of the Purchaser.

The Subcommittee believes, however, that if the tests are called for, they should be made as specified.

TESTS ON PIN TYPE INSULATORS

Preliminary Test. Before assembly, all shells shall be subjected to vigorous dry flashover potential at normal frequency 25 to 60 cycles for 3 minutes. If more than 5 per cent fail, the lot¹ may be retested. If on retest more than 3 per cent fail, the lot¹ shall be rejected.

Final Test. After assembly, the insulators shall be subjected to dry flashover test for two minutes. Voltages shall be such that insulators shall flashover occasionally. Insulators failing under this test shall be rejected.

TESTS ON CEMENTED TYPE OF SUSPENSION INSULATORS

Preliminary Tests. Before assembly, all shells shall be subjected to vigorous dry flashover potential at normal frequency 25 to 60 cycles for 5 minutes.

If any shell fails during the fourth or fifth minute of the test, the test shall be continued until no shell fails during the last two minutes of test. The excess time is based on the testing of quantities up to 100 at one time. For quantities greater than 100, the excess time after the last failure may be less than two minutes by agreement between manufacturer and Purchaser. If more than 5 per cent fails the lot² may be retested. If on retesting more than 3 per cent fails the lot² shall be rejected.

After assembly all units shall be subjected to flashover test at normal frequency 25 to 60 cycles for three minutes. Voltages shall be such that insulators shall flashover occasionally. All units failing under this test shall be rejected.

Mechanical Test. Not more than seven days after cementing all units shall withstand for three seconds without sign of distress a mechanical pull in line with the axis of the insulator amounting to approximately 40 per cent of the rated ultimate strength. This test shall be given before the final electrical test.

1. Note: In all cases where the term "lot" is used, it should be defined as including only the number of units on the testing pan at one time.

2. Note: In all cases where the term "lot" is used, it should be defined as including only the number of units on the testing pan at one time.

Puncture Test (For Pin and Suspension Units). Puncture voltage test shall be made on units which have passed the final routine flashover test. Rejection of units for puncture shall be based on the "Average Variation" in puncture voltage determined, as follows:

DEFINITION OF "AVERAGE VARIATION" IN PUNCTURE UNDER OIL TESTS

For this test purchaser will select from units offered for final inspection not more than $\frac{1}{2}$ of 1 per cent of the total quantity and not less than 3 units.

$V_1, V_2, V_3, \dots V_n$ = individual puncture values.

V = average puncture voltage.

$V = (V_1 + V_2 + V_3 \dots + V_n)/n$

Let

$a_1 = V - V_1 \quad a_2 = V - V_2 \quad a_3 = V - V_3 \quad a_n = V - V_n$

Consider all the values of a as positive, that is, neglect the signs.

Let a = average variation

A = average variation, per cent.

Then

$a = (a_1 + a_2 + a_3 \dots + a_n)/n$

$A = 100 a/V$

Example:

Five insulators punctured at; 150, 135, 145, 138, 142 kv. respectively.

$V = (150 + 135 + 145 + 138 + 142)/5 = 142$

$a = (8 + 7 + 3 + 4 + 0)/5 = 4.5$

$A = 100 \times 4.5/142 = 3.17$ per cent

If "Average Variation," A , exceeds 10 per cent, the entire quantity shall be rejected, or at the manufacturer's option and expense an additional 2 per cent may be tested. If the "Average Variation," A , obtained from this second test only exceeds 10 per cent, the entire quantity shall be rejected.

Ultimate Mechanical Strength (Suspension units only). Not more than 7 days after cementing, ten units shall be selected for this test from each 1,000 ordered. If any fail at less than 85 per cent of the manufacturer's rated ultimate strength, an additional 20 units shall be tested at the manufacturer's expense. If none fail at 85 per cent of manufacturer's rating, the lot shall be accepted and if any fail, rejected.

Expense of Material for Tests. As far as practicable, tests shall be made upon units which have some defect and are not salable but are otherwise acceptable to the inspector for the test in question. In addition, Purchasers shall be allowed to test commercial insulators to destruction up to $\frac{1}{2}$ of 1 per cent of the total number ordered. If additional units are desired for such tests, they shall be paid for by the purchaser.

We believe that the above completes the work assigned to the subcommittee. In the course of its discussions, two questions came up which it appears should be subjected to further laboratory study and the subcommittee suggests these for your consideration.

1st. The relative effect of 25- and 60-cycle tests.

2nd. It is believed that the mechanical strength

of a string of insulators decreases with time. The amount of this should be ascertained.

The subcommittee believes that the material included in the above report should be treated in the same way as the design test specifications previously reported on, that is, it should be published and subjected to criticism, so that it may be revised before any definite action is taken. It would be highly desirable, if possible, to have this material presented at the April meeting of the Institute in Pittsburgh, at which time the design test specifications are scheduled for discussion.

The subcommittee would like the permission of the Standards Committee to arrange for this, if possible.

Respectfully submitted,

P. JUNKERSFELD

Chairman, Insulator Subcommittee
of the Standards Committee, A. I. E. E.

Discussion

LIGHTNING DISTURBANCES ON DISTRIBUTION CIRCUITS (MACLAREN);
OPERATING EXPERIENCE WITH CURRENT-LIMITING REACTORS (POLLARD);
SHORT-CIRCUIT FORCES ON REACTOR SUPPORTS (DOHERTY AND KIERSTEAD);
STANDARDIZED INSULATOR TESTS
(INSULATOR SUBCOMMITTEE OF STANDARDS COMMITTEE);
PITTSBURGH, PA., APRIL 26, 1923.

E. C. Stone: As I understand this lightning situation, the lightning arrester must have large charging capacities. The lightning arrester must choke the dynamic current that may follow from the system. Those two conditions are almost diametrically opposite. However, in very low voltages, by which I mean under four or five thousand, the dynamic problem is comparatively simple, and you can hold down the dynamic current following with a low resistance which is not high enough to seriously interfere with your discharge but as you go to the high voltages, the problem of holding back the dynamic current without checking the surge discharge becomes more and more complicated and involves more and more complicated apparatus. At voltages of 150 to 220,000, you have to put so much insulation on to hold the line voltage, that the lightning arrester is not important. I will say that our problem for 234,000 volts is practically solved today by distributing the proper arresters. In that way we can get a high percentage of protection from four thousand volts up to some unknown quantity of 66 or 88 or 110.

I don't see the answer at the present time. Either the equipment is so expensive—I am talking about system protection rather than individual apparatus—if you have big transformers you can afford to pay a little bit for the lightning protection, but in general system protection costs so much that you can't afford to do it from perhaps 119 volts up, until you get to a voltage where your insulation is protection.

Karl B. McEachron: Attention is called in Prof. MacLaren's paper to the desirability of protecting the secondary distribution circuits, especially if those circuits are long and exposed. This point could well receive more consideration than has been given to it in the past. It is well known that the telephone companies have found it necessary to protect their subscribers' stations by the use of arresters, even when the exposed lines were not long. That such protection is necessary has been shown by the burnouts occurring where the circuits were unprotected.

Prof. MacLaren has shown that arresters having high resistance in the ground circuits fail to protect. A simple calculation will show how important this point is, being probably more important with distribution arresters than with the high-voltage equipments.

Assume that a 2300-volt arrester has an effective resistance of 25 ohms which is representative of arresters of this rating. With zero ground resistance, the discharge rate at double rated potential is $4600/25 = 184$ amperes. With a ground resistance of 200 ohms, the discharge rate is only 20 amperes. Thus, the introduction of this ground resistance has reduced the discharge rate to one-sixth of its original value.

Designers of lightning arresters endeavor to get as high a discharge rate as possible, but if one succeeds in reducing the resistance from 25 to 20 ohms or less, his efforts will be of little avail if the ground resistance is not kept low.

This paper agrees with the experience of others in that the best protection is secured where the density of lightning arresters is the greatest. This is, of course, to be expected.

W. B. Kirke: I should like to bring out a few points with regard to Messrs. Doherty and Kierstead's paper that have been particularly interesting to me in a similar study that I have made on magnetic forces in reactors at The New York Edison Co. If we refer particularly to Equation 7, we will find an expression for the magnetic forces due to the currents in the reactor windings.

FIG. 1

If we analyze this equation for one complete cycle, we will find that the average force for that period is proportional to the 1.5 term of Equation 7. If we add up all numerical coefficients of that Equation, $1.5 + 2 + 0.5$ without regard to sign, we will have a Fig. 4 which is proportional to the maximum value of the magnetic force during the first cycle. Equation 7 was derived by squaring Equation 6. If we had neglected the transient term which occurs in Equation 6 and is expressed by the figure of unity, we would have a force equation which gave over a complete cycle an average force proportional to the figure of 0.5, and a peak force proportional to the figure of 1 thus representing conditions after the transient has disappeared.

During the first cycle, however, with a totally offset current wave we found that the peak magnetic force was proportional to the figure of 4. This peak force, therefore, varies from a figure of 4 down to the figure of unity during the period of the transient, as shown in the accompanying figure.

In calculating forces in reactors under short-circuit conditions we are, therefore, likely to be greatly in error if the transient currents are not considered. As an illustration, we may take a 300-ampere circuit having a 3 per cent feeder reactor. For a short circuit at the terminals of the reactor, the effective short-circuit current, with sustained bus voltage, would be approximately 10,000 amperes and if this figure were used, it would give us magnetic forces corresponding to the figure of 0.5.

Reactors," published in the *Electrical World* in 1917. This article gave the first approximate formula which was worked out for the repulsion of coils with parallel axes. While its results are very close to the true values, a more accurate and convenient formula is given in the paper by the writer on "Some New Formulas for Reactance Coils," TRANS. A. I. E. E., 1919, p. 1681, formula (4). Curves for the force on coils with parallel axes are given in Fig. 3 of the A. I. E. E. paper.

Formulas and curves for the force exerted between coils with the same axis are given in the paper by the writer on "Repulsion and Mutual Inductance of Reactance Coils with the Same Axis" *The Electric Journal*, May, 1918, p. 166.

E. E. Berger: Referring to Mr. MacLaren's paper, it would seem that the problem in most cases of protecting low-tension circuits, such as 115 and 230 volts, was not very serious and that adequate protection could be supplied where needed at small cost. For 2300 and 13,200-volt service, past experience has proven that adequate protection in the form of lightning arresters is available and so the problem is simply a matter of placing arresters at the proper points of a system and in sufficient numbers. However, much valuable work can still be done in reducing the cost of such protection, or possibly increasing slightly the degree of protection.

D. W. Roper's paper, presented before the Institute in November, 1920, which I believe was the beginning of this class of investigation, has proven very valuable in determining what performance should be expected from lightning arresters designed for distribution circuits. I can say that the General Electric Company has been able to check in the laboratory to a large degree the results obtained by Mr. Roper on the Commonwealth Edison System.

My opinion is that more valuable information can still be obtained from operating lines, especially in regard to the magnitude of lightning disturbances. I feel that a very simple apparatus can be developed to measure and record the magnitude of lightning disturbances. From a study of such data taken over several lightning seasons, much light would be thrown on the whole lightning protection problem.

F. H. Kierstead: After Mr. Pollard candidly discusses his experience with current-limiting reactors of different designs he concludes that, while reactors have in the past been subject to failures of various natures, the modern reactor is a reliable piece of apparatus. Another way of putting Mr. Pollard's conclusions is that as a result of such operating experience modern reactors have been made reliable. The defects in the design and operation of early reactors which did not become apparent until the reactors had been given the test of service, have been corrected.

Failures of reactors may result from the following causes: 1—Over-voltages; 2—Insufficient thermal capacity; 3—Mechanical weakness; 4—Foreign conducting materials.

Since reactors are points of reflection, there was some apprehension as to the magnitude of the voltages that might be built up at these points, and in the early days of the design of current-limiting reactors careful consideration was given to the voltage that they might have to withstand. Experience has shown that as a result of this consideration only a very small number of failures can be attributed to over voltage and it is probable that some of these may have been due to foreign material as will be explained later.

It was always recognized that reactors should have liberal thermal capacity and it soon became the practise to construct them with materials not injured by high temperatures and I know of no failures of reactors due to high temperature that were constructed with heat resisting materials.

While it has always been recognized that the magnetic forces in reactors were large still, as pointed out by Mr. Stephens in his discussion, their exact magnitude and destructiveness was not

at first fully appreciated. Now that they are understood we should not expect a duplication of this trouble.

Experience has shown that the danger of failure due to foreign conducting materials falling or being drawn into a reactor by its magnetic field has not been fully appreciated by operators. Usually an examination reveals the cause of such a failure but sometimes the evidence is destroyed by the resulting arc. In one such case a reactor that failed due to no apparent cause was placed out of doors for some time. At a later examination positive evidence of iron rust was found on the conductors at a point where failure had occurred, clearly indicating that the failure had been caused by the presence of an iron body at this point. This is a source of trouble that can be eliminated by proper education of the operating force.

L. F. Woodruff: In 1920 Mr. O. R. Schurig and the writer undertook a study of the stresses in a-c. busbars and busbar supports due to short-circuit electromagnetic forces. A large number of oscillographic tests were made with transient-pressure-recording devices. A mathematical analysis of the motion of the bar was made on the assumption of "equivalent mass" and "equivalent stiffness" for the bar, and we obtained equations identical with those given by Messrs. Doherty and Kierstead. The oscillographic records furnished excellent checks with the theory. The results of our investigation were given in a general engineering laboratory report having a circulation only inside the General Electric Company.

It is obvious that the important principle brought forth is that conditions of electro-mechanical resonance are to be avoided. It is therefore desirable to calculate accurately the natural frequency of mechanical vibration of systems in which the equivalent mass and equivalent stiffness differ materially from the actual total mass and stiffness. The busbar is the most important illustration of such a case.

A busbar is a continuous beam, and if the assumption be made that each span is of the same length, all spans, except possibly those near the ends of the bar, will move in unison, and each span has therefore the end conditions of a beam fixed at both ends. We will set up the differential equation of motion of such a beam.

In Fig. 2 the slope of the neutral axis at any point equal to $\frac{\delta y}{\delta x}$. If the slope is assumed to be small, so that $\left(\frac{\delta y}{\delta x}\right)^2$ is

negligible in comparison with $\frac{\delta y}{\delta x}$, the curvature is approxi-

imately equal to $\frac{\delta^2 y}{\delta x^2}$ and the bending moment to $E I \frac{\delta^2 y}{\delta x^2}$,

where E is the modulus of elasticity of the material and I is the moment of inertia of the cross-section about the intersection of the neutral plane and the plane of the cross-section. The shear

is $\frac{\delta}{\delta x}$ (moment), or $E I \frac{\delta^3 y}{\delta x^3}$.

The net vertical force acting on the section $A B C D$ is the difference of the shears at $A C$ and $B D$, and is equal to the rate of change of shear along the X -axis times the distance $d x$, or

$$E I \frac{\delta^4 y}{\delta x^4} d x.$$

If there is no external force applied, this force must be used in producing vertical acceleration. If m is the mass per unit length of beam, the mass of the section $A B C D$ is $m d x$, and multiplying this mass by the expression for its acceleration, and equating this to the available force, we have

$$m d x \frac{\delta^2 y}{\delta t^2} = - E I \left(\frac{\delta^4 y}{\delta x^4} \right) d x, \quad \text{or} \quad \frac{\delta^2 y}{\delta t^2} + (E I / m) \left(\frac{\delta^4 y}{\delta x^4} \right) = 0 \quad (1)$$

Fundamental vibration, $140,000 D/L^2$; Second harmonic, $385,000 D/L^2$; Third harmonic, $757,000 D/L^2$; Fourth harmonic, $1,254,000 D/L^2$. For aluminum bars, Fundamental vibration, $197,000 D/L^2$.

The natural frequency of vibration of round wires has been calculated, as there is a possibility of resonance in such apparatus as power-limiting reactors, etc. For round wires of hard-drawn copper, the natural frequency is:

Fundamental vibration, $121,000 D/L^2$. For round aluminum wires: Fundamental vibration, $171,000 D/L^2$.

M. Mac Laren: Mr. McEachron's illustration of the effect of high ground resistance upon the discharge rate of an arrester I think rather overstates the case for Ohm's Law cannot be applied directly here. As A. L. Atherton has so clearly shown (Paper presented at Midwinter Convention of the A. I. E. E., February 1923) the surge impedance of the circuit will generally be much greater than the resistance of the arrester and its ground connection and has, therefore, a more controlling influence in the problem. At the same time, it is important to obtain low ground resistance and where this cannot be accomplished without considerable expense the arrester density should be increased.

Mr. McEachron's statement that the best protection is secured where the density of arresters is greatest needs qualification, for the data submitted in the paper show that this only

applies to the exposed circuits. There are many circuits in the city which have no arrester protection for which no injury from lightning has been recorded. One of the most important matters to determine for the exposed circuits is where the saturation point occurs beyond which it becomes economically undesirable to increase the arrester density.

Mr. Berger refers to the low cost of arrester protection for 115 and 230-volt circuits, and while this is true for an individual case, a large sum would be needed for an operating company to apply such protection at all generally to the system. For these reasons it was suggested in the paper that this type of protection might be included as part of the customer's service equipment.

R. E. Doherty: Mr. Dwight has kindly called attention to additional references to contributions which give methods of calculating the electromagnetic force. These will be added to the bibliography. Mr. Woodruff has contributed some interesting and valuable equations for calculating the oscillating frequency of bus bars, which are fixed at both ends; and has emphasized the point, referred to on the first page of the paper, that the motion of a bus bar may be represented by equations identical with those for the motion of the reactor. The new equations by Mr. Woodruff make it possible to calculate the natural oscillating frequency, using constants of the material directly, instead of an "equivalent mass" and "equivalent stiffness."

The National Engineering Societies

Their Problems of the Past, Present and Future

President's Address

BY F. B. JEWETT

IN selecting a subject for his annual address to the American Institute of Electrical Engineers the retiring President has such a wide latitude of choice as to make the proper selection one of considerable difficulty. If I followed my natural inclination I should doubtless choose as a topic one of the numerous outstanding engineering problems of the day and attempt to present for your consideration my views on it. However, the provision of our Constitution which assigns the address to the close rather than to the beginning of a presidential term seems to me to indicate a desire on the part of the Institute to have this address incorporate in some measure the ideas of the retiring President on matters of general concern to the Institute rather than his ideas on some specific engineering topic which could of course be expounded in a paper or discussion at one of the technical meetings. Whether or not this was the conscious intention of the Institute at the time the Constitution was adopted, I have elected thus to interpret the situation and in what follows I shall attempt to set before you for what they are worth my present ideas on some of the problems which confront this Institute, and to a large extent the other so-called Founder Engineering Societies. If these ideas are valid and if they serve in any measure to assist our Institute to grow and develop in a way which is healthy and for the best interests of its members, for the profession as a whole and for the good of the industry and the community which we represent, I shall feel that the remarks have been worth while.

In viewing the varied activities of our national engineering societies and the problems which now confront them one cannot help but be struck by the fact that the tremendous changes of the past decade, which have so altered our whole economic, social and political life, have brought a multitude of new problems to the engineering societies. That it will require the utmost of clear thinking on the part of our members and officers, if these problems are to be solved in a manner befitting the profession of which we are a part, is a necessary corollary. That the conditions which now confront us are intricate and perplexing is not at all strange in view of the increased perplexities of life in general. In fact it would be strange indeed if a professional society such as ours could have continued uninterruptedly along the lines marked out by its founders.

In common with the other great national engineering

societies, this Institute was the direct result of a feeling on the part of a group of men working in a particular field of engineering, that they and their art would profit from the establishment of a place of common meeting. It was the thought of the founders and has ever since been a guiding principle of the Institute that by thus providing a forum where engineers could meet as engineers and not as representatives of some particular business activity, and where they could discuss freely all matters of common technical interest, the art would be advanced most rapidly, the community would be best served and the members individually would receive the greatest personal benefit. The wisdom and foresight of the founders of the great national engineering societies and of the members of these societies who followed in their footsteps is evidenced not alone by the growth in size and vigor of the engineering societies but by the progress of the arts founded on engineering and for which the members of these societies have been most largely responsible. It is clear now as we look back over the period of their existence that the activities of these societies along the lines conceived by their founders have been a large, if not the largest, single factor in the stupendous engineering advances of the past thirty or forty years.

For many years following their founding the activities of all of the engineering societies were directed primarily to problems of a purely technical character. During this period there was relatively little of common concern tending to bring the various societies together. In fact there was relatively little tending to foster society interest in the general concerns of the community except where from time to time the purely technical features of some project of the moment attracted the interest and attention of one or other of the engineering bodies. But just as the growth and expansion of the fundamental sciences on which all engineering is based gradually wiped out the lines of demarcation which once separated physics and chemistry, for example, into two readily defined and wholly distinct sciences, so too the more general application of fundamental scientific knowledge and the growth of arts based on engineering broke across the barriers which once so definitely separated the civil, mechanical, mining and electrical engineering fields. Even before the outlines of these boundaries which once separated the great engineering fields began to grow indistinct, however, there was a pronounced indication of impending change within the several fields themselves.

So rapid and so extensive was the growth of the

industrial application of scientific knowledge that in every field of engineering, possibly more so in the field of electrical engineering than elsewhere, there sprang up great new industries, which, although they had their roots in a common field of technical knowledge, were nevertheless in many respects essentially distinct arts. While retaining undiminished their interest in those fundamental aspects of their profession which were of common technical concern, the groups of engineers who had specialized along these several arteries of development soon found themselves faced with a myriad of problems of interest to their fellow specialists but of relatively little concern to the specialists in other fields. The machinery existing in the engineering societies of the day was inadequate to satisfy the needs of all these diverse groups. This, as we are all aware, led inevitably to the formation of rather highly specialized engineering societies, such for example as the Institute of Radio Engineers or the Institute of Iron and Steel Electrical Engineers in the electrical field, and the Society of Automotive Engineers in the mechanical engineering field.

Frequently these newer societies were not purely technical in their aims but had to a greater or less extent a commercial background for part at least of their activities. In the main the active members of these specialized engineering societies were members of the founder societies and in general there was no conscious thought of any attempt to usurp the functions which had become recognized as the functions of the four national societies. The avowed purpose and desire of the founders of these societies was to handle those technical problems which were of special rather than of general interest, and to do such other things as were of special concern to the engineers who constituted their membership.

Once founded, however, it was but natural that the growth of these societies should sooner or later give rise to activities similar in whole or in part to some of the activities of the founder societies. As we are aware, this overlapping of activities between what might be termed the "parent" and the "offshoot" societies has from time to time resulted in confusion, just as the gradually overlapping fields of interest of the national societies have resulted in a confusion tending to bring about some form of joint action. On the whole, however, it seems clear that the formation of these specialized engineering societies has resulted in great benefit, not alone to the art but in fact to the founder societies as well, and the gradual clarification in overlapping fields and the spirit of cooperation and of joint action, of which there is growing evidence, bids fair to minimize the deleterious effect of such confusion as may arise.

Coincident with the expansion to the point of overlapping which has taken place in the fields of activity of the great national engineering societies and in the creation and growth of specialized engineering societies, whether wholly or partially technical in function, other

factors have developed which have tended to modify the simple setting which originally surrounded the national engineering societies.

The same forces which resulted in the formation of specialized engineering societies later brought into existence associations, of which the National Electric Light Association is an outstanding example, in which the purely technical aspects of engineering, such as concern the national societies or their offshoots, were initially of relatively minor concern. These associations, which embraced in a common membership groups of men with widely diverse interests, were essentially commercial in their origin. Such technical activities as they were originally interested in were concerned more with the commercial than the scientific aspects of engineering. Gradually, however, as they grew and their problems developed, there arose within these associations activities which tended to parallel or overlap similar activities in the founder societies or their more purely technical offshoots. As in the case of these offshoot engineering societies, the overlapping activities were very largely in the hands of engineers who were also members of the national engineering societies. So long as the overlapping affected merely the internal working of an industry the results were not essentially serious. When, however, it began to evidence itself in a conflict of findings which bore upon public policy or State regulation the results began to react adversely to the industry and to the engineering profession.

While all of the foregoing factors were at work there was another and even more important influence in process of development tending to modify the original concept of the national engineering society and to change the form and scope of some of its activities. In the early days of what we might term the engineering epoch of civilization—the fifty or so years immediately following Watt's work with the steam engine—the applications of science to industry were considered largely like any other commercial business of the preceding time, namely, as matters of private concern in which the State as a whole had little or no interest. Gradually, however, with the expansion of these newer technical industries it became clear that many of them were of interest and concern to the public in ways quite distinct from the older questions of their financial solidity and their legal or illegal acts viewed solely from the standpoint of private businesses. First, with the common carriers, later with the other so-called public utilities and still later with many businesses closely akin in function to age-long commercial organizations, there grew up gradually the idea of a general State control in the interests of the public.

Initially it was logical that this control should be entrusted to those designated officials to whom in the past had been entrusted the conduct of the State's relations to matters of common public concern. In the main these officials were essentially ignorant of technical matters, so that with the best of intentions

many schemes of regulation resulted disastrously through failure on the part of the supervisory officials to recognize fundamental engineering considerations.

Gradually with the increase in the magnitude and complexity of the things to be regulated by the State, or in some instances to be done by the State in the common cause, and with the increasing complexity of our modern application of a growing science to industry, there is developing an appreciation of the fact that we are more and more coming to live in what, for want of a better word, we may term a mechanical age. Further we are coming to realize that the proper direction of our affairs must to a large extent be based on the unbiased opinion of those who by training and experience are in position to know the fundamental factors which underlie satisfactory and proper physical operation; in a word, engineers. This does not mean necessarily the growth of a tendency to turn over to engineers the untrammelled control of undertakings which have a large public interest but which are primarily of an engineering character. There are too many other factors of far-reaching importance which enter into the State's relation to public utilities to make such a step either probable or desirable. What it does mean, however, is that there is a gradual and I think a rather rapidly awakening appreciation of the fact that in many directions the interests of the community make imperative the employment of men of engineering training and experience on the administrative boards charged with safeguarding the public interest. Further, there is indubitable evidence of a growing tendency in matters of great public concern involving engineering factors to seek the opinion of engineers as a basis for legislative and executive action—this on the assumption that engineers are by training and experience that group of the citizenry most competent to have a valid opinion on certain features of numerous problems affecting the State as a whole.

Growth in this direction is having a far-reaching effect, not alone on the relations of the engineering societies with each other but in their common relation to the public and to the State which represents the public. It is also having a determining effect on the proper scheme of engineering education, on the qualifications of men entitled to be classed as engineers and on the general ethics of the profession and of the relation which should exist between the State and those qualified to be classed as engineers.

In addition to the foregoing, which appears to me to be the deep underlying forces at work tending to modify our original concept of the national engineering society and to create our major problems for the future, there are certain more specific or more remote influences all tending to force us in the general direction of a closer and more intimate relationship between the national engineering societies and the development of cooperative organizations which can function for us effectively in all matters where common joint action is required.

Among these more specific influences are to be cited the Engineering Foundation and the National Research Council; the one the nucleus of what I believe is destined to be a great foundation entrusted to the guidance of the founder societies with funds contributed by those who have the faith to believe that the income from these funds will be expended wisely by the societies in fostering the growth of engineering and of the things with which engineers are vitally concerned. The other is a great national institution intended to coalesce in a common organization all of those activities of the nation interested in scientific research. As engineering and the engineering arts are the greatest consumers and beneficiaries of the results of scientific research, it is natural that the engineering societies should have a vital interest in the affairs of an organization like the National Research Council and in its success. With the establishment of the Engineering Division of the National Research Council there has been brought into being a mechanism which if properly directed will serve to tie the research activities of the engineering societies into the larger common undertaking.

Of the factors which bid fair to influence our course at a later date, but which for the moment have a less immediate bearing on our affairs, are questions of international relationships between engineering societies, whether for the better dissemination of knowledge and the advancement of the art or in the more practical affairs where benefit would be derived from a common standardization for the simplification of international trade.

In the foregoing I have attempted to state the factors which have been and are at work tending to modify the original concept of the national engineering society. I have not attempted even to enumerate all of the directions in which these forces have worked to change the form or character of our activities, nor have I attempted to discuss the relations of those regional engineering societies which have in the main the same relations to their constituent members as the national societies to their more widely distributed members. In a sense these regional engineering societies might be looked upon as sections of the national organizations established in order the better to carry out the aims of the larger organizations.

Having now surveyed the situation historically, let us make a direct comparison between the national engineering societies in the period prior to ten or fifteen years ago, with those same societies as we find them today. This should assist us in determining just how far their situation has been altered and the direction in which they should endeavor to progress if they are to achieve their initial purpose of rendering the greatest benefit to their members, to the art which is the creation of these members, and to the community of which the members are a part.

As has been indicated, these societies were initially,

and for many years subsequent to their formation, associations of engineers having a common interest in some one of the fields of civil, mechanical, mining or electrical engineering. These men were banded together in institute or society for the avowed purpose of bettering their professional condition through the presentation and discussion of papers on technical subjects, which papers and discussions would at the same time tend to advance the art and benefit the public. They were interested in matters pertaining to technical education primarily from the standpoint of their own particular field and only slightly less so in education as it related to engineering in general. The societies of those earlier days had few matters of common interest and few continuing relations as societies with either the State or the public of which they were a part. They grew up with different backgrounds of experience of their members, as is evidenced by the great diversity in their qualifications for membership and in the difference in their concepts of how the qualifications for membership could best be employed to attain what was apparently a common objective.

That the results obtained by the societies in those earlier years were eminently successful is evidenced by the stupendous growth of engineering and the engineering arts which took place during the period in question.

Contrast now this relatively simple situation with the conditions of today and the problems with which the engineering societies are now faced. The national societies have grown and prospered enormously and in addition there have come into being innumerable societies which cover specialized fields of engineering interest and which in some directions are paralleling the work of the founder societies. Further, there are associations primarily commercial in their origin, which have developed engineering interests somewhat akin to those undertaken by the national societies. The national societies are finding each day an increasing number of problems in which they have a mutual interest or an interest with one or other of the different organizations just enumerated. As a result there has come into being an almost inextricable mass of relationships and interests which is each day increasing in complexity.

Further than this, there has been a material change in the concept of the relationship which should exist between the national society and some at least of its members. No longer is the national society, through its national or sectional meetings, looked upon merely as the instrumentality through which the members could advance themselves and their art professionally. Today it is considered by large sections of our membership that the national society has a duty to its members in the direction of advancing their physical and financial wellbeing.

In addition to this there has come about a decided change in the concept of the relation which should

exist between the national societies acting for engineers and the State which represents the community. Evidence of this is clearly shown in the various attempts which have recently been made to coordinate the societies for certain common purposes in a federation which can speak for all on matters of common concern. That there have been and are difficulties in the carrying out of this idea has to do with the mechanism and with the diversities which exist in the constituent bodies themselves rather than in any fundamental divergence of opinion as to the necessity for some form of cooperative action in this direction.

So complex has the situation become and so insidious and alluring are many of the arguments which tend to a further complexity that it seems to me, in common with many other engineers, imperative that we take a rigid account of stock, determine anew what we believe should be our guiding principles under present conditions and then attempt the untangling of the skein in consonance with these principles.

As I view the matter, the original concept of the national engineering societies, as a mechanism for advancing the engineering art and the professional status of the members, and of exercising a controlling influence on the form and character of engineering education, is still the primary function of these societies. The means by which the several societies accomplish this end, whether through national conventions or sectional meetings is of secondary importance, nor is it necessary, as I view it, that there should be any attempt to monopolize the field to the exclusion of those societies having a membership primarily interested in some particular region of one of the major engineering divisions.

In the matter of influencing the form and character of engineering education there was never greater need of the sane and powerful influence which can be exerted only through the medium of great national professional societies. In recent years there have grown up in some of our institutions courses of instruction which purport to give young men an education destined to facilitate their rise in the engineering field or in the industries based on engineering. In the view of many engineers these courses, which directly or inferentially hold out the lure of some royal road to success, are detrimental rather than beneficial to the progress of engineering and to the arts depending upon it. To many these courses are detrimental not because of the subjects which they include but because they fail to take into account the fact that our engineering problems and our engineering industries are becoming each day more and more complex and more and more dependent on a strict and accurate knowledge of those fundamental sciences on which all engineering is based and without a knowledge of which no man can hope to build a solid future for himself or his industry. If this picture is correct, and if, as I fear, there is a tendency in some quarters for young men to consider that sound grounding in

science and engineering principles is of secondary importance, it will require the utmost of attention on the part of the national engineering societies to bring our whole educational machinery into proper alignment.

I believe very firmly that the chief executives of the complex technical industries of the future are destined to be drawn more and more largely from the ranks of those men whose course of study in college, university and technical school, and whose experience, has given them a broad and accurate knowledge of fundamental scientific and engineering principles. It is obvious of course that the successful administrator must be much more than a mere skilled scientist or technical engineer. He must in addition have an ability to lead and direct men and that facility which we term, for want of a better word, "business acumen." These characteristics seem to be rather a matter of inheritance than of formal training, and from the vast number of able young men who embark on engineering and science as a life work it would seem to me reasonable to expect that there should be found an adequate number possessing the characteristics required of a chief executive. On the other hand, in industries based on science or the engineering arts so much of success or failure depends, in the last analysis, on a clear and accurate understanding of fundamental underlying factors that it is difficult in many cases to conceive of these industries being administered successfully except by men who, while possessing the necessary administrative qualifications, are at the same time, through their own training and experience, in position to have an independent judgment on the technical conclusions which form the basis for administrative decision.

If this picture is correct the national engineering societies can perform a great service to the nation through the assistance which they and their members are able to render in helping our colleges, universities and technical schools properly to plan and carry out their educational programs.

On matters which relate to standardization and to the formulation of principles and rules for guidance to good practise, there is of course much with which the national engineering societies need not concern themselves. On the other hand, the rapidly growing interest of the State, not alone in the results of technical and commercial application of science through industry to the needs of the population but also to a greater and greater extent in the supervision of the industries which make these applications, is increasing the necessity for having this work done thoroughly and in unbiased fashion and put forth by bodies against whom can rest no suspicion of self-interest.

Our national engineering societies are in a unique position in this respect. The recognition that they are bodies which combine in a common membership, and solely through the bond of a common professional interest, the trained men of the various engineering fields, gives to their rules and their standards a force

and standing not to be obtained by the rules and standards of bodies known to be organized more or less for commercial reasons. The peculiarity of this position offers both a great opportunity and a great obligation for service from the national engineering societies. The realization of this opportunity and the discharge of this obligation does not mean necessarily that the national societies, individually or collectively, must of themselves do all of the detailed work which underlies the formulation of those things which go forth under the seal of their sanction. In many cases where the general interest of the industries, of the societies and of the public at large makes desirable the sponsorship of rules and standards by the national societies or their created agencies, the collecting and sifting of data and the formulation of the proper conclusions to be drawn from this work may best be done by groups or organizations outside of the engineering societies, in fact in many cases brought into being purely by the exigencies of business. In such cases it will suffice if the engineering societies, who are looked to to sponsor accurate and unbiased rules for any who may wish to use them, review the work of others merely from the standpoint of ascertaining that it is unbiased and represents the just conclusions to be drawn from all ascertainable facts.

In those matters of concern where the questions are broader than the interests of any particular group of engineers, where our own interests as engineers call for common action, and where the public at large and our legislators and executives have a right to expect an opinion from us as engineers, it seems clear that the efforts of the past few years in this direction must be carried forward as expeditiously as possible and a satisfactory mechanism found. Differences of opinion as to method, and difficulties which arise out of our various schemes of organization and qualifications for membership in the engineering societies, must not be allowed to stand in the way of our early ultimate success. So much publicity has been given to the organization of engineers along this line and so much has been said of the benefits to be derived from this organization that any substantial failure to achieve the results which the public has been led to expect would be forthcoming would I think lead to a state of affairs so disastrous to the engineering profession and to the public welfare that we dare not contemplate it.

Whatever, therefore, may be our individual opinions with regard to the composition or conduct of the Federated American Engineering Societies, which is our existing mechanism in this field, I am certain equally that a method must and can be found for making this organization, by evolutionary rather than revolutionary processes, all that we believe such an organization should be. It needs but a common will to succeed and a willingness to brush aside immaterial obstacles which stand in the way of achieving the ultimate objective.

As to those other interests, already mentioned, of the national societies, in the National Research Council and in the proper conduct of the trust which we have undertaken in the creation of Engineering Foundation, there is little further which need here be said. Our difficulties of the moment arise more from not having a simple, concise, thoroughly understood and agreed to picture of aim and objective than from any fundamental diversity of opinion. Until this objective is achieved and the case is set forward in a way which cannot be misunderstood, until we have organized the administration of our interests satisfactorily in conformity with the objective sought, and until we have established that close association between this administrative machinery and the governing bodies of the founder societies, without which lasting success and healthy development is impossible, it is futile and worse than futile to consider the details of intricate organization or plans for great expansion. The problem is ours and can be solved if we but set ourselves the task. It requires a critical clear-sighted analysis of the objective desired and of the methods needed to reach this objective, combined with a courage to put our conclusions into effect. When we succeed in doing this we will have built upon the groundwork already laid the foundation of a structure which will last through the ages, which will grow with time and which will be of immeasurable

benefit, not alone to us of the engineering societies, but to all who are in any way affected by our works.

In conclusion it seems to me that there never was a time in the history of our engineering societies, and particularly never a time in the history of our own Institute, when the necessity for these organizations was greater, nor when their benefit both to the individual and to the community was so thoroughly worth while. The considerations which brought our national engineering societies into being are still and ever will be the primary and chief functions of institutions like our own. But to these basic objects have, with the passing of time, been added other functions the satisfactory handling of which will enhance the value of the national societies, not alone to their members but to the industries with which these members are connected and through them to the public.

Our problem now and for the future, in addition to conducting successfully those things which are clearly ours to perform, is largely one of determining what of the new things continually arising we of all other groups are best qualified to perform, setting our hands to the doing of those things in a manner befitting our profession, and of refraining courageously from undertaking anything which will detract from the doing of those things which are peculiarly ours or which others can do as well or better.

Cable Charge and Discharge

BY CHARLES P. STEINMETZ*

Fellow, A. I. E. E.

Chief Consulting Engineer, General Electric Co., Schenectady, N. Y.

Review of the Subject.—Conductivity determinations of insulating materials, and therefore the determinations of the leakage resistance of a cable, condenser or similar structure, have always been more or less unsatisfactory, due to a phenomenon often called "soaking in of the charges."

In general, if a constant direct voltage is impressed upon a circuit, in the first moment large transient currents flow, representing the energy storage and adjustment in the magnetic and dielectric fields of the circuit. These transient currents however vanish very quickly, usually in a very small fraction of a second, and all the currents in the circuit or circuits then become constant. If a constant direct voltage is impressed upon a cable or similar structure, large transient currents also flow momentarily; but after these currents of energy adjustment in the electromagnetic field of the system have vanished, usually after a small fraction of a second, the remaining current is not constant, as in the usual electric circuit, but continues to decrease slowly, for minutes or even hours. If then the cable is discharged by short-circuiting it, after the large initial transient discharge current has passed and the voltage on the cable has become zero—in a small fraction of a second—the current coming out of the cable does not entirely vanish, but a small discharge current continues to flow for many minutes or even hours. Or, if the cable has been discharged by short-circuiting it for a short time, until its terminal voltage has become zero, and the short circuit is taken off, a terminal voltage and an electrostatic charge gradually build up again at the cable, reach a maximum after some minutes, and then gradually decrease again.

Various explanations have been proposed of this phenomenon as a hysteresis effect of the dielectric, etc.

It is shown in the following, that this phenomenon of the "soaking in of the charges" or the "electrification of the cable" is a true electric circuit transient, has nothing to do with hysteresis effects, but is the result of, and explained by the energy adjustment of a system with constant values of resistance, inductance and capacity, that is, is in no essential different from the usual rapid starting or stopping transient of the ordinary circuit, except that it is many thousands of times slower. This great slowness is due to the fact that the resistance in the transient circuit is the leakage resistance of the cable dielectric, and therefore extremely high, measured not in ohms but in hundreds of megohms.

If the dielectric of the cable consists of two or more materials, having different resistivities, or different specific capacities, or both, then the distribution of voltage through the dielectric gradually changes. At the moment of voltage application, the voltage distributes between the component dielectrics in proportion to their specific capacities; gradually however this voltage distribution changes to a distribution proportional to the resistivities of the component dielectrics, and electrostatic charges build up in the interior of the

dielectric, at the boundaries between the component dielectrics. The electric quantity has to be conducted through the dielectric, and due to the very high resistivity of the dielectric, this energy readjustment within the dielectric occurs with extreme slowness, giving a transient of a duration of many minutes, but a true electric transient nevertheless, like the usual transients of a duration of milliseconds.

In the discharge of the cable, the reverse occurs, and the internal charges gradually disappear by conduction through the dielectric.

This phenomenon is discussed in its various aspects, and the equations of the slow transient derived, in the following:

It is shown that this slow transient always is impulsive or exponential, and consists of $(n-1)$ terms, if the insulation is composed of n materials.

A number of conclusions are derived, some of which may be pertinent with regard to the mechanism of breakdown of insulation.

By this slow transient, the energy stored in the cable as condenser increases. Its apparent capacity increases. The conduction current, and therefore the $i^2 r$ losses in the dielectric, are much larger with alternating than with direct voltage. The distribution of dielectric stress between the component dielectrics changes and this may give a different dielectric strength for alternating voltage—at which the initial condition of stress distributions is permanent—and for direct voltage. Also, a time lag of insulation breakdown may result, which is not a temperature or deterioration effect. Under certain conditions, there may occur a negative time lag, that is, a condition where the insulation stands higher voltages when slowly and continuously applied than when rapidly applied for a short time.

I. Physical Consideration

1. CABLE CHARGE

IF an ideal condenser, that is, a condenser having constant capacity, $C = \frac{1}{k}$, and no losses, is con-

nected to a source of alternating voltage, e_0 , over a circuit of constant resistance, r_0 , and constant induct-

Presented at the Annual Convention of the A. I. E. E., Swampscott, Mass., June 26-29, 1923.

*Deceased.

ance, L_0 , it takes a charging current, which leads the terminal voltage by 90 degrees. This charging current does not pass through or into the dielectric of the condenser, but is limited to its terminals. It is preceded by a transient immediately after closing the circuit. This charging transient is oscillatory, if the circuit resistance r_0 is below, and is impulsive, if the circuit

resistance is above the critical value $2\sqrt{\frac{L_0}{C}}$. This

transient charging current usually is much larger than

the permanent alternating charging current, and usually vanishes in a small fraction of a second.

If the impressed voltage is continuous, the same starting transient occurs, but with its disappearance, after a fraction of a second, the current at the condenser terminals vanishes and the condenser acts as an open circuit on the continuous supply voltage, if the resistance of the dielectric of the condenser is really infinite.

If however the dielectric of the condenser has a finite, though very high, resistance r , at continuous impressed voltage e_0 the starting transient dies down not to zero,

but to a finite limiting current $i_0 = \frac{e_0}{r}$. With an

alternating impressed voltage, the charging current then does not lead the terminal voltage by exactly 90 degrees, but slightly less, and therefore contains an energy component of current i_0' . This energy current, though small compared with the total charging current, usually is larger than the conduction current i_0 which passes through the dielectric with a continuous voltage, as it represents not only the conduction through the dielectric, but also the losses in the dielectric due to the alternating field, of the nature of a dielectric hysteresis, etc.

This applies to an ideal condenser, that is, a condenser with perfectly uniform dielectric.

Tests show that in a real condenser, such as a cable, with a continuous impressed voltage e_0 , the current remaining after the passage of the starting transient that is, after a fraction of a second, usually is not the

conduction current $i_0 = \frac{e_0}{r}$, and is not constant, but

is larger than i_0 , often many times, and gradually but slowly decreases, for minutes and even hours, approaching the conduction current i_0 . There is thus a passage of current through and into the dielectric, for a considerable time. This often is expressed as the "soaking in" of current or of charge.

The resistance of the cable insulation therefore cannot be measured by impressing a continuous voltage and reading the current, but constant voltage has to be kept on the cable until the current has become constant. Usually this is expressed by saying that the cable has first to be electrified.

2. CABLE DISCHARGE

A similar difference occurs between the ideal condenser and the cable in the discharge.

If an ideal condenser, charged to terminal voltage e_0 , is discharged by short-circuiting its terminals, the discharge transient passes, usually within a fraction of a second, current and terminal voltage drop to zero and the condenser is dead. In a real condenser, as a cable however, after the passage of the discharge transient a small discharge current continues to flow, gradu-

ally decreasing, for minutes and even hours. Furthermore, if after the external discharge transient has passed and the terminal voltage dropped to zero, that is, after a fraction of a second (and usually also still after several seconds) the circuit of the cable is opened, the terminal voltage does not remain zero, but a terminal voltage reappears and gradually rises, for minutes, and corresponding charges build up on the condenser terminals, until a maximum "residual voltage" and "residual charge" has accumulated; then voltage and charge again decrease and finally vanish, often after many minutes or even hours. This residual charge may be quite considerable, sufficient to give dangerous shocks.

This phenomenon in the charge of a condenser, of the soaking in of the current and the formation of residual charges and residual voltages after discharge, does not seem to occur when the dielectric of the condenser is perfectly homogeneous, but is very pronounced when the dielectric is a composite of different materials of different electric characteristics (resistivity and specific capacity), especially if the structure of the dielectric is laminated, as in a cable.

This phenomenon is not always fully understood, and various attempts have been made to explain it as an effect of dielectric time lag, or as the result of a change of the specific capacity with time and voltage, as a hysteresis effect, etc. This is not so however, but it is a true circuit transient, as will be seen in the following, that is, a readjustment of the stored electric energy to changed circuit conditions, at constant values of circuit constants, r and C . It has nothing to do with hysteresis or time lag. The great interest of this slow transient consists in its very long duration, sometimes reaching into hours. This makes it many thousand times slower than the external condenser transient.

In a condenser with composite dielectric, like the laminated dielectric of the cable, energy storage occurs—and therefore results in transients at a change of circuit conditions—in the dielectric, at the boundaries between different dielectrics. This energy must be conducted over the resistance of the dielectric, and as this resistance is extremely high, the duration of this "internal transient," that is, "transient of internal energy readjustment," must be very great, compared with the duration of the "external transient," in which latter, the energy readjustment occurs over the resistance of the external or supply circuit; the latter resistance is measured in ohms; that of the internal transient in hundreds of megohms.

This great difference in duration, between the external transient of readjustment of terminal voltage to changed circuit conditions, and the internal transient of readjustment of internal charges within the dielectric, makes it possible to separate the two types of transient and treat them separately.

The external transient has passed and vanished, before the internal transient has appreciably started. Therefore, in dealing with the internal transient, the

external transient may be considered as non-existent, but the final circuit conditions brought about by the external transient (constant terminal voltage e_0) considered as the initial circuit condition for the internal transient. Inversely, when dealing with the external transient, the internal transient may be considered as non-existing, that is, its initial circuit condition considered as permanent.

Approximate magnitudes of the quantities are, for a 12,000-volt, 2-mile, 60-cycle, 3-phase cable at 20 kv. continuous impressed voltage:

External transient: 25 amperes, 240 cycles.

Duration of external transient: 0.005 sec.

60 cycles charging current: 5 ampere maximum.

Energy component thereof: 0.2 amperes.

Initial value of slow transient: 0.37 to 2.4 milliamperes, depending on age and temperature.

Final value of slow transient: 0.11 to 1.28 milliamperes, depending on age and temperature.

Duration of slow transient: 4 min.

Residual charge: 8 kv.

3. FORMATION OF INTERNAL CHARGES

Let the dielectric of a condenser be composite, consisting of layers of two materials—as impregnated paper and petrolatum in the cable—of different specific capacities and resistivities.

Let now the circuit be closed and a continuous voltage be impressed upon the condenser. By a rapid external transient, in a small fraction of a second, the terminal voltage of the condenser then becomes constant at the value e given by the supply voltage.

An electrostatic field K thus appears between the condenser terminals giving an electrostatic flux density D in the dielectric between the condenser terminals, and an electrostatic charge Q on these terminals.

At the first moment of terminal voltage e , there can be no electrostatic charge inside of the dielectric, since such charge would have to pass through a part of the dielectric, and due to the very high resistance of the dielectric, it takes a much longer time to conduct such internal charge through the dielectric, than the time required by the external transient to produce the terminal voltage e by supplying the terminal charges Q . Thus in the first moment of terminal voltage e no internal charge can yet exist.

A line of electrostatic flux must either terminate in an electrostatic charge, or continue into infinity or into itself. Since in the first moment of terminal voltage e , or at time $t = 0$, there can be no electrostatic charge inside of the dielectric, no line of electrostatic flux can terminate in the dielectric, and all lines of electrostatic flux therefore must pass through from terminal to terminal, in the first moment of terminal voltage e . That is, the flux density D between the cable terminals must in the first moment be uniform, and the initial voltage distribution between the component dielectrics thus must be such as to give the same flux density.

That is, the voltage must distribute between the different layers of the dielectric in proportion to their elastances, that is, the reciprocals of their capacities. That is, the voltage gradient in the two dielectrics must be proportional to the elastivities, or inversely proportional to the specific capacities of these two dielectrics. They would remain so, if there were no conductivity, that is, if the resistance of the dielectric were infinitely high. The transient thus were ended, and no further change occurs.

Due to the finite, (though extremely low) conductivity of the dielectrics, a current is conducted, or "leaks" through the dielectrics, and the current density of this current in the two dielectrics, is proportional to the electrical conductivities of these dielectrics and proportional to the voltage gradients in them. The initial voltage gradients however are proportional to the elastivities of the two dielectrics. The elastivities have no direct relation to the conductivities, and high resistivity may concur just as well with low elastivity, as in sulphur, as it may concur with high elastivity, in air, and inversely. It therefore is obvious that in general the current densities in the two dielectrics would not be equal. They would be equal only if it happened that the conductivities of the two dielectrics are proportional to their elastivities.

In general we therefore find, in the first moment of constant terminal voltage on the cable as condenser with composite dielectric:

All electrostatic charges are on the terminals.

Uniform and equal electrostatic flux density in both dielectrics.

No internal charges in the dielectrics.

Different current densities in the two dielectrics.

Voltage distribution between the two dielectrics by their respective capacities, that is,

Voltage gradients proportional to elastivities.

In general thus, in the initial moment of constant terminal voltage on a cable, the current densities in the two component dielectrics are different. This means that at every boundary between the two dielectrics a discontinuity or change of current density occurs, and more current flows towards the boundary from the one side, than leaves it on the other side. Consequently, an electrostatic charge builds up at the boundary between the two dielectrics, due to the difference between the two current densities on the two sides of the boundary. This electrostatic charge lowers the voltage gradient and thus the current density in the dielectric of higher current density, and raises it in the dielectric of lower current density, and thereby reduces the difference between the current densities in the two dielectrics and with it reduces the rate of building up of internal electrostatic charges on the boundaries between the two component dielectrics, until finally the current densities in both dielectrics become equal and any further building up of internal charge ceases.

The final condition thus is that of uniform current

density in both component dielectrics. That means, the voltage gradients in the two dielectrics are proportional to their respective resistivities, and therefore independent of the capacities or elastivities of the two dielectrics. The electrostatic flux densities are different in the two component dielectrics. Lines of electrostatic flux terminate within the dielectric, at the boundaries between the two component dielectrics, and they terminate in electrostatic charges located at these boundaries.

4. THE SLOW CABLE TRANSIENT

Thus there occurs, at constant terminal voltage, a gradual change in the dielectric of a cable as condenser with laminated composite dielectric, from an initial condition immediately after the appearance of the constant terminal voltage at the condenser, until final condition is reached, by a slow transient lasting many minutes and even hours. This consists of:

A change from the initial voltage distribution by capacity, to the final voltage distribution by the resistance of the component dielectrics.

A change from uniform electrostatic flux density and ununiform current density, to uniform current density and ununiform flux density.

The formation of internal charges at the boundaries between the two component dielectrics.

A current passes through the dielectric. This starts at a large value (though small compared with the external transient current) and first rapidly and then more slowly decreases, to a final minimum value of conduction current.

It thus consists of a permanent component, which is the conduction current sent by the terminal voltage through the resistance of the dielectric, and a transient component, by which the terminal voltage supplies the internal charges over a part of the resistance of the dielectric.

The energy of the permanent current is dissipated as heat in the resistance of the dielectric.

Half of the energy of the transient current is stored as the electrostatic energy of the internal charges at the boundaries between the two dielectrics, the other half is dissipated as heat in the resistance of the dielectric, over which the internal charges have to be conducted.

The energy electrostatically stored in the condenser therefore increases during the slow transient of internal charge, that is, of "soaking in of the charges," by half the energy of the transient component of the slow transient, and the apparent or effective capacity of the condenser correspondingly increases.

That is, the energy stored in the condenser, and the capacity of the condenser, reach a maximum at the end of the slow charge, when the conduction current has become a minimum. The stored energy and the capacity are a minimum at the beginning of the internal charge, that is, in the first moment of constant

terminal voltage at the condenser. The latter also is the case with an alternating supply voltage, since even at low machine frequencies the duration of a cycle is short compared with the duration of the slow transient, and the internal conditions of the condenser (such as voltage distribution by capacity and not by resistance) with alternating terminal voltage therefore correspond to the initial conditions of constant terminal voltage.

A condenser with composite dielectric thus does not have a constant capacity, but has one value of capacity—the minimum—for instantaneous voltage application or alternating terminal voltage, and another value—the maximum—for continuous voltage application.

A condenser with composite dielectric thus differs from a condenser with uniform dielectric in that in the latter energy is stored as electrostatic charge at the external terminals only, while in the former energy is stored as electrostatic charge in the dielectric also, and this latter energy can be supplied—or withdrawn, in the discharge—very slowly only, as it has to flow over the higher resistance of the dielectric, and thereby gives rise to the slow terminal transient, which often is misunderstood as a hysteresis or lag phenomenon, but is not such, but is a true resistance phenomenon, and as such independent of the frequency, but calculated from the ratio of resistances and capacities of the two component dielectrics.

5. EFFECT ON PUNCTURE VOLTAGE

As seen, at constant terminal voltage, the voltage distribution between the two component dielectrics changes between the initial and the final condition. That is, in the one dielectric the voltage gradient is higher in the initial conditions (and thus with alternating terminal voltage) than in the final conditions, and the reverse is the case in the other dielectric. Suppose now the first dielectric is operated closer to the limit of its dielectric strength. If then the terminal voltage is brought up rapidly, so that the initial condition of internal voltage distribution persists, at a certain terminal voltage the first dielectric will reach its disruptive gradient, and puncture of the insulation occurs. Suppose however, the voltage is brought up very slowly, so that throughout the entire voltage rise the final voltage distribution between the two dielectrics persists. At this final voltage distribution, the voltage gradient in the first dielectric is lower, for the same terminal voltage, and the disruptive gradient in the first dielectric is therefore reached only at a higher value of terminal voltage. That is, in this case a higher value of puncture voltage is required when the voltage is very slowly applied, than when the voltage is rapidly increased. This is the reverse of the usual experience—in general, the more rapidly the voltage is increased, the higher voltage the insulation will stand. However, this phenomenon of a lower voltage being sufficient for breakdown when rapidly applied than when slowly applied, has been repeatedly observed

with composite insulation. In this case, a constant voltage, applied at once, may break down the insulation, while even a higher voltage when very slowly applied, may not damage it—in the former case, the dielectric passes through the initial stage of voltage distribution, where it is overstressed, while in the latter case it has passed this stage at lower terminal voltage, while still below breakdown voltage, and at the higher terminal voltages had relieved itself by the readjustment of voltage throwing a higher gradient on the second and stronger dielectric.

Inversely, if the weaker dielectric is the second one, in which the voltage gradient in the final condition is higher than in the initial condition, then with a rapidly increasing terminal voltage the insulation may show a much higher puncture voltage than with a very slowly increasing voltage, since in the latter case the same terminal voltage gives a higher gradient and thus higher stress across the second dielectric, than the same terminal voltage so rapidly applied that the initial condition persists. In this case, the insulation therefore would show a marked time lag of disruptive strength, while in the above case we may speak of a "negative time lag," that is, slow voltage application increases the disruptive strength.

It is interesting to note that here, in the second case, we get a time lag of breakdown, which is not a temperature effect, but a straight resistance phenomenon, and get it under the assumption that the relation between breakdown and breakdown gradient is instantaneous, that is, that the breakdown occurs as soon as the breakdown gradient is reached.

6. A-C./D-C. RATIO OF PUNCTURE VOLTAGE

With alternating terminal voltage the internal conditions of the insulation always are the initial conditions. In the second case, when the voltage gradient increases with the time in the dielectrically weaker material, an alternating terminal voltage would give the same voltage gradient as exists in the initial conditions of a constant voltage equal to the maximum of the alternating voltage, and lower than the final voltage gradient of the constant voltage. Thus, if the breakdown is strictly mechanical, due to voltage stress, and no additional causes of breakdown occur with alternating voltage, then puncture would occur with an alternating voltage of a maximum equal to the constant voltage rapidly applied, but a very slowly applied constant voltage would cause a breakdown at a lower value of voltage than the maximum of alternating puncture voltage. That is, we would get a d-c./a-c. ratio of less than one. While this is against the usual experience it has been observed in a number of instances.

Dominating in the insulation puncture comes in the temperature effect, that is, local temperature rises which materially lower the breakdown voltage. As with alternating voltage energy losses occur, such as

dielectric hysteresis, etc., which do not exist with constant voltage, local heating would be greater and the puncture voltage therefore lower with alternating voltage.

Thus there are three different conditions met in a composite dielectric, which have no constant direct numerical relation with each other:

1. Very slowly applied constant voltage, giving an internal voltage distribution by resistance.
2. Fairly rapid constant voltage application, giving an internal voltage distribution by capacity.
3. Alternating current voltage supply, giving the same voltage distribution as 2, but with additional energy losses and heating, the latter depending on the rate of voltage application.

The ratio of puncture voltage, d-c. and maximum a-c. in the three cases, may have any value between less than one and two to three or even more, depending on the relative constants of the two component dielectrics, on time and on temperature, etc., and research in this direction should throw a great deal of light on the mechanism of breakdown.

7. A-C. AND D-C. RESISTANCE OF DIELECTRIC

With alternating terminal voltage the internal conditions of the composite dielectric are the initial conditions of constant voltage electrification. It follows, that with alternating terminal voltage the conduction current which passes into the dielectric is not the final or permanent value of the conduction current at constant terminal voltage, but is the—usually much larger—initial or transient value of conduction current, that is, the initial value of the slow charging transient, and the $i^2 r$ loss in the dielectric therefore is much larger under alternating terminal voltage, than under continuously applied constant terminal voltage.

Thus, assuming that there were no other losses but conduction losses in the cable dielectric under alternating voltage, that is, hysteresis, ionization, etc., were absent, then the energy component of the alternating cable charging current would be—usually much—larger than the conduction current with constant terminal voltage, and the resistance of the dielectric, from energy current and alternating terminal voltage, would be much lower than the resistance measured with direct current. Nevertheless, the alternating energy current and the resistance calculated from it are a true conduction current and true ohmic resistance effect, and are independent of the frequency, though they are often misunderstood and misinterpreted as time lag or hysteresis effects. As seen, they are ohmic resistance effects of the circuit between the internal charges and the external circuit. In addition thereto occur probably true hysteresis effects, ionization effects in air by ozonization, similar ionization effects in other materials, etc., which are still little understood. Also the effects of moisture and its movement under the dielectric field.

CABLE DISCHARGES

Suppose a cable as laminated composite condenser of two dielectrics, is charged to a constant terminal voltage, and stationary conditions of voltage distribution and internal charges reached.

We now short-circuit the cable.

By the rapid external transient it discharges, within a small fraction of a second, and terminal voltage and terminal charge drop to zero. In the first moment, the internal charges, at the boundaries of the two dielectrics, remain the same. These internal charges now discharge their energy—which was half the energy of the slow charging transient, as seen above—towards the cable terminals, through the very high resistance of the dielectric, by a slow transient, a current which starts with a maximum (though very small compared with the external discharge transient) and gradually decreases to zero.

Or we just disconnect the cable from the supply voltage, leaving it open-circuited, but charged. The terminal charges and the internal charges then supply the conduction current, which passes through the dielectric, and current, charges, terminal voltage and internal voltages decrease and finally die out gradually and proportionally to each other, on small exponential transients.

The most interesting case is to discharge the cable terminals by short-circuiting for a short time (a fraction of a second) until the external cable discharge transient has passed and terminal volts and terminal charges dropped to zero, but before any appreciable discharge of the internal charges has occurred, and then to open the circuit again. This leaves the cable with zero terminal voltage and zero terminal charge, but with internal charges at the boundaries between the two component dielectrics, and corresponding internal voltages. That is, by the withdrawal of the terminal charges the internal charges as bound charges are set free and their corresponding voltages appear. These voltage gradients produce currents through the resistance of the dielectrics. These slow transient currents decrease the internal charges and build up external or terminal charges, which appear as terminal voltage. Thus a transient terminal voltage gradually builds up, increases to a maximum and then decreases again and gradually dies down to zero. Of the energy of the internal charges, half is stored as terminal charge giving residual terminal voltage;—the other half is dissipated in the resistance of the dielectric in conducting the charge through the dielectric. Assuming that the energy stored by the internal charge was half the energy of the terminal charges of the condenser. When building up a residual terminal charge, this then would contain half the energy of the internal charges, or one-quarter the energy and therefore half the voltage of the initial terminal charges. Thus a very considerable residual voltage, capable of giving dangerous

shocks, may build up on a composite condenser like a cable.

8. CONCLUSIONS

In the preceding we have described the simplest case, of a laminated condenser consisting of two different dielectrics, and thus giving rise to a slow transient consisting of one exponential term.

If the condenser comprises n different dielectrics, the slow transient consists of $(n - 1)$ exponential terms, thus is more complex, but otherwise not essentially different. Observation of such slow transients on three-phase cables seems to show that they are not well represented by a single exponential slow transient, but are fairly well represented by the combination of two slow transients, the one being somewhat faster than the other. Such a case is shown in Fig. 1, with the observed currents marked by crosses. It gives three curves of the same cable, for three successive tests at different periods of the year and therefore different temperatures. This would correspond to a composite condenser having three different kinds of dielectric. In a three-phase cable we have impregnated paper as main insulation, petrolatum as impregnating material, and impregnated hemp in the triangular corner pieces between conductors and armor.

Structurally, we have considered a laminated shape, first, because it is mathematically by far the simplest case, and second, because most of the industrially important insulations are laminated; cable, condenser, high-voltage machine insulation, etc. In general, similar relations may be expected to exist in an irregularly unhomogeneous dielectric.

II. Mathematical Investigation

1. CABLE CHARGE

In the charge, or discharge, of a leaky laminated condenser, as a cable, two transients occur, an external transient giving the charge or discharge of the cable as a true condenser of constant capacity, over an external circuit containing resistance and inductance, and an internal transient, giving a readjustment of the internal charges and voltages over the resistances of the laminated dielectric.

The internal transient is so very much slower, that the external transient has completely died out, before the internal transient has appreciably started. As the result thereof, in investigating the internal transient, we may assume that the external transient has passed completely at the moment from which we began to count time for the internal transient.

The external transient is the usual transient of a condenser charge or discharge through an inductive circuit, thus of no further interest here.

The terminal conditions of the internal transient are: constant voltage impressed upon the dielectric:

$$e_1 + e_2 = e \quad (1)$$

where e_1 is the total voltage across all the layers of

conditions, that at $t = 0$, the voltage distribution in the dielectric is that due to capacity only. That is: $t = 0$:

$$\begin{aligned} e_1 \div e_2 &= k_1 \div k_2 \\ i &= A + B \end{aligned} \quad (15)$$

Substituting this into (14), and (14) into (15) gives:

$$A + B = \frac{e}{k^2} \left(\frac{k_1^2}{r_1} + \frac{k_2^2}{r_2} \right) \quad (16)$$

and since

$$A = \frac{e}{r} \quad (11)$$

it is:

$$B = \frac{e}{k^2} \left(\frac{k_1^2}{r_1} + \frac{k_2^2}{r_2} - \frac{k^2}{r} \right) \quad (17)$$

thus:

$$\begin{aligned} i &= \frac{e}{r} + \frac{e}{k^2} \left(\frac{k_1^2}{r_1} + \frac{k_2^2}{r_2} - \frac{k^2}{r} \right) e^{-\frac{g_1 + g_2}{C_1 + C_2} t} \\ e_1 &= \left\{ \frac{r_1}{r} - \left(\frac{r_1}{r} - \frac{k_1}{k} \right) e^{-\frac{g_1 + g_2}{C_1 + C_2} t} \right\} e \\ e_2 &= \left\{ \frac{r_2}{r} - \left(\frac{r_2}{r} - \frac{k_2}{k} \right) e^{-\frac{g_1 + g_2}{C_1 + C_2} t} \right\} e \end{aligned} \quad (18)$$

This gives the *initial conditions* of current and fractional voltages: $t = 0$:

$$\begin{aligned} i^0 &= \frac{e}{k^2} \left(\frac{k_1^2}{r_1} + \frac{k_2^2}{r_2} \right) \\ e_1^0 &= \frac{k_1}{k} e \\ e_2^0 &= \frac{k_2}{k} e \end{aligned} \quad (19)$$

and the *final conditions* of current and fractional voltages: $t = \infty$:

$$\begin{aligned} i' &= \frac{e}{r} \\ e_1' &= \frac{r_1}{r} e \\ e_2' &= \frac{r_2}{r} e \end{aligned} \quad (20)$$

thus:

$$e_1' \div e_2' = r_1 \div r_2$$

2. ENERGY STORAGE AND APPARENT CAPACITY

The energy stored by the external transient on the terminals of the cable as perfect condenser of capacity

$C = \frac{1}{k}$ is:

$$\begin{aligned} W_0 &= \frac{e^2 C}{2} \\ &= \frac{e^2}{2k} \end{aligned} \quad (21)$$

The energy stored by the two component dielectrics of the cable as composite condenser, is in the *initial conditions*, for $t = 0$:

$$\begin{aligned} W_1^0 &= \frac{e_1^0^2}{2k_1} \\ &= \frac{e^2 k_1}{2k^2} \\ W_2^0 &= \frac{e_2^0^2}{2k_2} \end{aligned} \quad (22)$$

and the total stored energy, in the initial conditions therefore is:

$$\begin{aligned} W^0 &= W_1^0 + W_2^0 \\ &= \frac{e^2}{2k} \\ &= W_0 \end{aligned} \quad (23)$$

that is, the same as in an ideal condenser, as was to be expected.

The energy stored by the two component dielectrics of the cable in the *final conditions*, for $t = \infty$, is:

$$\begin{aligned} W_1' &= \frac{e_1'^2}{2k_1} \\ &= \frac{e^2 r_1^2}{2k_1 r^2} \\ W_2' &= \frac{e_2'^2}{2k_2 r_2} \end{aligned} \quad (24)$$

and the total energy stored in the composite condenser in its final conditions, is

$$\begin{aligned} W' &= W_1' + W_2' \\ &= \frac{e^2}{2r^2} \left(\frac{r_1^2}{k_1} + \frac{r_2^2}{k_2} \right) \end{aligned} \quad (25)$$

The ratio of the final to the initial joules of stored energy, and therefore of the effective capacity in the final conditions, to the capacity in the initial conditions (which latter is the capacity as ideal condenser, and the capacity under an alternating terminal voltage) thus is:

$$\begin{aligned} \frac{C'}{C} &= \frac{W'}{W^0} \\ &= \frac{\frac{r_1^2}{k_1} + \frac{r_2^2}{k_2}}{\frac{r^2}{k}} \end{aligned} \quad (26)$$

The difference of the stored energy in the final conditions, over that in the initial conditions, that is, the increase of stored energy from initial to final conditions, then is:

$$\begin{aligned} W_i &= W' - W^0 \\ &= \frac{e^2 (r_1 k_2 - r_2 k_1)^2}{2k r^2 k_1 k_2} \end{aligned} \quad (27)$$

The energy supplied by the internal transient is:

$$\left. \begin{aligned} W_i &= \int_0^{\infty} e B e^{-ct} dt \\ &= \frac{e B}{c} \\ &= \frac{e^2 (r_1 k_2 - r_2 k_1)^2}{k r^2 k_1 k_2} \\ &= 2 W_i \end{aligned} \right\} \quad (28)$$

That is, of the energy supplied by the internal transient W_i , half is stored in the dielectric as the electrostatic energy of the internal charge, W_i , and the other half is dissipated as heat in the dielectric, in the $i^2 r$ of the current which conducts these charges through the dielectric.

The efficiency of formation of the internal charges thus is 50 per cent.

3. CABLE CHARGE BY ALTERNATING VOLTAGE

At first we may neglect the losses by dielectric hysteresis, by ionization in air and other materials, by the mechanical motion of moisture and all the other losses occurring in an alternating field, which do not exist in a constant field; that is, consider the ohmic resistances of the two component dielectrics as the only source of loss.

As we are interested only in the permanent condition of alternating cable discharge, we may also omit the initial or external transient, since this is the same as with constant supply voltage and is the same as the rapid charging transient of the ideal condenser. That is, assume that the external transient has passed and permanent conditions of the alternating terminal voltage been established.

The cable charging equations then are the same as those with constant impressed voltage, except that the terminal voltage e is not constant, but is alternating, and may be expressed by:

$$e = E \sin q t \quad (29)$$

where:

$$q = 2 \pi f \quad (30)$$

$$= 377 \text{ with } f = 60 \text{ cycles}$$

The equations then are:

the *external* equation (1):

$$E \sin q t = e_1 + e_2 \quad (31)$$

the *internal* equations (2):

$$\left. \begin{aligned} \frac{d e_1}{d t} &= k_1 i - \frac{k_1}{r_1} e_1 \\ \frac{d e_2}{d t} &= k_2 i - \frac{k_2}{r_2} e_2 \end{aligned} \right\} \quad (32)$$

Differentiating (31) and substituting (32) therein,

and then repeating the same operation gives the two equations corresponding to (6) and (8):

$$q E \cos q t + \left(\frac{k_1}{r_1} e_1 + \frac{k_2}{r_2} e_2 \right) = k i \quad (33)$$

$$\begin{aligned} q^2 E \sin q t + \left(\frac{k_1^2}{r_1^2} e_1 + \frac{k_2^2}{r_2^2} e_2 \right) \\ = \left(\frac{k_1^2}{r_1} + \frac{k_2^2}{r_2} \right) i - k \frac{d i}{d t} \end{aligned} \quad (34)$$

Multiplying (31) with $\frac{k_1 k_2}{r_1 r_2}$; (33) with $-\left(\frac{k_1}{r_1} + \frac{k_2}{r_2}\right)$, and adding to (34), eliminates e_1 and e_2 , and

leaves the differential equation for i :

$$\begin{aligned} k \frac{d i}{d t} + k_1 k_2 \left(\frac{1}{r_1} + \frac{1}{r_2} \right) i \\ = E \left\{ \left(\frac{k_1 k_2}{r_1 r_2} - q^2 \right) \sin q t \right. \\ \left. + q \left(\frac{k_1}{r_1} + \frac{k_2}{r_2} \right) \cos q t \right\} \end{aligned} \quad (35)$$

This is integrated by:

$$i = C_1 \cos q t + C_2 \sin q t \quad (36)$$

Substituting (36) into (35) and equating the coefficients of $\sin q t$ and $\cos q t$ to zero, gives:

$$\left. \begin{aligned} C_1 &= q E \frac{k q^2 + k_1 k_2 \left(\frac{k_1}{r_1^2} + \frac{k_2}{r_2^2} \right)}{k^2 q^2 + k_1^2 k_2^2 \left(\frac{1}{r_1} + \frac{1}{r_2} \right)^2} \\ C_2 &= E \frac{q^2 \left(\frac{k_1^2}{r_1} + \frac{k_2^2}{r_2} \right) + \frac{k_1^2 k_2^2}{r_1 r_2} \left(\frac{1}{r_1} + \frac{1}{r_2} \right)}{k^2 q^2 + k_1^2 k_2^2 \left(\frac{1}{r_1} + \frac{1}{r_2} \right)^2} \end{aligned} \right\} \quad (37)$$

In the expressions (37), the r , as resistances of the dielectric, are very large quantities, and in first approximation, the terms containing r in the denominator, can therefore be neglected, giving:

$$\begin{aligned} C_1 &= \frac{q E}{k} \\ &= 2 \pi f C E \end{aligned} \quad (38)$$

which is the standard expressions of the alternating reactive charging current of a condenser of capacity C , and:

$$C_2 = \frac{E}{k^2} \left(\frac{k_1^2}{r_1} + \frac{k_2^2}{r_2} \right) \quad (39)$$

(39) is $A + B$ of equation (16), that is, it is the initial value of the slow transient charging current of constant voltage E . That is:

The energy component of the alternating charging current of a conductor with composite dielectric, equals the initial charging current of the condenser at the same continuous impressed voltage, that is, the initial value of the slow constant voltage charging transient, and therefore is larger, often many times, than the true or final conduction current A , which passes through the condenser at constant voltage.

Correspondingly higher also are the $i^2 r$ losses, so that in a cable, the $i^2 r$ losses due to the true ohmic resistance of the dielectric, are higher with alternating than with continuous voltage.

The alternating charging current thus is:

$$\left. \begin{aligned} i &= \frac{q E}{k} \cos q t + \frac{E}{k^2} \left(\frac{k_1^2}{r_1} + \frac{k_2^2}{r_2} \right) \sin q t \\ &= 2 \pi f C E \cos q t + (A + B) \sin q t \end{aligned} \right\} \quad (40)$$

Substituting (40) into (31) and (33) gives:

$$\left. \begin{aligned} e_1 &= \frac{k_1}{k} E \sin q t \\ e_2 &= \frac{k_2}{k} E \sin q t \end{aligned} \right\} \quad (41)$$

4. CABLE DISCHARGE

When a leaky laminated condenser, such as a cable, is charged at a continuous voltage e and kept at this voltage until stationary conditions are reached, that is, the adjustment of internal charges and voltages is completed—which may take hours—and the impressed voltage e then withdrawn and the cable discharged, the discharge transient again in general consists of two components, the external transient of short duration and the internal transient of long duration, and the two transients may be dealt with separately, as the duration, of the internal transient usually is so many thousand times longer than that of the external transient, that the external transient has entirely passed, before the internal transient has appreciably begun.

The external transient thus can be treated as the discharge of a typical condenser through an external circuit, by the standard equations, thus is of no further interest here. The investigation of the internal transient, just as in the condenser charge, can be greatly simplified by separating it from the external transient, that is, counting the time from the moment when the external transient has passed, and thus using as terminal conditions for $t = 0$ the circuit conditions left after the vanishing of the external transient, but before the beginning of the internal transient.

A leaky laminated condenser, such as cable, may be discharged

1. by short-circuiting it.
2. by open-circuiting it.

3. by closing the external circuit by a resistance r_0 (or a resistance r_0 and an inductance L).

In either case, 2 or 3.

(a) The cable may first be short-circuited for a moment, until the external transient has passed and the terminal voltage dropped to zero for $t = 0$, or

(b) The cable may at once be open-circuited, in case 2, at terminal voltage e , so that no external transient occurs, but the external charge leaks through the resistances of the dielectric, or, in case 3.

The cable may at once be closed by the resistance r_0 (and inductance L), so that the external charge due to the previously impressed voltage e passes partly through the external circuit, partly through the resistance of the dielectric.

This case 3 is of interest only, if the external resistance r_0 is of the same magnitude as the internal resistances r_1 and r_2 of the dielectric, that is, extremely high, many megohms. With the usual resistance of external circuits, the external circuit is essentially a short circuit for the internal transient, and case 3 thus becomes case 1. As the result hereof, the general case of an external circuit of resistance and inductance is of little importance, since at the very slow rate of change of the internal transient, the inductances which may usually be met in external circuits, are negligible.

5. SHORT-CIRCUIT DISCHARGE

As the rapid external discharge transient is of no special interest—being the same as in an ideal condenser—we may assume that the external transient has passed and count the time for the internal transient from the moment when terminal voltage and terminal charges have dropped to zero, but before the internal charges have begun to discharge, thus leaving the cable with zero terminal voltage and zero charge at the terminals, but with internal charges and corresponding voltages in the two component dielectrics. That is:

$$t = 0 \quad e = e_1 + e_2 = 0$$

The equations then are the same as those of the slow or internal condenser charge, (2) to (9), and are integrated by:

$$i = B e^{-ct} \quad (42)$$

and

$$\left. \begin{aligned} c &= \frac{\frac{1}{r_1} + \frac{1}{r_2}}{\frac{1}{k_1} + \frac{1}{k_2}} \\ &= \frac{g_1 + g_2}{C_1 + C_2} \end{aligned} \right\} \quad (13)$$

The coefficient B is determined by the terminal conditions $t = 0$.

At $t = 0$, before the external transient starts, it is:

$$e_1' + e_2' = e$$

and:

$$e_1' \div e_2' = r_1 \div r_2$$

that is, the voltages are distributed by the resistances, if we assume that stationary conditions of cable charge had been reached.

This gives:

$$\left. \begin{aligned} e_1' &= \frac{r_1}{r} e \\ e_2' &= \frac{r_2}{r} e \end{aligned} \right\}$$

By the passing of the external transient, the terminal voltage drops from e to 0, that is, this transient impresses a voltage $-e$ upon the condenser, and as during the short time of the external transient, no readjustment of internal charges can occur, the transient voltage $-e$ distributes by the capacities, that is, the two components:

$$e_1'' \div e_2'' = k_1 \div k_2$$

and as:

$$e_1'' + e_2'' = -e$$

it follows:

$$\left. \begin{aligned} e_1'' &= -\frac{k_1}{k} e \\ e_2'' &= -\frac{k_2}{k} e \end{aligned} \right\}$$

The initial voltages e_1 and e_2 thus are made up of the two components, that existing before the external transient and that impressed by the external transient: It thus is:

$$\left. \begin{aligned} t = 0: e_1 &= e_1' + e_1'' = \left(\frac{r_1}{r} - \frac{k_1}{k} \right) e \\ e_2 &= e_2' + e_2'' = \left(\frac{r_2}{r} - \frac{k_2}{k} \right) e \end{aligned} \right\} \quad (43)$$

Substituting (43) into (6), gives:

$$\left. \begin{aligned} k i &= \left\{ \frac{k_1}{r_1} \left(\frac{r_1}{r} - \frac{k_1}{k} \right) \right. \\ &\quad \left. + \frac{k_2}{r_2} \left(\frac{r_2}{r} - \frac{k_2}{k} \right) \right\} e \end{aligned} \right\} \quad (44)$$

and, substituting (42) into (44) gives:

$$B = -\frac{(k_2 r_1 - k_1 r_2)^2}{r r_1 r_2 k^2} e$$

Thus:

$$i = -\frac{e}{r} \frac{(k_2 r_1 - k_1 r_2)^2}{r_1 r_2 k^2} e^{-\frac{r_1 + r_2}{C_1 + C_2} t} \quad (45)$$

As seen, the cable discharge current is the same as the cable charging current, except that the former does not contain the constant term.

6. DISCHARGE BY EXTERNAL OPEN CIRCUIT

Assuming that a leaky laminated condenser, such as a cable, is charged to a voltage e , and then open-circuited and allowed to discharge. Or that, before open-

circuiting, the condenser is short-circuited for a short time, long enough to discharge the external transient, but short enough not to affect the internal transient.

The conductance equations are (2):

$$\left. \begin{aligned} e_1 &= r_1 i_1 \\ e_2 &= r_2 i_2 \end{aligned} \right\} \quad (46)$$

The capacity equations are (3), since $i = 0$:

$$\left. \begin{aligned} \frac{d e_1}{d t} &= -k_1 i_1 \\ \frac{d e_2}{d t} &= -k_2 i_2 \end{aligned} \right\} \quad (47)$$

Thus, substituting (46) into (47), gives:

$$\left. \begin{aligned} \frac{d e_1}{d t} + \frac{k_1}{r_1} e_1 &= 0 \\ \frac{d e_2}{d t} + \frac{k_2}{r_2} e_2 &= 0 \end{aligned} \right\} \quad (48)$$

These two differential equations are integrated by:

$$\left. \begin{aligned} e_1 &= B_1 e^{-\frac{k_1}{r_1} t} \\ e_2 &= B_2 e^{-\frac{k_2}{r_2} t} \end{aligned} \right\} \quad (49)$$

where:

$$\left. \begin{aligned} B_1 &= \frac{k_1}{r_1} e \\ B_2 &= \frac{k_2}{r_2} e \end{aligned} \right\} \quad (50)$$

and B_1 and B_2 are determined by the terminal conditions.

The total voltage across the condenser terminals then is:

$$e' = e_1 + e_2 = B_1 e^{-\frac{k_1}{r_1} t} + B_2 e^{-\frac{k_2}{r_2} t} \quad (51)$$

a. If the cable has been charged up to the constant voltage e , and this voltage e kept on sufficiently long to get permanent condition, then the internal charges and internal voltages are distributed by the resistances. If now the circuit has opened, without, by a momentary short circuit, discharging the external transient, then it is, at

$$t = 0: e' = e; e_1 \div e_2 = r_1 \div r_2 \quad (52)$$

thus:

$$\left. \begin{aligned} e_1 &= \frac{r_1}{r} e = B_1 \\ e_2 &= \frac{r_2}{r} e = B_2 \end{aligned} \right\} \quad (53)$$

thus:

$$\left. \begin{aligned} e_1 &= \frac{r_1}{r} e e^{-\frac{k_1}{r_1} t} \\ e_2 &= \frac{r_2}{r} e e^{-\frac{k_2}{r_2} t} \\ e' &= e \left\{ \frac{r_1}{r} e^{-\frac{k_1}{r_1} t} + \frac{r_2}{r} e^{-\frac{k_2}{r_2} t} \right\} \end{aligned} \right\} \quad (54)$$

b. If the condenser is momentarily short-circuited to pass the external transient, it is for $t = 0$: $e' = 0$.

The change from $e' = e$ to $e' = 0$ occurs by the external transient, in such short time that no readjustment of the charge can occur, but upon the voltage distribution by resistance $e_1 \div e_2 = r_1 \div r_2$ is superimposed a voltage distribution of $-e$ by capacity, that is, by $e_1 \div e_2 = k_1 \div k_2$. Thus it is, at: $t = 0$: $e = 0$.

$$\left. \begin{aligned} e_1 &= \left(\frac{r_1}{r} - \frac{k_1}{k} \right) e = B_1 \\ e_2 &= \left(\frac{r_2}{r} - \frac{k_2}{k} \right) e = B_2 \end{aligned} \right\} \quad (55)$$

thus:

$$\left. \begin{aligned} e_1 &= e \left(\frac{r_1}{r} - \frac{k_1}{k} \right) e^{-\frac{k_1 t}{r_1}} \\ e_2 &= e \left(\frac{r_2}{r} - \frac{k_2}{k} \right) e^{-\frac{k_2 t}{r_2}} \end{aligned} \right\} \quad (56)$$

and:

$$\begin{aligned} e' &= e \left\{ \left(\frac{r_1}{r} - \frac{k_1}{k} \right) e^{-\frac{k_1 t}{r_1}} + \left(\frac{r_2}{r} - \frac{k_2}{k} \right) e^{-\frac{k_2 t}{r_2}} \right\} \\ &= e \left(\frac{r_1}{r} - \frac{k_1}{k} \right) \left(e^{-\frac{k_1 t}{r_1}} - e^{-\frac{k_2 t}{r_2}} \right) \\ &= \frac{e}{2} \left\{ \frac{r_1 - r_2}{r} - \frac{k_1 - k_2}{k} \right\} \left(e^{-\frac{k_1 t}{r_1}} - e^{-\frac{k_2 t}{r_2}} \right) \end{aligned}$$

The maximum value of e' is given by:

$$\frac{d e'}{d t} = 0 = \frac{k_1}{r_1} e^{-\frac{k_1 t}{r_1}} - \frac{k_2}{r_2} e^{-\frac{k_2 t}{r_2}}$$

at the time:

$$t_0 = \frac{\lg \frac{k_1}{r_1} - \lg \frac{k_2}{r_2}}{\left(\frac{k_1}{r_1} - \frac{k_2}{r_2} \right) \lg e} \quad (57)$$

7. GENERAL TRANSIENT OF CONDENSER

Let a condenser of capacity

$$C = \frac{1}{k}$$

be connected to a source of power supply of voltage e_0 , over a supply circuit of resistance r_0 and inductance L_0 , where e_0 in general is a function of time, but may contain a constant term. That is, e_0 may be a constant voltage, or an alternating voltage, an oscillation, impulse or other transient, etc.

Let the dielectric of the condenser be composite, consisting of n materials, and let

e_s = total voltage across all the layers of material s ,

i_s = current in material s ,

r_s = resistance of all the layers of material s ,

C_s = capacity and thus $k_s = \frac{1}{C_s}$ = elastance of all

the layers of s , where: $s = 1, 2, \dots, n$. The external charging equation of the condenser then is:

$$e_0 = \sum_1^n e_s + L_0 \frac{d i}{d t} + r_0 i \quad (58)$$

where:

i = external current.

The conduction equation of material s then is:

$$e_s = r_s i_s \quad (59)$$

and the capacity equation of material s is:

$$\frac{d e_s}{d t} = k_s (i - i_s) \quad (60)$$

Eliminating i_s from (59) and (60) gives:

$$\frac{d e_s}{d t} = k_s i - \frac{k_s}{r_s} e_s \quad (61)$$

Equation (58) is the external, and equation (61) the internal condenser equation. These equations contain the current i and the n voltages e_s .

Differentiating (58) and substituting (61) therein, gives a second equation in i and e_s . Again differentiating and substituting (61) gives a third equation in i and e_s , and so by successively differentiating and substituting (61), we get a series of $n + 1$ successive equations in i and e_s , of the form:

$$\begin{aligned} \frac{d^m e_0}{d t^m} &= \sum_1^n \frac{k_s^m e_s}{r_s^m} + L_0 \frac{d^{m+1} i}{d t^{m+1}} + r_0 \frac{d^m i}{d t^m} \\ &\quad + \sum_1^n S_p \frac{d^{m-p} i}{d t^{m-p}} \end{aligned} \quad (62)$$

$$S_p = (-1)^{p-1} \sum_1^n \frac{k_s^p}{r_s^{p-1}} \quad (63)$$

and:

$$m = 0, 1, 2, \dots, n \quad (64)$$

(where: $\frac{d^0 u}{d t^0} = u$).

From the $(n + 1)$ equation (62), the n quantities e_s can be eliminated, leaving one equation in i , of $(n + 1)^{\text{st}}$ order. Denoting:

$$\left. \begin{aligned} Q_m &= \sum \left\{ \prod (m) \frac{k_s}{r_s} \right\} \\ Q_0 &= 1; \quad Q_n = \prod_1^n \frac{k_s}{r_s} \end{aligned} \right\} \quad (65)$$

thus

That is: denoting by Q_m the sum of all the products of $\frac{k_s}{r_s}$ in groups of m , that is:

$$Q_0 = 1$$

$$Q_1 = \frac{k_1}{r_1} + \frac{k_2}{r_2} + \dots + \frac{k_n}{r_n}$$

$$Q_2 = \frac{k_1 k_2}{r_1 r_2} + \frac{k_1 k_3}{r_1 r_3} + \dots + \frac{k_2 k_3}{r_2 r_3} + \dots$$

.....

$$Q_n = \frac{k_1 k_2 k_3 \dots k_n}{r_1 r_2 r_3 r_n}$$

Multiplying (62) by Q_{n-m} and adding the $(n+1)$ equations, the terms with e_s cancel, and we get the final differential equation in i .

$$\sum_0^n Q_{n-m} \frac{d^m e_0}{dt^m} = L_0 \frac{d^{n+1} i}{dt^{n+1}} + (r_0 + L_0 Q_1) \frac{d^n i}{dt^n} + \sum_0^{n-1} \left\{ L_0 Q_{n-m+1} + r_0 Q_{n-m} + \sum_1^m S_p Q_{n-m-p} \right\} \frac{d^m i}{dt^m} \quad (66)$$

This is a differential equation of $(n+1)^{st}$ degree, showing that the general cable transient contains $(n+1)$ terms.

With the exception of S_1 and Q_0 , all the S and Q in equation (66) contain r_s in the denominator. r_s however, as the resistance of a part of the dielectric, is a very large quantity, and the terms S and Q , which have r_s in the denominator, therefore are very small quantities, hence can in first approximation, be neglected in comparison with the terms L_0 , r_0 and $S_1 Q_0$.

Doing so, equation (66) simplifies to:

$$\frac{d^n e_0}{dt^n} = L_0 \frac{d^{n+1} i}{dt^{n+1}} + r_0 \frac{d^n i}{dt^n} + S_1 \frac{d^{n-1} i}{dt^{n-1}} \quad (67)$$

and by (63)

$$\left. \begin{aligned} S_1 &= \sum_1^n k_s \\ &= k = \frac{1}{C} \end{aligned} \right\} \quad (68)$$

Separating the permanent term from equation (67) leaves as the transient:

$$L_0 \frac{d^{n+1} i}{dt^{n+1}} + r_0 \frac{d^n i}{dt^n} + \frac{1}{C} \frac{d^{n-1} i}{dt^{n-1}} = 0 \quad (69)$$

This equation is integrated by the exponential:

$$i = B e^{-ct} \quad (70)$$

and, (70) substituted into (69) gives:

$$L_0 c^{n+1} - r_0 c^n + \frac{1}{C} c^{n-1} = 0 \quad (71)$$

Equation (71) gives:

$$(n-1) \text{ roots: } c = 0 \quad (72)$$

and 2 roots:

$$c = \frac{r_0 \pm j q}{2 L_0} \quad (73)$$

where:

$$q = \sqrt{\frac{4 L_0}{C} - r_0^2}$$

or:

$$c = \frac{r_0 \pm s}{2 L_0} \quad (74)$$

where:

$$s = \sqrt{r_0^2 - \frac{4 L_0}{C}}$$

Thus:

$$i = e^{-\frac{r_0}{2 L_0} t} (C_1 \sin q t + C_2 \cos q t) \quad (75)$$

or:

$$i = B_1 e^{-\frac{r_0-s}{2 L_0} t} + B_2 e^{-\frac{r_0+s}{L_0} t} \quad (76)$$

(75) respectively (76) is the external charging transient of the condenser, and C_1 and C_2 respectively B_1 and B_2 are the terminal conditions, determined by the terminal condition of the external circuit, in the usual manner:

$$t = 0: \quad i = 0; \quad e_s = 0 \quad (77)$$

The $(n-1)$ roots $c = 0$ (72), mean, that under the assumption made in (67), the internal transients are permanents, that is, are so slow that they do not come into consideration during the life time of the transient (75) (76).

Substituting (75) (76) into the general equation (66), the terms with L_0 , r_0 and $\frac{1}{C}$ vanish. Separating again the permanent term, leaves as the transient term for the determination of the remaining $(n-1)$ roots, which give the internal transient, the expression:

$$\sum_0^{n-1} \sum_1^{n-m} S_p Q_{n-m-p} \frac{d^m i}{dt^m} = 0 \quad (78)$$

This is integrated by:

$$i = B e^{-ct} \quad (79)$$

and, (79) substituted into (78) gives:

$$\sum_0^{n-1} \sum_1^{n-m} S_p Q_{n-m-p} (-c)^m = 0 \quad (80)$$

As easily seen, in (78) all the coefficients are positive, and in (79), the successive coefficients alternately have positive and negative signs. Herefrom it follows, that all the $(n-1)$ roots of (80) are positive. That is:

The slow or internal transient of a composite condenser, containing n different materials in its dielectric,

consists of $(n - 1)$ separate and real exponential transients:

$$i = \sum_{m=1}^{n-1} B_m e^{-c_m t} \quad (81)$$

where:

c_m are the $(n - 1)$ roots of equation (80), and B_m coefficients derived from the terminal conditions.

As all the roots of (80) are positive, they are easily derived by approximation.

The terminal condition of the internal transient is:

$$t = 0: e_s = e \frac{k_s}{k} \quad (82)$$

and, substituting (82) into (62), and substituting (81) therein, gives the constants B_m .

Applying this to the internal transient for $n = 3$, gives:

$$(80) \quad \sum_{m=0}^2 \sum_{p=1}^{3-m} S_p Q_{3-m-p} (-c)^m = 0$$

$$\left. \begin{aligned} c &= \frac{m \pm s}{2k} \\ s &= \sqrt{m^2 - 4kn} \end{aligned} \right\} \quad (83)$$

where:

$$\left. \begin{aligned} m &= \frac{k_1(k_2 + k_3)}{r_1} + \frac{k_2(k_3 + k_1)}{r_2} + \frac{k_3(k_1 + k_2)}{r_3} \\ n &= k_1 k_2 k_3 \left(\frac{1}{r_1 r_2} + \frac{1}{r_2 r_3} + \frac{1}{r_3 r_1} \right) \\ k &= k_1 + k_2 + k_3 \end{aligned} \right\} \quad (84)$$

and:

$$(58) \quad e_1 + e_2 + e_3 = e$$

$$\frac{d e_1}{d t} + \frac{d e_2}{d t} + \frac{d e_3}{d t} = 0$$

$$(61) \quad \frac{d e_s}{d t} = k_s i - \frac{k_s}{r_s} e_s$$

$$(62) \quad k i = \frac{k_1}{r_1} e_1 + \frac{k_2}{r_2} e_2 + \frac{k_3}{r_3} e_3$$

$$(62) \quad -k \frac{d i}{d t} + \left(\frac{k_1^2}{r_1} + \frac{k_2^2}{r_2} + \frac{k_3^2}{r_3} \right) i = \frac{k_1^2}{r_1^2} e_1 + \frac{k_2^2}{r_2^2} e_2 + \frac{k_3^2}{r_3^2} e_3$$

$$(81) \quad i = B_1 e^{-c_1 t} + B_2 e^{-c_2 t} \quad (81)$$

$$t = 0: e_s = \frac{k_s}{r_s} e$$

$$k (B_1 + B_2) = e \left\{ \frac{k_1^2}{r_1^2} + \frac{k_2^2}{r_2^2} + \frac{k_3^2}{r_3^2} \right\}$$

$$k (c_1 B_1 + c_2 B_2) + \left(\frac{k_1^2}{r_1} + \frac{k_2^2}{r_2} + \frac{k_3^2}{r_3} \right) (B_1 + B_2) = e \left\{ \frac{k_1^3}{r_1^3} + \frac{k_2^3}{r_2^3} + \frac{k_3^3}{r_3^3} \right\} \quad (85)$$

III. Numerical Calculations

1. SINGLE TRANSIENT

The slow cable transient is measured by impressing

FIG. 1—D-C. CHARGING CURRENT, IN MILLIAMPERES AT 20 KV., OF CABLE NO. 245, PHILADELPHIA, 13,000 FT.

One conductor against other two and lead sheath. Avg. of 6 tests (by kenotron).

+ $i = 1.20$	+ $0.681 e^{-0.00420t}$	+ $1.39 e^{-0.0268t}$
^ $i = 0.63$	+ $0.407 e^{-0.00592t}$	+ $1.48 e^{-0.0363t}$
o $i = 0.108$	+ $0.206 e^{-0.00828t}$	+ $0.190 e^{-0.0317t}$

a constant voltage upon the cable terminals and then reading volts and amperes, for a number of minutes, until the current has become practically constant. For this purpose, the voltage is brought up rapidly to the desired value, but great care must be taken not to over reach, since any reduction of the voltage gives wrong results. The voltage should be very constant, as the current fluctuates greatly with slight voltage variation; a small voltage increase causing a large increase of current, while a small voltage decrease may even cause a reversal of current. Therefore it is best to plot the observed values of current with the time as abscissas, smooth this curve and from it then take numerical values.

Assuming that the curve is to be represented by the single exponential transient, as the simplest form:

$$i = A + B e^{-ct}$$

The simplest way of calculating A , B and c is to take from the curve three values of current at equal time intervals:

$$t_1; \quad t_1 + t_0; \quad t_1 + 2t_0$$

choosing the three times so as to cover the whole reliable part of the curve, that is, t_1 and $t_1 + 2t_0$ are near the ends of the curve just sufficiently away from the ends, not to be affected by the greater error of the curve ends. For instance, if readings have been taken over 8 minutes, 1, 4 and 7 minutes are good numerical values.

It is then:

$$\left. \begin{aligned} i_1 &= A + B e^{-ct_1} \\ i_2 &= A + B e^{-c(t_1+t_0)} \\ i_3 &= A + B e^{-c(t_1+2t_0)} \end{aligned} \right\}$$

thus:

$$\frac{i_1 - i_2}{i_2 - i_3} = e^{-ct_0}$$

$$\frac{(i_1 - A)(i_3 - A)}{(i_2 - A)^2} = 1$$

Hence:

$$\left. \begin{aligned} A &= \frac{i_1 i_3 - i_2^2}{i_1 + i_3 - 2i_2} \\ c &= \frac{\log(i_1 - i_2) - \log(i_2 - i_3)}{t_0 \log e} \\ B &= (i_1 - A) e^{+ct_1} \end{aligned} \right\}$$

Given are:

The impressed voltage : e

and the capacity of the cable: $C = \frac{1}{k}$

From the observation of the slow transient follow:

A , B and c

It is then, by equation (11):

$$A = \frac{e}{r}$$

Hence:

$$r = \frac{e}{A}$$

It is by the equations:

$$(7) \quad k_1 + k_2 = k$$

$$(12) \quad r_1 + r_2 = r$$

$$(13) \quad c = \frac{\frac{1}{r_1} + \frac{1}{r_2}}{\frac{1}{k_1} + \frac{1}{k_2}}$$

thus:

$$\frac{k_1 k_2}{r_1 r_2} = \frac{k}{r} c = a$$

$$(16) \quad A + B = \frac{e}{k^2} \left(\frac{k_1^2}{r_1} + \frac{k_2^2}{r_2} \right)$$

thus:

$$\frac{k_1^2}{r_1} + \frac{k_2^2}{r_2} = \frac{k^2}{e} (A + B) = b$$

From these 4 equations follows:

$$(r_2 - r_1) \sqrt{1 - \frac{4a^2}{b^2}} r_1 r_2 = \frac{4a}{b} r_1 r_2 + \left(r - \frac{2k^2}{b} \right)$$

From this equation, and (12), r_1 and r_2 are calculated. This is most conveniently done by approximation. From (7) and (13) then are calculated k_1 and k_2 .

2. NUMERICAL INSTANCE

An instance is shown, in Fig. 2, the complete charging and discharging transient of a 12-kv. three-phase cable of 13,000 ft. length and the capacity, from

FIG. 2

one conductor to the other two conductors and the armor, of $C = 0.74 \mu f$, supplied with a constant voltage of 20 kv. over a circuit of resistance $r_0 = 200$ and inductance $L_0 = 0.5$ h.

CHARGE

The rapid external charging transient is:

$$e = 20,000 \{ 1 - e^{-200t} (\cos 1570 t + 0.125 \sin 1570 t) \}$$

volts

$$i = 25 e^{-200t} \sin 1570 t \text{ amps.}$$

Duration: 0.005 sec.

The slow internal charging transient is:

$$i = 0.108 + 0.206 e^{-0.008t} \text{ milliamperes.}$$

Duration: 125 sec.

The fractional voltages are

$$e_1 = 4200 + 11,200 e^{-0.008t} \text{ volts}$$

$$e_2 = 15,800 - 11,200 e^{-0.008t} \text{ volts}$$

$$\text{Initial energy of charge: } W_0 = 148 \text{ J.}$$

$$\text{Final energy of charge: } W' = 406 \text{ J.}$$

$$\text{Energy of internal charges: } W_i = 258 \text{ J.}$$

DISCHARGE

The rapid external short-circuit discharge transient is:

$$e = 20,000 e^{-200t} (\cos 1570 t + 0.125 \sin 1570 t) \text{ volts.}$$

$$i = -25 e^{-200t} \sin 1570 t \text{ amperes.}$$

The slow internal transient of discharge current by short circuit is:

$$i = -0.206 e^{-0.008t} \text{ milliamperes.}$$

The slow internal transient of building up of residual voltage at open circuit following short-circuit discharge of terminal charges, is:

$$e' = 11,100 (e^{-0.0022t} - e^{-0.027t})$$

This residual voltage starts in 37 sec. reaches a maximum value of 8160 volts in 100 sec. and has a duration of 455 sec.

3. DOUBLE TRANSIENT

When analyzing charging current measurements of three-phase cables, made by d-c. voltage, as shown in Fig. 1, a single exponential often does not satisfy the data, but the decrease of current during the first few minutes is far more rapid than later on, giving the curve the appearance of the sum of two exponentials and one constant term, the two exponentials being of different duration, though both are very slow compared with the duration of the external transient.

Assuming then the transient of the form:

$$i = A + B_1 e^{-c_1 t} + B_2 e^{-c_2 t}$$

Suppose now t_1 is the time at which the shorter transient $B_2 e^{-c_2 t}$ has died out. Then for the part of the curve: $t \geq t_1$,

$$i = A + B_1 e^{-c_1 t}$$

and for this part of the curve, it is:

$$A = \frac{i_1 i_3 - i_2^2}{i_1 + i_3 - 2 i_2}$$

Calculating thus A for various values of t_1 , $t_1 + t_0$, $t_1 + 2 t_0$, such as: 2-4-6; 3-5-7; 4-6-8; 2-5-8; 1-2.5-4 minutes, we find a series of values for A , and for that range of time, in which approximately the same values of A are given, we can assume that the single transient equation applies, and the more rapid transient has already died out.

From this range of time we then calculate B_1 and c_1 , either by the $\Sigma \Delta$ method, or as in the preceding (III. 1) and so get the slower transient. Subtracting this from the total transient, then gives the faster transient $B_2 e^{-c_2 t}$, and from this the values B_2 and c_2 .

This is done in Fig. 1, where the marked points give the observed numerical values, and the three curves the double transients calculated therefrom.

Discussion

For discussion of this paper see page 615.

Dielectric Strength Ratio Between Alternating and Direct Voltages

BY J. L. R. HAYDEN

Member, A. I. E. E.

and

W. N. EDDY

Associate, A. I. E. E.

Both of the General Electric Company, Schenectady, N. Y.

Review of the Subject.—High-Voltage insulation testing has been and is usually still done by alternating voltages.

High direct voltage was made available for testing purposes by the development of the kenotron tube. When used for testing insulation direct voltage has several advantages over alternating voltage. (1) The power necessary is often much less with direct voltage than with alternating voltage. In apparatus of high electrostatic capacity, such as long high-voltage cables, the size of the alternating-voltage testing transformer becomes excessive, thousands of kilovolt-amperes being necessary. Direct voltages are therefore preferable as they necessitate only a few kilowatts. (2) Excess direct voltage is less likely to permanently damage the insulation than excess alternating voltage. (3) If direct voltage is used conductivity tests can be made and the action of the material on the application of the voltage more thoroughly studied.

As the use of high direct voltage for testing purposes is found to be increasing, it is important to determine the relation between the insulation stress produced by direct and that produced by alternating voltages.

Little is definitely known of what is called the "dielectric strength ratio of insulation" which is the ratio of the direct disruptive voltage to the crest value of the alternating disruptive voltage. In general, this ratio might be expected to be unity. While such is the case with air some engineers have claimed, however, that some solid insulations stand a higher direct than alternating voltage.

Therefore, a very extensive set of investigations was made, with direct and with alternating voltages, on liquid and solid insulations of homogeneous and non-homogeneous structure, over a range of temperature, thickness and rate of voltage application. Their dielectric strength ratios were determined and are given and discussed in the paper.

It was found that the dielectric strength ratio may be greater than unity, and sometimes very much so, that is, that the material may stand higher and sometimes very much higher direct voltages than

alternating voltages, but also that the ratio with other materials may be less than unity, that is, the material may stand higher alternating than direct voltages.

Ratios less than unity were given by oils, petrolatum, powdered glass, etc., that is, they stood higher alternating than direct voltage, though the difference rarely exceeded 10 per cent.

Ratios above unity were given by paper, cloth, solid glass and mica, etc., indicating a greater strength for direct than for alternating voltages.

The dielectric strength ratio of some materials, such as laminated paper, was found to vary with the condition and in general increase with decreasing temperature, decreasing thickness and increasing rapidity of voltage application.

Some materials, such as petrolatum impregnated cable paper, gave a very high ratio, some times exceeding two, while the component materials did not differ much from unity, petrolatum being a little below and air-dry paper a little above unity.

It is believed that the observation of the dielectric strength ratio and its changes with the condition of test, will give us a powerful tool for the investigation of insulation, and assist in solving the problem of understanding the mechanism of the breakdown of insulation in an electric field.

AS the operation of electrical apparatus and circuits depends on their insulation, the maintenance and test of insulation is of foremost importance.

Insulation testing, even of direct-current apparatus, is usually done by alternating voltage, since high alternating voltages are easily obtained by the alternating-current transformer.

Two serious disadvantages arose in the use of alternating high potential testing: First, in apparatus of considerable capacitance such as underground cables, the charging current at the high test voltage is excessive, requiring uneconomically large and expensive transformers. Second, in other apparatus, corona and other dielectric losses incident to the abnormally high alternating test voltage (of three and a half and more times the normal operating voltage), may permanently damage the insulation.

With the development of the kenotron vacuum tube

as rectifier, high direct voltages became available. As there is no permanent charging current with direct voltage, a kenotron rectifier of a few kw. capacity could replace a testing transformer of many hundred kw. In the absence of the intensive corona and the high dielectric losses incident to an alternating field, damage of apparatus by the high testing voltage was less to be feared with direct voltage testing.

At first it was expected that the striking distance with direct voltage would be equal to that of the maximum value of the alternating voltage, and tests made with air as dielectric corroborated this. However, engineers familiar with high-voltage, direct-current transmission claimed that apparatus could stand materially higher direct voltages than alternating voltages. When high direct voltages became more available, tests made with them showed that some solid insulation, such as that of cables, stand a higher direct voltage than alternating voltage, and it was hoped then that a constant ratio between the disruptive strength

Presented at the Annual Convention of the A. I. E. E., Swampscott, Mass., June 26-29, 1923.

of direct and of alternating voltage could be found, by which the one could be expressed in terms of equality with the other. A series of tests made abroad on cables gave 2.5 as the average ratio between the direct voltage and the (effective or root-mean-square) alternating voltage which has the same disruptive effect.

Further tests made by various engineers here and abroad gave inconsistent results and different ratios between the disruptive effect of direct and alternating voltage, so that now no fixed ratio between direct and alternating voltage can be universally applied.

As the result of several years experimental investigation we have come to the conclusion, and expect to show in the following, that:

1. The disruptive effect on insulation of a direct voltage in general is different from that of an alternating voltage of a peak value equal to the direct voltage.

2. The puncture or disruptive effect of the alternating voltage (peak value) may be greater, and sometimes very much greater, than that of the direct voltage of equal value, but it may also be less. That is, the ratio: "Direct voltage divided by the peak value of the alternating voltage which gives the same disruptive effect", which we may call "dielectric-strength ratio", varies from values less than unity, when the direct voltage stress is more severe, to values much above unity, when the alternating voltage stress is more severe.

3. In air, the dielectric-strength-ratio is probably unity.

4. In solid insulation, the dielectric-strength ratio depends on the mechanical, physical, and thermal conditions of the material, and in general, seems to tend towards unity, the more homogeneous the material is.

5. In one and the same material, the dielectric-strength-ratio may vary considerably with temperature, thickness, rate of voltage application, etc.

6. In general, it seems that the mechanism of failure of insulation under high alternating voltage stress is materially different in some features from that under high direct voltage stress, and no universal and constant dielectric-strength-ratio can therefore be expected, but dependent on the feature which dominates in the failure different values must result.

The dielectric-strength ratio has been defined in the previous literature in two ways, either as the ratio: Direct voltage divided by effective or root-mean-square value of alternating voltage (in which case air would have the ratio $\sqrt{2} = 1.41$) or otherwise the ratio: Direct voltage divided by the peak value of alternating voltage, which gives to air the convenient ratio 1. We use herein, and recommend for general acceptance, the latter definition, as more rational. It gives the value 1 to air, and in general the values tend toward 1, and it gives the value 1, if the nature of the alternating voltage puncture is the same as that of the direct voltage puncture, since a direct voltage and an alternating voltage with the same peak value, should be equivalent.

Although the values given in the following tables are

the averages and abstracted from thousands of individual tests, made under the greatest possible precautions, so that the experimental errors are small, they are not so consistent as to draw final conclusions from single recorded values (though these values usually are averages of 10 or 25 tests), and the conclusions are drawn from the general trend of groups of individual values. The reason for variations in results is the inherently erratic nature of disruptive tests. Dielectric tests made with air can be duplicated within two to three per cent, but in liquids like oil erratic variations occur between successive tests made with all precautions, amounting to 20 per cent to 30 per cent and more.¹ In solid insulation, the phenomenon of dielectric disruption apparently is still more complex, and the individual test results therefore are still more erratic, so that acceptable conclusions can be drawn only from the comparison of the averages of very numerous tests.

The results of this investigation seem inevitably to lead to the conclusion that the dielectric rupture under high-voltage stress is a far more complex phenomenon than is usually assumed. Puncture is not due to a mere effect of electrostatic stress, or a mere heating effect, or any specific deterioration effect, etc., but it results from a number of different effects combined in different degrees. While it is somewhat disappointing no universal "dielectric strength ratio" can be determined, which is applicable to all conditions and all apparatus, we believe that dielectric-strength-ratios can be derived for definite classes of insulation under definite operating conditions, and that the determination and study of the dielectric strength-ratio will give us an additional and powerful tool in the study of insulation failure and its causes.

Methods of Tests and Apparatus

The principal source of high, direct voltage used in the tests was the kenotron. This is a two-element vacuum tube containing a filament cathode supported within a cylindrical plate as anode. The filament is kept incandescent by means of either a transformer or a storage battery. In operation the kenotron acts simply as a unidirectional conductor, passing through only the half waves of one polarity. Fig. 1 shows some of the principal circuits used for kenotron rectification. (a) is the simplest connection. In this the kenotron is in series with the supply transformer and a condenser storing the rectified voltage. This gives a direct current, every second half cycle the vacuum becomes conducting. The principal advantage of such a connection is its simplicity, and if the load is small compared with the condenser capacity, the voltage is quite steady. Diagram (b) shows the bridge type of connection. This has the advantage of passing through both half waves in such a way that they produce the same

1. "Three Thousand Tests on the Dielectric Strength of Oil," by Hayden and Eddy, presented before Convention of A. I. E. E. at Niagara Falls, June 26-30, 1922.

polarity on the receiving circuit. Diagram (c) shows the full wave or double half wave type which has the principal advantage of requiring an alternating voltage source of only approximately one-third of the direct voltage. The purpose of the condenser is to smooth out the pulsations of the direct voltage. It is readily seen that the half wave connection (a) requires more capacitance than a full wave connection either (b) or (c). The capacitance required for satisfactory smoothing is dependent on the load. In testing long cables no capacitance additional to that of the cable is required. But laboratory tests on short lengths of cable or other test pieces of low electrostatic capacity necessitate the use of the condensers shown above. On account of the small direct current conducted by any type of insulation the voltage fluctuation of such a rectifier can be reduced

the electrodes. All voltage readings were taken on the low side of the supply transformer and the high-tension voltage, whether alternating or direct, was obtained from a calibration curve which had been made against a sphere gap in parallel with the sample or an equivalent load. All direct-voltage data below 3000 volts were taken on a special direct-current generator with field control, the voltage being read by an indicating voltmeter in series with multiplying resistance. Whenever possible both alternating and direct voltage punctures were taken on the same sample of insulation. For instance, if the sheet of insulation under test was large enough for 10 puncture tests, 5 would be taken on alternating and 5 on direct voltage. At no time were more than 5 punctures taken on alternating voltage without then taking an equal number on direct voltage or vice versa so as to give the closest possible comparison. Each value, given in the tabulations below, usually is the average of 10 to 25 tests. Practically all of the tests were repeated at different times by different operators and under different experimental conditions.

FIG. 1—KENOTRON RECTIFIER CONNECTIONS

below 2 per cent without the necessary condensers becoming large.

Both the alternating and the direct-voltage data were taken on the same transformer. The direct voltage was obtained by means of the full-wave kenotron connection (c) Fig. 1 described above, using sufficient capacitance in parallel with the sample to reduce the ripples in the voltage wave to less than 2 per cent under the conditions of tests. In taking all spark voltage values special attention was given to the rate of increasing the voltage, keeping this rate as nearly the same as possible at the value noted in the data.

The various types of insulation were tested in various forms and shapes and with various electrodes but care was always taken to have no sharp corners or edges on

Results of Tests

A. OIL, PETROLATUM AND CABLE PAPER

A series of tests were made on the materials entering the insulation of high-potential cables, such as petrolatum and cable paper, and the results of these tests are given in Table I. In the same table are also given the results with transil oil No. 6, as of similar character to petrolatum but far more fluid. Oil and petrolatum were tested between 2.54 cm. spheres, but cable paper was tested between 5 cm. plates. The alternating voltage values are the maximum of the voltage wave.

The table gives the tested materials: Transil oil No. 6 alone, petrolatum alone, manila paper of 0.2 mm. thickness in air dry condition alone, and the same paper impregnated with petrolatum. The table also gives the length of the gap between the spheres for oil and petrolatum, and the number of layers of cable paper used. Then it gives the approximate rate of voltage increase in per-cent-per-second of the puncture voltage. Then follow the values of direct voltage in kilovolts, and of alternating voltage, peak values for the four temperatures 25 deg., 50 deg., 75 deg. and 100 deg. cent., and finally in the four last columns the values of the "dielectric-strength ratio" derived by dividing the direct voltage by the alternating voltage. As seen, values are given for three rates of increase in terms of the puncture voltage as follows: 20 per cent, 5 per cent and 0.1 per cent rise of this voltage per second. Each of the numerical values given in Table I is the average of a minimum of 10 to 25 observations, but in many cases as many as a hundred repetitions were made.

a. Oil—Its Dielectric-Strength Ratio. The table shows incidentally that the dielectric strength of oil, with direct voltage as well as with alternating voltage, decreases somewhat with increasing temperature, but not to any great extent.

TABLE I
OIL, PETROLATUM AND CABLE PAPER

As would be expected from the erratic behavior of oil, discussed in a previous paper, the values of the dielectric-strength ratio of the oil, given in the last four columns, differ from each other more than any possible error of observation. However, in general the data show fairly conclusively a dielectric-strength ratio somewhat below unity,—specifically a general average of $R = 0.923$. In other words, this ratio of 92 per cent indicates that *oil has a greater dielectric strength under alternating than under direct voltage*, by about 8 per cent.

A Comparison of Ratios at Different Temperatures. The combined averages of all the ratios at 25 deg. and 50 deg. cent. is $R = 0.900$; but the combined averages of all the ratios at 75 deg. and 100 deg. cent. is $R = 0.947$. This change shows that the dielectric-strength ratio increases with increasing temperature or, as we may say, becomes more normal at higher temperatures by approaching closer to the value of unity.

Ratios at Different Gap-Lengths. The average ratio for the short oil gap is $R = 0.975$; the average ratio for the long gap is 0.871. This difference shows conclusively that the dielectric-strength ratio of oil seems to become more abnormal, that is, differs more from unity, with increasing length of oil gap. This conclusion, however, requires further corroboration.

Ratios as Affected by Rate of Increase of Voltage. For slower rate increase of voltage, 2 per cent per

second, the ratio averages $R = 0.909$; for the faster rate of 5 per cent per second it averages $R = 0.929$. The conclusions drawn from this small change of 2 per cent also require further corroboration.

b. Petrolatum—Its Dielectric-Strength Ratio. Petrolatum is stated to be an amorphous hydrocarbon, essentially of the paraffin series. At room temperature it has the consistency of vaseline, and as a closely related hydrocarbon it shows the same general characteristics as transil oil.

As seen from the table, the dielectric strength of petrolatum, under direct or alternating voltage, does not appreciably change with the temperature, between 25 deg. and 100 deg. cent., nor is there appreciable change in the dielectric-strength ratio.

The averages of the dielectric-strength ratio, taken from the table:

At:	25 deg.	75 deg.	100 deg. cent.
$R =$	0.952	0.968	0.952

Thus the ratio is essentially constant.

Again as regards variation in gap-length:

At: 2mm. 4mm. length of gap between spheres:
 $R = 0.956$ 0.959 respectively, which is also essentially constant over this small range of gap.

The average of all values of dielectric-strength ratio for petrolatum is: $R = 0.957$. Therefrom it is evident petrolatum shares with oil the characteristic that its

dielectric strength is less for direct voltage than for alternating voltage, but the difference is not so great.

If the abnormal behavior of oil were due to differences in the mechanical motion produced in the ingredients of its unhomogeneous structure by the continuous dielectric field, the resultant concentration of the weaker ingredients might account for its lesser strength under the continuous direct voltage than under the alternating voltage stress, and the far more viscous petrolatum would show still less the effect of any movement and concentration—as is, in fact, the case.

c. Dry Unimpregnated Cable Paper—Its Dielectric Strength Ratio. Incidentally tests with direct and alternating voltage show no definite difference in effect on the dielectric strength of cable paper, within the range of temperature, and rate of voltage rise used in the tests. But there is a very pronounced effect on the dielectric-strength ratio, as seen from the three sets of values in the last four columns of the table which tabulate 48 results, each the average of a number of tests. Ratios are given for the three general factors viz., for temperatures from 25 deg. cent. to 100 deg. cent., for thickness from 4 to 32 layers of 0.2 mm. paper, and for rates of voltage rise from 0.1 of 1 per cent per second to 20 per cent per second. Although individual values may fall somewhat out of line, there is a very pronounced grouping of the results. The highest values of dielectric-strength ratio occur at the lowest temperature, at the lowest thickness and at the highest rate of voltage rise (shown in the table at the top left-hand corner). On the contrary, the lowest values of the ratio occur at the highest temperature, the thickest insulation, and the slowest rate of voltage rise (shown at the bottom right-hand corner). It is interesting to note that with dry paper, unlike oil, the ratio extends to both sides of unity. There are some values materially above 1, and there are also values below 1.

To get the general trend of variation of the ratio, with each separate feature, we average all the values for the same temperature, or for the same thickness, or for the same rate of voltage rise, and thus get the effect of one variable, segregated from the effect of the others. This grouping of data gives the results recorded below.

Temperature, Thickness, and Rate Data for Dry Unimpregnated Cable Paper.

Temperature:	25 deg.	50 deg.	75 deg.	100 deg.
Average ratio: $R =$	1.158	1.088	1.092	1.057

There is a consistent decrease of ratio with increasing temperature.

Thickness:	4	8	16	32 layers
Average ratio: $R =$	1.277	1.133	1.027	0.947

There is a consistent decrease of ratio with increasing thickness, from values considerably above 1 to values below 1.

Rate of voltage rise:	20 per cent	5 per cent	0.1 of 1 per cent per sec.
Average ratio: $R =$	1.231	1.079	0.987

There is a consistent decrease of ratio with decreasing rate of voltage application, down to values below unity.

The total average of all the values of the dielectric-strength ratio of cable paper is slightly above unity: $R = 1.100$. In other words, dry cable paper shows a slightly lesser dielectric strength for alternating than for direct voltage. Conversely stated, unimpregnated paper requires, on an average, a 10 per cent higher direct voltage than the peak alternating voltage, to puncture the same thickness of paper under otherwise identical conditions.

Since a laminated structure, consisting of a number of layers of unimpregnated cable paper, thus shows also a small deviation from the normal dielectric-strength ratio but opposite to that of either oil or petrolatum, it is of interest to consider the combination of both—that is, cable paper impregnated with the insulating hydrocarbon.

d. Cable Paper Impregnated with Petrolatum. If untreated cable paper (with a dielectric-strength ratio slightly above unity, viz: 1.100) is impregnated with petrolatum (which alone has a ratio slightly below unity—0.957) we might expect as a result of the combination of the two a ratio close to unity. On the contrary, the tests of impregnated paper show consistently very high ratios,—much higher indeed than dry paper,—and give an average ratio $R = 1.773$.

This result is very startling and its significance on insulation strength and failure is still far from being understood. The phenomenon of extra high ratio has, however, been checked and corroborated with data on several other materials of similar character.

Significant also is another factor—the enormous increase of dielectric strength, due simply to impregnation of the paper.

To get the general trend of the variation of the dielectric-strength ratio with the three controllable variables, namely temperature, thickness, and rate of voltage application, the tabulated data are again grouped for the purpose of comparison.

Temperature, Thickness, and Rate Data for Cable Paper Impregnated with Petrolatum.

Temperature:	25 deg.	50 deg.	75 deg.	100 deg.
Average ratio: $R =$	2.038	1.644	1.510	1.531

Thus the ratio consistently decreases with increasing temperature.

Thickness:	2	4 layers
Average ratio: $R =$	1.857	1.646

Thus the ratio decreases with increasing thickness

Rate of voltage rise:	20 per cent	5 per cent	0.1 of 1 per cent per sec.
Average ratio: $R =$	1.861	1.576	1.783

Thus the general trend is apparently that the ratio decreases with increasing slowness of voltage application, although the slowest rate shows a partial recovery.

This last group of data illustrates the difficulty of the investigation of the action of solid insulating material

and emphasizes the complexity and limited knowledge of the phenomena occurring in insulating materials under electric stress. The values averaged in the middle figure (1.576 at 5 per cent rate) were taken some weeks before the other two sets of tests, and while apparently the same materials were used and treated in the same manner and the general trend of variation is the same, a considerable difference occurs in the numerical values. It is interesting to note that the ratio of direct voltage to peak alternating voltage of petrolatum-impregnated cable-paper, $R = 1.773$, in the comparison of direct voltage with the root-mean-square value results in the ratio— $\sqrt{2} (R = 1.773) = 2.501$. This value is the same as has been proposed as the results of extensive tests made abroad on cables.

B. MICA AND GLASS

Table II gives data on some inorganic insulation, such as mica and its compositions, and also glass. The

TABLE II
MICA, GLASS AND PARAFFIN

Material	Elec- trodes	Gap length cm.	No. of layers	kv. per mm.		Dielec. str'gth ratio
				Direct	Alter- nating	
Clear Mica, 0.12 to 0.18 mm. thick.....				100.5	98.0	1.025

			4	21.5	12.7	1.69
			8	66.4	27.5	(2.42)
Mica Tape with stick- ing compound.....			2	24.5	9.6	2.55
			4	48.1	20.2	2.38
Glass Tubing 0.7 to 0.85 mm. thick.....	diam. 2.54 cm.			kv. per mm.		1.469
				68.0	46.3	
				kv.	kv.	
Powdered Glass.....	2.54 cm. spheres	1.90 2.54		37	44.5	0.832
				51.9	53.8	0.965
Powdered Glass made into paste with No. 6 transil oil.....	2.54 cm. spheres	0.63 0.95		50.8	61.6	0.922
				71.2	73.8	0.965
Cast Paraffin 0.9 to 2.2 mm. thick.....				kv. per mm.		1.036
				17.4	16.8	

table gives the name of the material, the data on sizes of electrodes, and either the gap length or number of layers; there are also the voltages of the tests using either direct or alternating voltage, and their ratio—that is to say, the dielectric-strength ratio of these materials. Here, as in the preceding table, each numerical value is the average of a number of tests—

usually 10 or 25. For some of the materials, such as clear and pasted mica, glass, etc., the dielectric strength is given in kilovolts per mm. so as to compare the averages of the different tests made with slightly different thicknesses of material.

The Dielectric-Strength Ratio of Mica in Several Forms. Clear mica gives a dielectric-strength ratio very little above unity, that is, in pure mica the dielectric strength is practically the same for alternating as for direct voltage. Possibly this low value of ratio indicates very low dielectric losses. Built-up or “pasted” mica however already shows a materially lesser strength for alternating than for direct voltage, a ratio of 1.245. Mica tape shows still much higher ratios, and mica tape put together with some organic sticker shows very high values. A comparison is made in the following averages:

Clear Mica.....	a ratio of	1.025
Pasted Mica.....	“ “ “	1.245
Mica Tape.....	“ “ “	1.646
Mica Tape held by a sticker..	“ “ “	2.46

Therefore the combination of two different materials in a laminated structure, here as in the preceding section A of impregnated paper, seems to raise the ratio. The ratio increases with the increase in the difference between the materials.

Apparently there is also a slight decrease of ratio with increasing thickness of the insulation, such as observed in the preceding studies.

The Dielectric-Strength-Ratio of Glass and Paraffin. Glass was tested, in the form of thin walled glass tubes, with mercury as inner electrode and tinfoil as outer electrode. Somewhat against expectation, glass, as the average of a number of tests, gave a high ratio — 1.469; that is to say, glass is dielectrically much stronger against direct than against alternating voltage. Whether or not this high ratio indicates a lack of homogeneity of the structure of the glass — as a colloidal solution — we cannot yet judge.

The glass of the tubes was powdered and the powdered glass in air was tested between 2.54 cm. spheres. Next, the powdered glass was mixed with No. 6 transil oil to form a paste, and this paste tested between 2.54 cm. spheres. Both the glass powder with the spaces between the particles filled with air, and that with the spaces filled with oil, show a dielectric-strength ratio slightly below unity (total average 0.921). That is, glass in solid form has a much greater dielectric strength for direct than for alternating voltage; as powder, however, its dielectric strength is less for direct than for alternating voltage. The explanation of this difference is still unknown.

In the same table have been added the averages of a number of tests made on thin cast disks of paraffin. They show a ratio close to unity, slightly above 1. — 1.036. This result seems reasonable.

TABLE III
VARNISHED CAMBRIC AND PARAFFINED PAPER

C. VARNISHED CAMBRIC AND PARAFFINED PAPER

Table III gives data on two kinds of insulating cloth — black and yellow varnished cambric, and cable paper impregnated with paraffin. Cable paper impregnated with paraffin gives in general the same characteristic as cable paper impregnated with petrolatum, as might be expected — that is, a high value of the ratio.

The data on both kinds of varnished cloth seem to show a decrease of dielectric strength with increasing temperature, and also a decrease of the dielectric-strength ratio with increasing temperature and possibly also with increasing thickness. Thus, grouping the average values as was done in previous cases, the results are as follows:

Temperature and Thickness Data for Yellow Varnished Cloth.

Temperature; 25 deg. 50 deg. 75 deg. 100 deg. cent.
Average Ratio: $R = 1.297$ 1.222 1.171 1.003
Thickness: 1 2 3 layers
Average Ratio: $R = 1.231$ 1.193 1.080
The total average is $R = 1.186$.

The similarity of the change of the ratio in varnished cloth, with that in impregnated paper, raises the question whether it is not a general characteristic of compound laminated structures, to have a high dielectric-strength ratio at low temperatures, low thicknesses, and high rates of voltage rise, and conversely to have this ratio decrease with increasing temperature, increasing thickness and increasing slowness of voltage application.

Discussion

For discussion of this paper see page 615.

Cable Geometry and the Calculation of Current-Carrying Capacity

BY DONALD M. SIMONS

Associate, A. I. E. E.
Standard Underground Cable Company, Pittsburgh, Pa.

Review of the Subject.—The main purpose of this article is to express the calculation of current-carrying capacity in simple formulas. The allowable current for underground cables is usually limited by the maximum permissible temperature of the insulation. The temperature rise is of course a function of the ability of the cable system to dissipate the heat generated. The chief difficulty in the calculation of current-carrying capacity is the determination of the thermal resistances of the path through which the heat must flow.

The main part of this paper deals with the errors in the standard formulas for calculating the thermal resistance and geometric properties between the conductors and the sheath. A graphical method of correcting the errors is obtained in terms of what is called the "geometric factor," the results are tabulated for 2, 3 and 4-conductor cables throughout the range of practical sizes and an empirical formula is given. The check between the results of the graphical correction method and the published experimental data on this subject is very satisfactory, and emphasizes the errors in the standard formulas.

The thermal resistance between the sheath and the duct is mentioned briefly, and an approximate method of finding the resistance between the duct and the region at base temperature is outlined.

The previous work is then combined into a simple formula giving the allowable current for n -conductor cables, there being any number

of similar cables in the duct bank. The formula is also enlarged to cover the case of cables in the metric and square inch systems, and cables buried directly in the ground. The method of including the effect of induced sheath currents in single-conductor cables and of dielectric losses is shown. Finally, the procedure to use in case the cables in the duct bank are not all of the same type is outlined.

In Appendix A the geometric factor for three-conductor cables under three-phase voltage is discussed, Russell's formula for this geometric factor being compared with the experimental determinations and an empirical formula for it is given. A formula is also given for the calculation of dielectric losses in three-conductor cables. The geometric factors for three-conductor cables in all other connections (i. e., the geometric factor for one conductor against the other two and sheath, or between any two conductors, etc.) are then derived in terms of the two geometric factors already obtained.

In Appendix B are given examples of the calculation of current carrying capacity under various conditions, and of dielectric loss.

In Appendix C an example is given which shows the error introduced by using an approximate formula for the calculation of the thermal resistivity of the insulation of a three-conductor cable based upon experimental measurements, the case taken up being a table in the Research on the Heating of Buried Cables.

INTRODUCTION

THE limit in the current-carrying capacity of underground cables is the allowable temperature of the insulation at the hottest point, usually the conductor surface, (unless economic or other considerations are determining factors). For a given allowable temperature at the conductor surface and a known temperature of the earth, the allowable temperature rise is obtained. The allowable current is of course that current which is just sufficient to produce the allowable rise, due to the heat generated in the conductors as $I^2 r$ loss, neglecting dielectric losses for the present.

The total temperature rise of a cable is usually divided into three distinct parts: T_A , the rise of the conductors above the lead sheath; T_B , the rise of the sheath above the duct; T_C , the rise of the duct above the base temperature of the earth. The thermal path may be considered as analogous to an electrical circuit with three resistances in series. In such an electric circuit the difference of potential across each of the elements would be equal to the product of its electrical resistance by the current flowing. In this thermal path, the difference of temperature across each of the elements will be equal to the flow of heat in watts, multiplied by the thermal resistance of the element in thermal ohms.

In the present paper, the T_A rise will be considered

Presented at the Annual Convention of the A. I. E. E., Swampscott, Mass., June 26-29, 1923.

primarily, though the other ones will be mentioned briefly, and it will be attempted to compare the various divergent methods of calculating T_A , pointing out the known errors in the various formulas, and a new method will be developed for graphically correcting them.

THE GEOMETRIC FACTOR

The temperature rise between the conductors and the lead sheath, as stated above, is equal to the product of the total watts generated in the conductors by the thermal resistance between the conductors and the lead sheath, and our problem is to determine this thermal resistance.

For single-conductor cables the thermal resistance may be obtained in thermal ohms per unit length of cable by the standard formula

$$R_{th} = \frac{\rho \log_e (R/r)}{2 \pi} \text{ thermal ohms per unit length} \quad (1)$$

in which ρ is the thermal resistivity of the insulating material, R is the radius over the insulation, and r is the conductor radius. This formula is rigid and exact for homogeneous insulation.

For three-conductor cables several different formulas have been given, all in the form:

$$R_{th} = \frac{\rho \log_e F_1}{6 \pi} \quad (2)$$

in which F_1 is a function of the dimensions of the cable,

and is given in quite different form by different writers. The following are the various values of $\log_e F_1$:

$$\log_e F_1 = \log_e \frac{1 - \alpha\beta + \sqrt{(1 - \alpha^2)(1 - \beta^2)}}{\alpha - \beta}$$

Mie's formula (3)

$$\text{where } \alpha = \left(\frac{r + a}{R} \right)^3 \text{ and } \beta = \left(\frac{a - 3r}{a + 3r} \right) \cdot \alpha$$

$$\log_e F_1 = \log_e \frac{R^6 - a^6}{3 R^3 a^2 r}$$

Russell's formula No. 1 (4)

$$\log_e F_1 = \log_e \frac{R^3 - a^3}{a^3 - (a - r)^3}$$

Russell's formula No. 2 (5)

In all the above formulas R is the radius of the cable under the lead sheath, a is the radius of the centers of conductors, and r is the conductor radius. It might be mentioned that Mie's formula has been also derived by Matsumoto. Reference to the source of these formulas is given in footnote 1.

It will be noted in formula (2) that the dimensions of the cable occur only in the logarithmic function, and we shall therefore call $\log_e F_1$ the *geometric factor of the cable*, and use the symbol G_1 for it.

ERRORS IN THE FORMULAS

The available formulas for G_1 are based on certain stated assumptions. Unfortunately the values of G_1 calculated by the various formulas are quite different for cables of ordinary makeup. This indicates that the assumptions on which the formulas are based are not valid for the usual cables.

Mie states that his formula is correct for very thick insulation with small conductors and also for very thin insulation. Russell says that his formulas are correct for the case of very small conductors very far apart. It has been noted that these qualifications have not in general been heeded, and in many cases the technical press shows that the formulas have been used regardless of the size of conductor. It is desired to show that the differences in these various formulas are very great in the range of practical cables.

Formulas (3), (4) and (5) contain three variables, but since the function in each case is a ratio, it can be expressed in terms of two parameters. These will be chosen as (α) the ratio of total insulation thickness between conductors and lead to conductor diameter or $\frac{T + t}{d}$, and (β) the ratio of belt insulation thickness to conductor insulation thickness, or t/T , in which

T equals the conductor insulation thickness, t equals the belt insulation thickness, and d equals the conductor diameter.

We may show the geometric factor for all cables of equal belt and conductor insulation thickness ($t/T = 1$) if we plot the geometric factor as a function of

$\frac{T + t}{d}$; in other words, the thermal resistance of all

cables of a given kind of insulation having the same value of this function will be the same regardless of their absolute size. Careful examination has been made of the usual forms of cable, and also the unusual cases, and it has been found that practically all present day cables fall within the limits of about 0.2 to 2.0

for the ratio $\frac{T + t}{d}$. The geometric factors in this

range are plotted and shown in Fig. 1. In addition to the geometric factors from (3), (4) and (5), the geomet-

FIG. 1—GEOMETRIC FACTOR OF THREE-CONDUCTOR CABLES
Comparison of calculated values by different formulas. $t/T = 1.0$.

ric factor obtained from Atkinson's experimental work is also plotted, concerning which more will be said later. The differences are obviously great.

Before proceeding further, it is of interest to examine Fig. 1 and attempt to determine the errors for extreme

cases. A ratio $\frac{T + t}{d}$ equal to zero would mean a

cable (with finite conductors) of no insulation whatsoever. For this case, the thermal resistance and therefore the geometric factor must be zero, and thus both of Russell's formulas are seen to be in large error for small values of the ratio. For large values of the ratio, all the formulas approach the same correct value.

For instance for a ratio of $\frac{T + t}{d}$ equal to 10, which

1. Mie, G., *Elektrotechnische Zeitschrift*, 1905, p. 137.

Russell, A., *Alternating Currents*, 1914, p. 187.

Matsumoto, H., *Electrotechnical Laboratory, Tokyo, Third Section*, 1916, Report No. 24.

is of course an improbable practical case, G_1 has the following values for the formulas (3), (4) and (5) respectively; 4.35, 4.37 and 4.39. The most striking fact is that the curves for Russell's formulas do not pass through the origin as they should.

The errors in the various formulas are explained by their originators and are easily understood. If the twisting of the conductors is neglected, the problem is one of plane geometry, the figure to be solved being that of a cable cross-section, consisting of three circles in the vertices of an equilateral triangle, which represent the conductors, surrounded by a fourth circle representing the sheath. The approximate formulas which have been obtained have not used this actual

circles representing the conductors. For large values of the ratio $\frac{T+t}{d}$ the substituted figure very closely approaches the three conductors.

Russell substitutes a different figure for the three conductors in his formula No. 2, his substituted figure being an oval inside the circle representing each conductor, and tangent to the conductor surface at the point nearest the cable center. For the sheath, he uses a figure tangent to the actual sheath at the points nearest the conductors and bending inward toward the cable center at the points between. Russell's formula No. 1 is derived by a different approximate

FIG. 2—THE SUBSTITUTED FIGURES FOR THREE-CONDUCTOR CABLES
Three conductors against the sheath.

figure, due to mathematical difficulties. Mie substitutes a figure for the three conductors, which coincides with the circles representing the three conductors at the regions nearest the sheath. His substituted figure consists of three ovals if the conductors are relatively small, and is a continuous curve dipping in between conductors if the conductors are relatively large. He uses the actual sheath. Knowing the equations of his substituted figure and of the sheath, Mie obtains a rigid expression for the thermal resistance between them. The error is of course due to the fact that the substituted figure is used in place of the three

method, the method of images, and no way has been devised here for graphically showing the errors in this formula.

The large error in Russell's formula No. 2 is easily explainable. The location of the greatest amount of flow of heat is undoubtedly between the conductors and the sheath through the shortest path between them and this is especially true for thin insulation. If substituted figures are to be used, the substituted sheath and substituted figures for the three conductors should be correct at this point to minimize the errors. A revision of Russell's formula No. 2 has therefore

been made with the condition that the figures representing the conductors shall be tangent to the conductors at the points nearest the sheath rather than nearest the center of the cable, the substituted sheath being the same. This auxiliary formula has been derived for later purposes of checking, and has the following form:

$$G_1 = \log_e \frac{R^3 - a^3}{(a + r)^3 - a^3} \quad (6)$$

The substituted figures are immediately understandable from Fig. 2 in which the actual conductors and sheath are shown as well as the substituted figures used in three of the formulas, Fig. 2A being a case of a relatively small value of the ratio, while Fig. 2B is for a large value of the ratio. The dotted lines are the flow lines of heat, which are defined as being lines normal to the isothermals, and such that the spaces between lines all have equal thermal resistances. The equations for these lines were obtained from Mie's formula for this purpose.

GRAPHICAL CORRECTION FOR THE ERRORS

The method devised for graphically correcting the geometric factor will now be explained. Mie's formula when applied to a cable contains errors, but it gives a *rigid solution* for the thermal conductance and geometric factor between his substituted figure and the sheath. Now the conductance between the three conductors or the substituted figure and the sheath is inversely proportional to the geometric factor. If therefore, we can by any means obtain the ratio of the conductance from Mie's substituted figure to the sheath to that from the three actual conductors for any particular cable, the product of this ratio by the geometric factor by Mie's formula will be the correct geometric factor of that cable. The same remark would of course apply to any other of the substituted figures, but since Mie's is the closest to the actual conductors, his formula and substituted figure have been chosen for this purpose.

The problem of correction is of course to graphically determine the ratio of the conductance from Mie's substituted figure to the true conductance. Due to the symmetry of a cable, it is sufficient to consider only one-half conductor. Fig. 3 shows 60 angular degrees, or one-half conductor, of the three-conductor cable shown in full in Fig. 2A. The flow lines shown were calculated by Mie's formula for them and are strictly the flow lines from Mie's figure to the sheath. Mie's equation for flow lines contains an auxiliary angle η ; the line for η equal to zero is the shortest line between conductor and sheath, while the line for η equal to 180 deg. is the one midway between conductors. In Fig. 3, the lines have been plotted for η from 0 deg. to 180 deg. by steps of 10 deg.

By the definition of flow lines therefore, the conductance between the substituted figure and the sheath is

the same along all of the paths between flow lines. If we take the conductance along any of these paths as unity, then the total conductance between Mie's figure and the sheath for this section would be 18 in Fig. 3.

The conductance from the conductor to the sheath must now be determined in the same units. Mie's figure coincides with the conductor for the first eight or nine paths, and each of these paths therefore has also a conductance of unity. For the subsequent paths, the conductance from the conductor to the sheath is through a longer path than from Mie's figure. Since conductance is inversely proportional to length of path, the conductance to the sheath for any particular path may be found by multiplying the conductance from Mie's figure (or unity) by the ratio of the average length of path from Mie's figure to its average length from the conductor. The conductance from the conductor to the sheath may therefore be determined

FIG. 3—FIGURE FOR GRAPHICAL CORRECTION OF THREE-CONDUCTOR CABLE

$$\frac{T + t}{d} = 0.5 \quad t/T = 1.0$$

path by path, the total conductance being the sum of the conductances of the 18 paths. This sum will be a number smaller than 18. If we now calculate the geometric factor for this particular cable by Mie's formula, and multiply it by the ratio of conductances, the correct geometric factor will be obtained.

The above method is described because of its clarity. The actual method used is based on the same principle though applied differently. The difficulty with the actual application of the method described is that a sufficient number of flow lines must be taken. It was found that the correction factor obtained by this method using 36 paths of flow instead of 18 as in Fig. 3 was slightly different, and that if 72 paths were used a still different geometric factor would be obtained, the answer obviously approaching a limit for an infinite number of flow lines. The calculation of flow lines is very laborious, since they must be plotted point by point, each point being obtained by solving an equa-

tion of degree equal to twice the number of conductors in the cable, and over forty separate figures of this kind were required.

The method actually used is the following, which is equivalent to using an infinite number of flow lines. A large figure was drawn for each case similar to Fig. 3 such that the radius of the sheath was equal to 10 inches, and the conductor, Mie's figure, and the flow lines for each 10 deg. of η were plotted on it. The length of each line from the conductor to the sheath and from Mie's figure to the sheath was carefully measured by a map measurer, and for each line the ratio of the length from Mie's figure to its length from the conductor was obtained, this being the true relative conductance along the line. The conductance from Mie's figure along each line was taken as unity.

The value of conductance between Mie's figure and the sheath was plotted against η as abscissa, the curve being of course a straight line parallel to the base. In other words, the conductance between Mie's figure and the sheath may be represented as the conductance

ratio of the two areas will be called the graphical correction factor.

This whole process was carried out graphically on a large scale for various proportions of $\frac{T+t}{d}$ for equal

belt and conductor insulation thickness ($t/T = 1$), for half belt ($t/T = 0.5$), and for cables having no belt ($t/T = 0$). In each case the geometric factor was calculated by Mie's general formula for an n -conductor cable, the graphical correction factor was obtained as described, and multiplying these two together a corrected geometric factor was obtained. This identical process was carried out for two (round duplex), three and four-conductor cables; the results are tabulated in Table I. For practical use, the data of Table I should be expressed in curve form, G_1^* being plotted

against $\frac{T+t}{d}$. A separate curve should be drawn for each value of t/T . In the remainder of the article,

between opposite sides of a rectangle. The relative true conductances were then plotted on the same figure against η , the true total conductance of conductors to sheath being represented by the summation of all the ordinates of this figure. The area of the figure corresponding to Mie's conductance was calculated and the area corresponding to the true conductance was measured by a planimeter. The ratio of these two areas is the ratio of conductances from the two figures, which, multiplied by Mie's geometric factor for the cable, will give its true geometric factor. The

when it is stated that the value of G_1 was obtained from Table I, it will be understood to mean from curves based on Table I.

The sources of error in the method will now be examined. The main difficulty is the fact that the flow lines are strictly the flow lines from Mie's figure and not the flow lines from the actual conductors. The more closely the substituted figure coincides with the three actual conductors, the smaller will this error be, and

* G_2 is shown in curve form for three-conductor cables in this reprint only.

it was for this reason that it was decided to perform the graphical correction from Mie's formula. Another error is the assumption that the conductances along any path are inversely proportional to the length, which would be true only if the flow lines were parallel. The flow lines, however, are quite closely parallel, and this error seems of negligible amount, especially since the method used is equivalent to the use of an infinite number of flow lines.

A certain amount of evidence in regard to the error of using incorrect flow lines may be obtained by the following method. The method described above consists in correcting Mie's geometric factor to the true geometric factor which is unknown. We have, however, two other formulas with substituted figures and *known* geometric factors, namely Russell's formula No. 2 and the auxiliary formula (6). The former contains very large errors and will not be used. We may, however, apply this same graphical method to the calculation of the geometric factor of the auxiliary formula, (which was derived for this purpose) and determine how closely this corrected value agrees with its actual geometric factor. In other words, on the diagrams used for the calculation of the true geometric factor of the cable, the figures substituted for conductors and sheath by the auxiliary formula may be drawn (they are shown in Fig. 2). The lengths of flow lines from Mie's figure to the sheath are compared with the lengths between the two substituted figures of this formula, and areas proportional to the relative conductances are obtained as before, the ratio of which is the graphical correction factor transforming Mie's geometric factor into the auxiliary geometric factor. This was done for three-conductor cables of equal belt and conductor insulation thicknesses for four values of

the ratio $\frac{T+t}{d}$

Table II shows the actual geometric factor of the auxiliary formula, and its value obtained by graphically

TABLE II
CHECK OF METHOD OF CORRECTION
3-Conductor Cables, $t/T = 1.0$

$\frac{T+t}{d}$	G_1 (Mie)	Graphical correction factor	G_1 of (6) by graphical correction	G_1 calculated by formula (6)	Error
0.3	1.015	0.764	0.775	0.769	+ 0.8%
0.5	1.369	0.824	1.128	1.125	+ 0.3
1.0	1.978	0.880	1.741	1.748	- 0.4
2.0	2.681	0.928	2.475	2.479	- 0.2

correcting Mie's formula, and it will be seen that the maximum error is only 0.8 per cent which is a very satisfactory check. A comparison of Table II with the corresponding section of Table I will show that the per cent error which has been corrected in Table II is many times greater than the error corrected for the actual cable. We cannot, however, assume from this that the corrected geometric factors of Table I are

accurate to considerably more than 0.8 per cent, since an inspection of the figures would indicate that Mie's flow lines are probably more nearly the flow lines of the substituted figures of the auxiliary formula than they are of the actual conductors. The check of Table II, however, at least indicates that the error in Table I is probably quite small.

COMPARISON WITH EXPERIMENTAL DETERMINATIONS OF GEOMETRIC FACTOR

Fortunately another method of obtaining the geometric factor is available. The geometric factor shown in formula (2) is exactly the same for the calculation of not only thermal resistance but also of electrical resistance or capacity, the only difference in the formulas being in the constants used. If, therefore, it should be possible to obtain any one of certain electrical quantities experimentally, this determination

would make it possible to find the geometric factor and thus all the other quantities. This has been done experimentally by Atkinson² and Sacchetto³, who measured the resistance between three conductors and the sheath (as well as in other connections) of three-conductor cable models, composed of three tubes uniformly spaced and surrounded by a fourth tube, all located in a tub of electrolyte. Various sizes of tubes and spacings were used, and both have obtained sets of curves, in terms of charging current for the former, and capacity for the latter; from these values, three conductors against the sheath, it is possible to calculate the geometric factor in terms of our parameters by formulas (21) and (19) given in Appendix A. This method of obtaining the geometric factor is

2. Atkinson, TRANSACTIONS A. I. E. E., 1919, page 971.
3. Sacchetto, l'Elettrotecnica, 1921, page 533.

theoretically correct, the only possible error being the experimental errors such as the location of the electrodes, which undoubtedly were reduced to a minimum. It is therefore possible to obtain values of the geometric factor by calculation from the experimental data of these two, and some of Atkinson's values have already been shown in Fig. 1.

Table III has been drawn up comparing the various experimental determinations of the geometric factor with the values obtained herein by correction from Mie's formula, shown in column (4). Column (5) shows the geometric factor obtained from Atkinson's experimental data, and column (6) that from Sacchetto's. The last two points shown in this column are for the actual values of the ratio used by Sacchetto while the others were obtained by drawing a curve through his points and reading off the values corresponding to our values of the ratio.

Column (7) shows the per cent deviation of our values from Atkinson's experimental values. The check seems quite good, especially when compared with the errors in the standard formulas as shown in Fig. 1. As to this small residual error, it is believed that in general

for the small values of the ratio $\frac{T+t}{d}$, where the

graphical correction is large, Atkinson's value is undoubtedly more nearly correct, while for the larger values of the ratio where the graphical correction is small, the new values are probably more nearly correct.

Referring to Sacchetto's values, it will be noted that the first one is quite close, while after that the values are low. Mie's value of the geometric factor is definitely always too small. The last five values from Sacchetto's data are 3 to 5 per cent lower than Mie's values and these values must therefore be definitely in error by at least that amount.

EMPIRICAL FORMULA FOR GEOMETRIC FACTOR

Since we have obtained the values of the geometric factor, it is of course immediately possible to derive empirical formulas which will coincide with the data of Table I. For three-conductor cables, the following formula (7) applies:

$$G_1 = (0.85 + 0.2\beta) \log_e [(8.3 - 2.2\beta)\alpha + 1] \quad (7)$$

$$\text{where } \alpha = \frac{T+t}{d} \quad \text{and} \quad \beta = t/T$$

Between $\alpha = 0.3$ and 2.5 , this formula will give a value of the geometric factor agreeing to within 1.2 per cent with the values of Table I. Throughout most of the range, the check is within 0.5 per cent.

For an n -conductor cable it was thought that it would probably be more valuable to express a general formula at some sacrifice of accuracy than to obtain a very complicated expression or to have a different

formula for each number of conductors. Formula (8) has therefore been derived:

$$G_1 = \log_e \left[\frac{n(8T+t)(T+t)}{4dT} + 1 \right] \quad (8)$$

where n = number of conductors in the cable.

TABLE IV
PER CENT DEVIATION OF FORMULA (8) FROM
GEOMETRIC FACTOR

α	2-Conductor			3-Conductor			4-Conductor		
	β			β			β		
	1.0	0.5	0.0	1.0	0.5	0.0	1.0	0.5	0.0
0.3	-8.8	-12.4	-15.2	+1.1	-1.3	-3.9	+7.2	-0.3	+3.6
0.5	-4.1	-6.9	-9.3	+1.5	+1.2	-0.4	+4.2	+3.9	+5.0
1.0	-0.9	-2.3	-3.3	-0.9	+1.6	+3.3	-1.3	+1.3	+6.8
1.5	0.0	-0.5	-1.7	-0.7	+1.3	+4.3	-2.9	+0.9	+8.8
2.0	+0.2	0.0	-0.5	-1.5	+1.0	+4.8	-3.4	+1.5	+7.8

Table IV shows the error of this formula based upon the geometric factor as derived in this article. It will be noted by comparison with the correction factors shown in Table I that in most cases the error of formula (8) is much less than that of even Mie's formula, except for certain cases of non-belted cables. Cables without belts which are not in the Type *H* form are not of great practical importance, however, and it is believed that the simplicity and ease of application of this formula would make it convenient to use in cases where greater accuracy is not necessary. The simplicity is such that G_1 may be readily calculated on the slide rule, while it is dangerous and laborious to do so with Mie's or Russell's formula No. 1, since they are sixth degree expressions for three-conductor cables. It is believed that such a formula as this will be valuable when properties of cables are investigated mathematically, where for instance, the maximum or minimum value of some function is desired.

The formula is exact for single-conductor cables, since when $n = 1$ and $t = 0$, formula (8) reduces to:

$$G_1 = \log_e \frac{d + 2T}{d} = \log_e (D/d) = \log_e (R/r)$$

SECTOR-SHAPED CONDUCTORS

The expression "sector-shaped conductor" includes such a large variety of shapes that it seems necessary to obtain an approximate value of the geometric factor. It has been noted that the capacity of a sector cable is about 10 to 15 per cent greater than that of a cable of the same insulation thickness and same copper cross-section with round conductors. Approximate results can therefore be obtained if the geometric factor is obtained by reading a value from Table I on the basis of round conductors of the same area and the same insulation thickness, and then *decreasing* this geometric factor by 10 per cent.

It was hoped that a geometric factor might be obtained by the graphical method used for the case of round conductors. It was found, however, that Mie's

flow lines were so far from being the correct flow lines for the sector conductors that no consistent results could be obtained.

Russell has given an approximate formula for three-conductor cables with sector conductors, which also applies only to the case of very small conductors with very thick insulation. This formula is obtained by a transformation of his formula No. 2, and the geometric factor is given in the following form:

$$G_1 = \log_e \frac{2R^3 - (c^3 + b^3)}{c^3 - b^3} \quad (9)$$

in which R = the cable radius under the lead sheath

c = the maximum distance from the cable center to the conductor surface

b = the minimum distance from the cable center to the conductor surface.

It is difficult to state the exact error in formula (9), since our data are not definite enough for sector cables. However, it is quite interesting to note that although this formula is based on two approximations, the first being the approximation leading to Russell's formula No. 2 which introduces a large error, and the second being an approximation transforming his formula No. 2 into formula (9), these two apparently neutralize each other, with the result that formula (9) gives results for three-conductor cables with *round* conductors which are much more accurate than those obtained by either of his other formulas.

THERMAL RESISTANCE AND TEMPERATURE RISE BETWEEN CONDUCTORS AND SHEATH

Having obtained the values of the corrected geometric factor, it is immediately possible to calculate the temperature rise, T_A , of cables having from one to four conductors, and of course a similar process could be used to determine the geometric factor and temperature rise for cables with more conductors if desired. The formulas follow:

$$\text{Thermal resistance} = \frac{0.00522 \rho G_1}{n} \text{ thermal ohms per foot of cable} \quad (10)$$

(Between the n -conductors and the sheath).

Temperature rise, conductors above sheath,

$$T_A = \frac{0.00522 W \rho G_1}{n} \text{ degrees C} \quad (11)$$

where G_1 is obtained from Table I or from formulas (7) or (8)

n = number of conductors per cable

ρ = thermal resistivity of the insulation in watt-centimeter-centigrade units

$W = I^2 r$ loss in watts per foot of cable.

$$0.00522 = \frac{1}{2\pi \times 12 \times 2.54}$$

The thermal resistivity may of course be obtained

by inverting formula (11), if the temperature rise of the conductors above the sheath is known for a given loss in the conductors. It is especially important to use the correct value of the geometric factor for the determination of the thermal resistivity of cables, and it was thought that it might be interesting to illustrate this by a particular case, namely the Research on the Heating of Buried Cables. See Appendix C.

CURRENT CARRYING CAPACITY

The allowable current for underground cables is usually determined from temperature considerations except for very low-voltage cables where voltage drop may be the controlling feature. In certain cases, the laws of economy may determine the size of conductor, especially if the load factor is high. In what follows, however, only the temperature problem will be considered, but it should be borne in mind that in certain cases, the results should be tested for line drop and by Kelvin's Law.

The fundamental law on which the calculation of current carrying capacity as limited by temperature rise is based has been called "Ohm's Law for Heat." This may be expressed as follows: Temperature difference (centigrade) equals watts per foot times thermal resistance in thermal ohms per foot. This applies to a steady, continuous load, which is the only condition which will be covered in this paper.

So far the thermal resistance between the conductors and sheath is the only one that has been considered. Before giving a formula for the allowable current, we must determine the temperature rises, T_B and T_C , between the sheath and the duct, and the duct and base respectively. To do this, we must solve for the thermal resistances corresponding to these rises.

What may be roughly called the thermal resistance between the lead sheath and the duct, in other words a quantity which multiplied by the watts dissipated is equal to the temperature rise, (although it of course is not truly a thermal resistance) is primarily a function of the outside diameter of the cable and the thermal emissivity of the lead sheath. This thermal resistance may be expressed by the following formula:

$$r_{th} = \frac{0.00411 E}{D} \text{ thermal ohms per foot} \quad (12)$$

in which E is an approximate constant which might be called the surface resistivity of the sheath, almost independent of D , and expressed in degrees centigrade per watt per square centimeter, and D equals the outside diameter of the cable in inches. It might be thought that the size of the duct should be included in the formula for this thermal resistance. If the heat were transferred between the sheath and the duct by conduction, the size of the duct would enter in a marked degree. The transfer of heat, however, is by conduction in part only, and mostly by radiation and convection. The fact that T_B is almost independent

of the size of duct can be illustrated by saying that for the same loss the sheath rise in a small duct is not very different from the sheath rise of a cable suspended in free air.

The duct rise, T_c , is the most difficult to determine, and in the present state of knowledge complicated mathematical calculations would probably not be justified. We will let H be the thermal resistance per foot between the duct and the region at base temperature or "sink." For a relatively small cylinder buried in the earth, the thermal resistance per foot is proportional to $\rho' \log 4l/D$, ρ' being the earth's resistivity, D the outside diameter of the cable, and l the distance between the cable axis and the surface of the earth. This formula due to Kennelly is practically standard in the calculation of the temperature rise of the sheath of a cable buried directly in the ground according to European practise. The temperature rise between a duct bank and the base is a similar problem, and an equivalent cylinder could be substituted for the duct. The ratio of the diameter of this cylinder to the depth below the surface would, however, be much greater than for the case of a cable buried in the ground, and errors in the formula would be greater. In fact, such a procedure is quite similar to using Russell's formula for the geometric factor for cables with large conductors and thin insulation. However, this is probably the best that can be done at present, and the errors and variations in the thermal resistivity of the soil are much greater than the errors which would be introduced by the formula. It is for this reason that the condensed rather than the full form of Kennelly's formula will be used.

We will therefore offer the following formula for H :

$$H = 0.00522 \times \rho' \times \log_e \frac{4l}{L} \text{ thermal ohms per foot of duct} \quad (13)$$

in which ρ' = the thermal resistivity of the soil

l = the distance between the earth's surface and the center of the duct structure

L = the length of one side of a square duct bank.

If the duct structure is not square in cross-section, the geometric average of the two dimensions should be used for L .

Formula (13) is merely a first approximation, and may be used with the data of Shanklin⁴ for the thermal resistivity of the soil. Its mathematical error has been investigated by calculating the temperature rise based on (13) and comparing it with the temperature rise calculated on the basis that the temperature rise of each duct is the rise due to the heat which it dissipates plus the rises due to the adjacent ducts, assuming that the thermal gradient as derived from (13) is true for short distances. It was also assumed that the duct

structure was homogeneous with the soil in thermal characteristics. For ducts buried from 2 to 8 feet below the surface of the earth and for structures containing up to 16 ducts, the maximum difference between the two methods was only 8 per cent. This method incidentally also makes it possible to approximate the thermal gradient within the duct structure.

Atkinson⁵ states that H may vary between 0.6 and 1.6 depending on the size of duct structure and upon the nature of the surrounding soil, and that 1.0 seems to be a reasonably safe average figure for conduits containing up to about 16 ducts. This is borne out by formula (13), using average values of soil resistivity. For practical numerical calculation, where the constants of the soil are unknown, 1.0 may be taken as an average value for H , and this has been done in the numerical examples in Appendix B.

The total thermal resistance, conductors to base for cables in ducts is of course equal to the sum of the three thermal resistances, H being multiplied by the number of similar cables in the duct to express the thermal resistance in terms of the watts per foot of cable, since all the cables are effective in heating the duct. The total thermal resistance therefore is:

$$R_{th} = \frac{0.00522 \rho G_1}{n} + \frac{0.00411 E}{D} + N H \quad (14)$$

thermal ohms per foot

If we substitute 850⁶ for ρ , 1200 for E , and 1.0 for H , (14) reduces to the following simple form:

$$R_{th} = \frac{4.44 G_1}{n} + \frac{4.93}{D} + N \quad (14')$$

thermal ohms per foot.

For armored cables buried directly in the ground, the total thermal resistance is given by a somewhat different expression. The thermal resistance between conductors and sheath is of course the same as for cables in ducts. Cables in the ground, however, usually have a protective covering of armor and jute wrappings around the lead sheath, whose thermal resistance is given by an expression similar to that for the insulation of a single-conductor cable. The thermal resistance between the outer surface of the cable and the region at base temperature is given by (13), using the outside diameter of the cable for L . If there are several cables buried fairly close together, there will in addition be an apparent increase of thermal resistance of one cable due to the presence of the others, and another term must be added represented by the summation sign,⁷ which is intended to indicate that the process must be

5. Atkinson, JOURNAL of A. I. E. E., 1920, page 831.

6. This would apply to impregnated paper or varnished cambric insulation, and 650 may be used for rubber.

7. This term is derived on the assumption that the temperature gradient is the same as that between two concentric cylinders of diameters $4l$ and D , [an assumption mathematically justified by formula 13] which is undoubtedly closely true if the cables are not too far apart.

4. Shanklin, TRANSACTIONS of A. I. E. E., 1922, page 92.

performed for all neighboring cables, excepting the one under consideration, all the cables being supposed identical in dimensions.

The total thermal resistance, conductors to base, for cables buried directly in the ground is therefore the following:

$$R_{th} = 0.00522 \left[\frac{\rho G_1}{n} + \rho'' \log_e \frac{D'}{D} + \rho' \log_e \frac{4l}{D'} + \rho' \sum \log_e \frac{4l_n}{2x_n} \right] \quad (15)$$

thermal ohms per foot

The following symbols apply to (14), (14') and (15):
 G_1 = the geometric factor from Table I, or formulas (7) or (8).

ρ = the thermal resistivity of the insulation in degrees C/watt/cm.³

ρ' = the thermal resistivity of the soil in degrees C/watt/cm.³

ρ'' = the thermal resistivity of protective coverings for armored cable in degrees C/watt/cm.³

n = the number of conductors in each cable.

N = the number of similar, loaded cables.

D = the diameter over lead of the cable in inches.⁸

D' = the outside diameter of an armored cable in inches.

E = the surface resistivity of the sheath in degrees C/watt/cm.²

H = the thermal resistance per foot of the duct from (13).

l = the distance in inches between the earth's surface and the center of the cable buried in the ground.

l_n = l of any other nearby cable.

x_n = the distance in inches between the axis of the cable under consideration and that of any other cable.

The total temperature rise for a given current per cable, there being N similar cables in the duct bank, (or in the ground), can be found by multiplying R_{th} by the $I^2 r$ loss per foot of cable, or the T_A , T_B and T_C rises may be determined separately by multiplying each of the three terms respectively of (14) by the watts.

The more usual problem is to find the allowable current for a given group of cables. The allowable temperature rise can be determined by subtracting the ground temperature from the allowable temperature of the insulation as determined by the A. I. E. E. rule or otherwise; if this rise is divided by the total thermal resistance, the allowable $I^2 r$ watts per cable are obtained. From the known conductor resistance, it is

therefore possible to calculate the allowable current. The entire process may be expressed in the following formula giving the allowable current for n -conductor cables, there being N similar cables in the duct:

$$I = 0.281 \times \sqrt{\frac{A (T_o - T_g)}{n R_{th}}} \quad (16)$$

where I = allowable current in amperes per conductor.

T_o = allowable temperature of the insulation according to A. I. E. E. Standardization Rule in degrees cent.

T_g = base temperature of the ground in degrees cent.

A = cross-section of conductor in circular mils. and R_{th} is obtained from (14) or (14') for underground cables in ducts, from (15) for cables buried directly in the ground, and from (10) for submarine cables, T_A being the only rise in that case.

The constant in front of the radical is calculated in connection with the circular mils, A , so that the resistance is taken at 65 deg. cent. (an average operating value) including an increase of 2 per cent for stranding and 2 per cent for cabling. If the "skin" or "proximity" effects are appreciable, the constant should be divided by the square root of the ratio of a-c. to d-c. resistance. If A is expressed in square millimeters, the constant in front of the radical becomes 12.47 and if it is expressed in square inches, the constant becomes 317.0. The constant 0.281 is actually equal to $0.40/\sqrt{\rho_0}$ where ρ_0 is the resistivity of the copper in microhms per cm. cube (2.03 at 65 deg.), and from one point of view, the value of the resistivity at the operating temperature should be used. However, the variation of $\sqrt{\rho_0}$ between 55 and 85 deg. cent. is only 5 per cent, corresponding to working pressures of 30,000 and about 110 volts. Furthermore, it has been stated⁵ that this variation is in part at least compensated for by changes in the surface thermal resistivity of the sheath. The use of a constant 0.281 at an average temperature thus seems allowable.

Formula (16) is believed to present the advantage of applying to the general case of N cables, each of n -conductors, and if formula (8) is used for the geometric factor, the allowable current is expressed directly in terms of the cable dimensions. Since formula (14') is based on the constants used by Atkinson, and since the geometric factor of this paper agrees so closely with his geometric factor, this formula will give allowable currents for single-conductor, or three-conductor cables which will agree with those obtained by means of his tables⁵.

DIELECTRIC LOSS

The effect of dielectric loss may be included by assuming (1) that the power factor throughout the entire insulation is the same as that at the hottest point, and (2) that the loss is concentrated in the conductors and must flow through the entire thermal path. The second

8. The outside diameter of a 3-conductor cable with round conductors is of course the following:

$D = 2.155 (d + 2T) + 2t + 2 \times \text{lead thickness.}$

For sector cables, the outside diameter is equal to that of a round conductor cable of the same make-up minus from 0.3 to 0.4 times d , depending upon the shape of the sector.

assumption is of course correct for the sheath and duct rises. These two assumptions tend to give the maximum effect of dielectric loss, especially for low loss cables, though in certain cases, the effect may be greater. The assumptions do not lead to much error, since the whole effect normally is relatively small.

Since the allowable temperature of the conductor is known for a given voltage, the dielectric loss can be calculated in watts per foot by (22) based on the power factor of the insulation at that temperature. The temperature rise due to dielectric loss will then equal the loss in watts per foot multiplied by the total thermal resistance per foot from (14). The effect of the dielectric loss upon carrying capacity is obviously to diminish the temperature rise allowable for the $I^2 r$ loss. Mathematically it can be conveniently included in the calculation by finding the temperature rise due to dielectric loss as explained and subtracting this rise from T_0 in equation (16).

For the case of single-conductor cables, the first term of formula (14), should be divided by 2 for this purpose, since it has been shown⁹ that the temperature rise of the conductor above the sheath of a single-conductor cable is *half* as great for a given dielectric loss as for the same loss in the conductor.

INDUCED SHEATH CURRENTS

In the case of single-conductor cables bonded at both ends, the heat due to the flow of induced currents in the sheaths may have considerable effect upon the current-carrying capacity. The additional heat is generated in the sheath and therefore does not affect T_A , but does increase the T_n and T_c rises directly. If the total effective resistance due to sheath currents be calculated by a standard formula¹⁰ and the conductor resistance at the desired temperature be known, the allowable current may be calculated conveniently by increasing the second and third terms in (14) by the ratio of the total effective resistance to the conductor resistance. (See Example 4 in Appendix B).

DIFFERENT TYPES OF CABLE IN THE SAME DUCT BANK

Formula (16) refers specifically to the case where all the cables in a duct line are exactly the same. In practise, a duct bank often contains cables of different sizes and voltages, and this formula does not apply. For the case of two different types of cable in the duct bank, a formula giving the allowable current for one type in terms of the dimensions of the two types has been derived, but it is rather formidable looking, and the following method may be easier of application. Find the allowable rise for each type of cable by sub-

tracting the temperature of the earth from the allowable temperature of the insulation according to the A. I. E. E. rule. Express the total rise symbolically in terms of the unknown allowable watts per foot loss and the known thermal resistances. In each case, equate the total temperature rise to the allowable rise and obtain two equations for the two unknown watts per foot loss. These two equations are easily solved and the allowable watts for each type will be obtained. Note that the total rise for one type of cable is equal to the $I^2 r$ watts of that type times the total thermal resistance from (14), plus the duct rise due to the other type of cable which will equal NH times the watts per foot of cable of the other type. Both watts are of course equal to $n I^2 r$. r , the conductor resistance per foot being known, the only unknowns will be the currents which may be solved from the watts. (For illustration see Example 2). The method will of course apply to any number of types of cable.

The effect of dielectric loss may be included by subtracting the temperature rise due to dielectric loss in each type from the allowable temperature for that type. The effect of induced sheath currents may be included by multiplying the terms in equation (14) corresponding to T_n and T_c by the ratio of total effective resistance to conductor resistance.

CONCLUSION

Inasmuch as the values of the geometric factor derived herewith are checked so closely by Atkinson's experimental values, it is believed that it may be stated confidently that the geometric factor, three conductors against the sheath, is known to an accuracy of 1 or 2 per cent, which seems quite sufficient since multi-conductor cables are actually not homogeneous due to the fillers. If it is desired to use a formula rather than to read the value from curves, formula (7) is by far the most accurate for three-conductor cables and (8) is fairly accurate for most practical n -conductor cables, up to $n = 4$ at least. Both are quite simple and can be easily calculated by slide rule. Of the older more standard formulas, Mie's is much the most accurate, especially in its condensed form, and this has been recognized in this country by Powell¹¹ in his work on current-carrying capacity.

The data of the present article have been expressed in terms of a "geometric factor." Atkinson's data are given in terms of charging current and Sacchetto's in terms of capacity. The data might equally well be given in terms of insulation resistance, dielectric loss, or even thermal resistance. In whatever form the data are given, formulas may be written with equal ease by which all the other quantities can be determined. The difficulty is, however, that such formulas, while mathematically correct, tend to give a false physical conception, such for instance as a formula for temperature rise in terms of charging current. The geometric factor

has been introduced in order that all the formulas may be written directly in terms of the fundamental specific qualities of the insulation and a factor which is purely dimensional.

The writer would like to emphasize here that no possible criticism is offered of Mie's or Russell's formulas, not only because both writers have carefully stated the limitations of their formulas, but also because he is an admirer and constant user of the latter's works in general and of this particular article of the former. His desire has been to show the magnitude of the errors which will occur if the formulas are used outside of the range for which they were intended, and to determine an alternative formula which will apply to the case of the more usual cables.

Appendix A

GEOMETRIC FACTORS OF THREE-CONDUCTOR CABLES FOR OTHER CONNECTIONS

In the body of this article the geometric factor three conductors against the sheath is the only one which has been considered, inasmuch as this is the only one of interest in connection with heat flow. When calculating dielectric losses and capacity, however, it is necessary to know the geometric factor under three-phase voltage, as well as under other connections, and while this has no direct bearing on current-carrying capacity, (except for the calculation of dielectric losses) it is so related to the geometric factor itself that this phase of the matter seems to have a proper place in this appendix. The geometric factor under three-phase voltage will first be discussed and then formulas will be given to obtain the geometric factor for the other connections in terms of the two geometric factors already obtained, all for three-conductor cables only.

GEOMETRIC FACTOR UNDER THREE-PHASE VOLTAGE

The usual formula for the geometric factor under three-phase voltage is given by Russell in a form which may be expressed as follows:

$$\log_e F_2 = \log_e \left[\frac{3 a^2}{r^2} \cdot \frac{(R^2 - a^2)^3}{R^6 - a^6} \right] \quad (17)$$

In order to simplify the constants in the formulas to be given, we will define the *geometric factor under three-phase voltage* as $(3/2) \log_e F_2$, symbolized as G_2 . As in the case of Russell's formula No. 1 for the geometric factor three conductors against the sheath, formula (17) was obtained by the method of images, and it has not been possible to graphically correct the errors. This formula is theoretically correct only for the case of small conductors far apart, and it seems worth while to investigate the magnitude of the errors for the case of the usual practical cables.

While no graphical correction has been devised, it is possible to calculate this geometric factor also from the experimental work of Atkinson and Sacchetto. In Fig. 4 are plotted the geometric factors for cables with

equal belt, belt equal to half the conductor insulation thickness, and no belt, as calculated by Russell's formula, and as obtained from Atkinson's data. The three points obtained by Sacchetto within the range of practical cables are also shown by points surrounded by circles.

Fortunately Russell's formula for the geometric factor under three-phase voltage gives values much closer to the experimental values than his formula for the geometric factor three conductors against the sheath, though the per cent error becomes fairly large

for small values of the ratio $\frac{T+t}{d}$. As in the case

of his formula for the geometric factor three conductors against the sheath, Russell's curves do not pass through the origin, but they come much closer in this case than in the former. It might be mentioned that one of Atkinson's points seems to be in error, namely his curve for 14 milliamperes, and since a continuous curve could

FIG. 4—THE GEOMETRIC FACTOR OF THREE-CONDUCTOR CABLES, UNDER 3-PHASE VOLTAGE

The full lines are from Atkinson's Experimental Data.

The broken lines are calculated by Russell's Formula.

The three points surrounded by circles are from Sacchetto's Experimental Data.

The dot-dash lines are an interpolation between zero and Atkinson's lowest point.

not be drawn including data from this curve, this one value has not been included in the curve shown.

Since Atkinson's experimental data for the geometric factor between three conductors and the sheath has been so closely checked by the geometric method shown in the body of this article, and since his curves approach Russell's curves in the region where they should, it is believed that his data may safely be taken as correct for this geometric factor. Further evidence of Atkinson's correctness is that two of the three points obtained by Sacchetto shown in Fig. 4 fall exactly on his curve, the other point being not far off. Sacchetto's other two points (not shown) are for values of

$\frac{T+t}{d}$ much larger than ever found in practical cables and where Russell should be accurate; they do not seem to be as close to Russell's values as would be expected.

From Table I, $G_1 = 1.76$ [or 1.77 by formulas (7) or (8)]. Now $T_0 = 85 - 25 = 60$ deg. cent. Assume $T_c = 20$ deg. cent. $A = 211,600$ circular mils, $n = 3$, and $N = 4$. Therefore from formula (14'),

$$R_{th} = \frac{4.44 \times 1.76}{3} + \frac{4.93}{2.85} + 4 = 8.34$$

thermal ohms per foot

By (16)

$$I = 0.281 \sqrt{\frac{211,600 (60-20)}{3 \times 8.34}} = 164$$

amperes per conductor

Example 2. A duct bank contains four three-conductor cables, 1/0 A. w. g. round, insulated with 9/32 inches plus 9/32 inches impregnated paper, 9/64 inches lead, for 25,000 volts working pressure, and five two-conductor cables (round duplex) 500,000 circular mils round, insulated with 3/32 inches plus 3/32 inches impregnated paper, 9/64 inches lead, for 4000 volts working pressure. What are the allowable currents?

We will call the first cables Type No. 1, and the latter Type No. 2. The earth temperature will be taken as 20 deg. cent. The following are the constants, T_0 being equal to 85 minus the working pressure:

	No. 1	No. 2
$\frac{T+t}{d}$	1.51	0.23
t/T	1.00	1.00
G_1	2.43	0.81
n	3	2
N	4	5
D	2.86	2.48
T_0	60	81
A	105,500	500,000

The thermal resistances for the two types separately are 9.33 and 8.79 thermal ohms per foot by (14').

Let W_1 and W_2 be the allowable watt losses per foot, and I_1 and I_2 the allowable currents.

$$\text{Then } \begin{cases} 9.33 W_1 + 5 W_2 = 60 - 20 = 40 \\ 4 W_1 + 8.79 W_2 = 81 - 20 = 61 \end{cases}$$

$$\text{Solving } \begin{cases} W_1 = 0.75 \\ W_2 = 6.60 \end{cases}$$

$$\text{But } \begin{cases} W_1 = 3 I_1^2 r_1 \\ W_2 = 2 I_2^2 r_2 \end{cases}$$

the numerical coefficients at the end being necessary to include the number of conductors in the cable, if r is the resistance per foot of conductor. r_1 and r_2 may be calculated from resistance tables and are 0.000118 and 0.0000267 ohms per foot respectively at the operating temperatures, including increases of 2 per cent for stranding and 2 per cent for cabling. Therefore

$$I_1 = 46.1, \text{ and } I_2 = 352 \text{ amperes per conductor.}$$

Example 3. What is the dielectric loss in a three-conductor cable, 350,000 circular mils sector, insulated with 19/64 inches plus 7/64 inches paper, 9/64 lead for

33,000 volts working pressure, 60 cycles, assuming a permittivity of 3.3 and a power factor at operating temperature of 0.015?

$T = 0.297$ inches, $t = 0.109$, $d = 0.681$, $t/T = 0.37$, $(T+t)/d = 0.597$. From Fig. 4, $G_2 = 2.63$ [or 2.68 by formula (18)]. Diminishing the latter by 10 per cent, because the conductors are sector-shaped $G_2 = 2.37$. By formula (22), Dielectric loss

$$= \frac{0.000958 \times (33/\sqrt{3})^2 \times 60 \times 3.3 \times 0.015}{2.37}$$

$$= 0.43 \text{ watts per foot.}$$

Example 4. As a final example, the case of a current-carrying problem including dielectric loss and sheath loss will be given. Find the kv-a. carrying capacity of a line composed of four single-conductor cables (one being a spare) to operate at 110,000 volts, three-phase with the neutral grounded, the frequency being 60 cycles. The conductors are 400,000 circular mils, insulated with 40/32 inches impregnated paper, 5/32 inches lead. The cables are arranged in the vertices of an equilateral prism, the distance between centers of cables being 6 inches, and they are bonded at both ends at least. It will be assumed that $k = 3.3$ and that the power factor of the insulation is 0.015 at the operating temperature. $T = 1.25$ inches, $d = 0.728$ inches, and the outside diameter of the cable, $D = 3.54$ inches. The geometric factor, $\log R/r$, therefore equals 1.49. There are three loaded cables in the duct, and therefore $N = 3$, and of course $n = 1$. The allowable temperature will be taken as 50 deg. cent., and the earth temperature as 20.

By formula (22), the dielectric loss is 0.86 watts per foot of cable, remembering that for single-conductor cables, the constant of that formula must be divided by 9. The total thermal resistance for dielectric loss, conductor to base, by (14') equals 7.7 thermal ohms per foot, the first term in (14') being divided by 2, as stated in the text, for single-conductor cables. The temperature rise due to dielectric loss is therefore $7.7 \times 0.86 = 6.6$ degrees.

The additional effective resistance due to induced sheath currents is (by Clark and Shanklin's formula) equal to 0.0108 ohms per 1000 feet, figuring the lead resistance at 30 deg.; the conductor resistance itself calculated at 50 deg. and increased 2 per cent for stranding is equal to 0.0295 ohms per 1000 feet. The ratio of total effective resistance to conductor resistance is therefore 1.37.

Formula (14') may now be applied as follows: $R_{th} = 4.44 \times 1.49 + 1.37 \times 4.93/3.54 + 1.37 \times 3 = 12.6$ thermal ohms per foot. Therefore from (16),

$$I = 0.281 \sqrt{\frac{400,000 (50-20-6.6)}{1 \times 12.6}} = 242$$

$$\text{amperes per cable.}$$

Thus the vacuum dielectric begins to leak when the electrodes are hot enough. It is now well known that the electric gradient across the space is not uniform under these conditions, and that a space charge is produced. Space charge is a very common term now. This space charge is nothing but a charge soaked into the vacuum dielectric. The transient in establishing this space charge is very rapid due to the high velocity with which electrons move in vacuum, but it still is an absorption transient, such as this paper describes for cables. Nevertheless the vacuum is homogeneous.

Passing to the case where we actually have matter, the next case in the order of difficulty would be conduction through a gaseous dielectric. We can make a gaseous space between electrodes conducting by means of an ionizing agent. This might be a source of X-rays acting uniformly on the gaseous space or ultra-violet radiation acting on the electrodes. The distribution of gradient and charge for this kind of conduction is fairly well known. I think Mie was one of the first analysts who worked it out, and you will find his work described in J. J. Thompson's "Conduction in Gases." When current flows across a uniformly ionized air space, the gradient again is not uniform, but again space charges are produced. These space charges may be called soaked in, or absorbed charges, if you like. Again the transient in establishing such charges is of very short duration because the ions in gases also move very rapidly, but the transient exists nevertheless in spite of the homogeneity of the gaseous space.

In solid and liquid insulations the carriers of the current probably move with very slow velocity so that the time in establishing the stored up charges will be relatively very long. I do not happen to know definitely that you do get absorbed charges in strictly homogeneous liquid or solid dielectrics, but I strongly suspect that that is the case.

I do recall that in some respects the conductivity in some homogeneous dielectrics is similar to the conductivity in gases. For example, with the same gradient larger leakage may be obtained with the electrodes far apart than when close together. This shows that dielectrics do not have a simple ohmic resistance, and it seems to me that even in a homogeneous medium space charges or soaked-in charges may be produced, resulting from the nature of conduction in the dielectric.

D. E. Howes: The labor involved in obtaining reliable dielectric strength values for such a large number of conditions is enormous—a fact, which will be concurred in by all who are familiar with insulating materials.

The results in the Hayden and Eddy paper bear out the fact, which the practical engineer should consider an axiom,—that the most satisfactory test which can be given a commercial machine or material is that which corresponds most nearly to the conditions under which it is expected to be used. Short cuts should be carefully investigated before being adopted, as was wisely done by the writers of this paper. I can take no exception to their experimental procedure or results obtained. Further, I do not intend to attempt to fully explain the reasons for some of their observations. It would be, perhaps, impossible and at any rate hardly worth while. What I do wish to point out is that, from theoretical considerations alone, it is fundamentally wrong to expect any very simple or reliable dielectric strength ratio as defined by the authors of this paper, at least for practical insulating materials.

Let us borrow again Maxwell's conception (*El. & Mag.*, Vol. 1, page 453) of a composite dielectric, a conception which has proven so valuable and so actually real.

Consider two adjacent elements or strata of dielectric in series, located any place you please in a composite dielectric, whose specific inductance capacities, specific resistances are respectively denoted by K_1 , K_2 and ρ_1 , ρ_2 .

Suppose a direct voltage be applied to the outer surfaces. It will divide between the two dielectrics so that the potential gradients will be in the ratio of ρ_1 and ρ_2 . If, however, the volt-

age is changing rapidly, either pulsating or alternating, the voltage gradients in medium 1 and 2 will be in the ratio of K_2/K_1 .

Suppose $\rho_1/\rho_2 = 1$, $K_1/K_2 = 2/4$. Then for direct voltages the gradients in the two media would be equal. For a rapidly changing voltage, the gradients in 1 and 2 would be in the ratio of 2/1 and we would expect medium 1 to fail prematurely, so that in this case the maximum value of the alternating voltage breakdown might be less than for direct voltage, unless of course, it had a much greater dielectric strength. Thus, the distribution of stress may be widely different, even though the total voltage applied be the same. With a different stress distribution throughout the insulating material, we would expect the dielectric strength to be different. Only the most homogeneous material could be expected to have a dielectric strength ratio of unity. It would be reasonable to expect that it would not vary widely for a uniform grade of material subjected to a uniform test. For this reason, direct voltage may have a limited application where its significance, relative to alternating voltage test values, has been predetermined.

It is evident that ρ_1 and ρ_2 will not vary with temperature according to the same law. Continuing, with reference to the above conception and its extension by Maxwell to account for absorption or residual charge, it is obvious that if the rate of change of voltage be very slow in comparison with commercial frequencies the relative potential gradients in different component parts of the dielectric may be determined partly by the specific resistances of those components. In other words, let us ask this question,—What is the rate of change of potential that determines whether the relative gradients shall be according to K_2/K_1 , or as ρ_1/ρ_2 ? Is there a sharp dividing line?

In view of the well known phenomenon that a condenser exhibiting absorption does not become fully charged for quite an appreciable time, it seems reasonable to expect that there is no sharp dividing line, but that both factors contribute, and the relative importance of each will depend upon the rate of change of voltage. When the rate is very slow, the specific resistances of the component media are dominant in effect while, when the rate is rapid, the specific inductive capacities control. Thus, it is evident that the dielectric strength ratio has little meaning unless we specify very closely the rate of application of voltage.

When we consider the fact that nearly all practical solid insulating materials are composite, and analyze how they should behave under different types of fields, we must realize how little real additional information concerning dielectric behavior this so-called dielectric strength ratio actually tells us. It is realized that, on the whole, the phenomena are not as simple as explained, but I believe that in general the theoretical considerations are very well born out by the experimental data given in the authors' paper. For obvious reasons, then, I do not think that direct voltage should be employed for testing insulating materials which in service are to be subjected to alternating potentials, where the dielectric strength is to be determined. Direct voltages lower than this, however, should be useful in routine cable testing to indicate any gradual changes in their quality.

I am of the opinion that we should not draw any new conclusions as to the ultimate nature of a dielectric breakdown from the consideration of this paper. Aside from known effects of temperature etc. I believe insulation failure is dependent upon the maximum voltage attained for an appreciable length of time, regardless of its form. The ultimate cause of breakdown is doubtless, cumulative ionization, although this itself is influenced by numerous other factors.

In conclusion, I wish to express the opinion that the real nature of the mechanism of dielectric failure will not be found by any commercial or practical engineering tests that we may devise but by indirect methods. By this I mean that we should study it from a purely scientific viewpoint to determine the location and behavior of an electron in it.

D. M. Simons: I have just come across a recently published article which bears so directly upon the papers by Dr. Steinmetz

and Messrs. Hayden and Eddy that I thought it might be interesting to mention it briefly, particularly one test that was made. I am referring to an article by Grünwald entitled "The Breakdown Strength of Solid, Laminate Insulating Materials with Various Types of Electrical Stress," (*Archiv für Elektrotechnik*, 1923, Vol. XII, p. 79). Grünwald performed breakdown tests on insulation not only with alternating and continuous voltages but with various types of impulse. He did not show the effects of different rates of applying the voltage, or of different temperatures, but his work is of interest on account of the variety of impulses impressed on the insulation. His tests were mostly upon mica, and unfortunately no tests were made upon impregnated paper. Grünwald includes also a mathematical section, and while he does not obtain a solution for n -layers, he obtains an equation for the voltage distribution across two layers of insulation as a function of time, and it is interesting to note that this equation (13) can be transformed to agree with Steinmetz's equation (18).

Before proceeding to describe what I believe is the most interesting test made by Grünwald, I would like to ask if any breakdown tests have been made upon a dielectric which already contains residual charges. We might consider the case of a dielectric which has widely different breakdowns for slowly applied and rapidly applied voltages. Dr. Steinmetz has very clearly explained that the difference in breakdown strength is due to the fact that for the rapidly applied voltage the voltage distribution is determined by the relative permittivities of the layers, while for the slowly applied voltage the resistivity is the determining factor. My particular thought is what would happen if a continuous voltage close to but below the breakdown voltage was impressed on this dielectric until the residual charges had completely soaked in, and a rapidly applied voltage was then impressed on the dielectric. It seems to me that in this case the voltage distribution would be determined by the internal charges and would be according to resistivity, and the ratio of d-c. to a-c. breakdown would be reduced to or toward unity.

Grünwald did not perform this test, but he did the opposite. That is, he performed breakdown tests on condensers which had previously been charged in a direction opposite to the final test voltage, and he found that this had a very great effect in lowering the breakdown strength. As far as I can determine he broke down the previously charged condensers with single steep-front impulses only, and found that in general for this type of surge, the breakdown value was about *halved* if the condenser was previously charged in the opposite direction.

It seems that breakdown tests on dielectrics which have previously been charged in either direction may throw additional light on the fundamentals of the behavior of solid dielectrics.

Herman Halperin: In his opening remarks, Dr. Steinmetz made some comments about the relative slow progress that has been made in the art of insulation. I think these papers are a definite step in the progress that seems to be needed. The first two papers deal with stresses and the last with heat conduction through complicated structures of conductors and insulations such as multi-conductor cables.

In Dr. Steinmetz' paper, he refers to the decrease in the internal transient current and gives an example which indicates a ratio of about 20 to 1. In some tests made in Chicago on long underground lines, we find that the final current was as small as 1/150th or 1/200th of its initial value. If we tried to find the equation for this decrease of current against time by using an equation with one transient, we would obtain a curve which would hold only for the data taken for one minute or so; and it was during the first minute of the test that the decrease in current was very rapid. Perhaps it would be necessary to use another transient term, as Dr. Steinmetz points out, in order to equate the entire curve.

In connection with the d-c. a-c. ratio, after we do find just what is exactly the ratio for one kind of electrical apparatus, for instance, underground cable, it would still seem necessary to

discover it for joints connected with the cable. This further complicates the situation because we might secure a dielectric strength ratio of 1.78 for one cable and probably something different for the joints; and in making a test the whole line has to be subjected to the voltage at one time.

In Mr. Simons' paper, he has, I think, done a great deal in showing how accurately the thermal resistivity of a complicated arrangement of conductors and insulation can be determined. In the appendix, he shows that his more correct method would indicate an error of about 20 per cent in some results which were published by a research committee in England; so these accurate methods greatly help correlate the various researches.

Mr. Simons deals mostly with the determination of the geometric factor. But, of course, for the installed cable in this country, there are other very important factors in heat dissipation such as H , the thermal resistance of the earth per foot of duct, and the resistance of duct structure itself. While there may be variations for the thermal resistivity of insulations of as much as about 50 per cent, the heat dissipating ability of the duct structure and surrounding soil may vary several hundred per cent. A large percentage of the total drop from copper to the base soil temperature is through the soil and duct structure and there is a great deal of work to be done in this field.

H. B. Dwight: Mr. Simons has made a distinct advance in the calculation of the geometric factor of multi-conductor cables and has produced by his graphical method more accurate results

FIG. 1

than were available before. The publication of this graphical method, however, brings up at once the question whether a direct and accurate mathematical calculation cannot be made. This would be especially desirable in the present case, for the graphical method, besides having the errors of measurement inherent in any graphical method, has the theoretical approximation in that the flow lines are not those pertaining to true circles, a fact which is pointed out in the paper.

A graphical method was justified because the formulas which had been published for multi-conductor cables were all approximate, since they assumed that the electric charge on each conductor was equivalent to a charge concentrated at a point of the section of the cable. This, however, gives rise to equipotential surfaces which are not circular, and so cannot coincide with the surfaces of the round wires or cables.

It appears that practically all formulas for capacitance have been based on charges concentrated at points, or uniformly distributed along lines or over surfaces. This is true, at any rate, of the published formulas for multi-conductor cables. Clark Maxwell states in Chapter 7 of his book on Electricity and Magnetism published in 1873 that every electrical problem of which we know the solution has been constructed by the inverse process of finding the shape of the conductors from the potential due to assumed charges of electricity. He also states that the only method by which one can expect to solve a new problem is by reducing it to one of the cases in which a similar problem has been constructed by the inverse process. Maxwell's statement has been quoted in fairly recent articles, and the limitation which he gives that the inverse process must always be used and that one cannot start with an assumed shape of conductor seems to hold in the most recent calculations of capacitance. A general method which would correctly use the direct process of starting with given shapes of conductors would therefore be very useful.

I wish to present an accurate method using the direct process of calculation of capacitance and geometric factor of multi-conductor cables. This method consists in first assuming a uniform charge on the surfaces of the round conductors and their images. From this the resulting charge at any point of the conductors can be calculated. This may be called the first additional charge, and it is in the form of a Fourier series, that is, a series involving $\cos A$, $\cos 2 A$, $\cos 3 A$, etc. The cosines often disappear when integrated around the circle. The second additional charge can now be calculated, resulting from the first additional charge, and so on, until the terms become small.

This method has been used to determine the capacitance of a single-phase overhead line, and the result for a given example agreed with the result by the standard hyperbolic cosine formula to six significant figures. The formula for a two-conductor cable is given herewith. That for a three-conductor cable is longer.

Capacitance of two-conductor cable

$$= \frac{1}{2 \log F_c}$$

$2 \log F_c$

$$= \log \frac{(s-a-u)(s-a-r)(s+a-u)(s+a+r)}{ru(2a+r)(2s-u)}$$

$$+ \sum_{n=1}^{\infty} \frac{L_n}{n} \left[1 - \left(\frac{r}{s-a-u} \right)^n - \left(\frac{-r}{s+a-u} \right)^n + \left(\frac{-r}{2a+r} \right)^n \right]$$

$$- \sum_{n=1}^{\infty} \frac{M_n}{n} \left[1 - \left(\frac{u}{s-a-r} \right)^n - \left(\frac{u}{s+a+r} \right)^n + \left(\frac{u}{2s-u} \right)^n \right]$$

$$u = \frac{R^2 r}{a^2 - r^2} \quad s = \frac{R^2 a}{a^2 - r^2}$$

$$A_n = \left(\frac{r}{s-a} \right)^n - \left(\frac{-r}{2a} \right)^n + \left(\frac{-r}{s+a} \right)^n$$

$$F_n = - \left(\frac{u}{s-a} \right)^n + \left(\frac{u}{2s} \right)^n - \left(\frac{u}{s+a} \right)^n$$

$$B_n = - \left(\frac{r}{s-a} \right)^n \sum_{k=1}^{\infty} \frac{1/n+k-1}{1/n-1/k} \left(\frac{u}{s-a} \right)^k F_k$$

$$- \left(\frac{-r}{2a} \right)^n \sum_{k=1}^{\infty} \frac{1/n+k-1}{1/n-1/k} \left(\frac{-r}{2a} \right)^k A_k$$

$$- \left(\frac{-r}{s+a} \right)^n \sum_{k=1}^{\infty} \frac{1/n+k-1}{1/n-1/k} \left(\frac{u}{s+a} \right)^k F_k$$

$$G_n = - \left(\frac{u}{s-a} \right)^n \sum_{k=1}^{\infty} \frac{1/n+k-1}{1/n-1/k} \left(\frac{r}{s-a} \right)^k A_k$$

$$- \left(\frac{u}{2s} \right)^n \sum_{k=1}^{\infty} \frac{1/n+k-1}{1/n-1/k} \left(\frac{u}{2s} \right)^k F_k$$

$$- \left(\frac{u}{s+a} \right)^n \sum_{k=1}^{\infty} \frac{1/n+k-1}{1/n-1/k} \left(\frac{-r}{s+a} \right)^k A_k$$

For C_n and H_n use the same formulas as for B_n and G_n except change A to B and F to G .

For D_n and I_n change B to C and G to H , etc.

$$L_n = A_n + B_n + C_n + \dots$$

$$M_n = F_n + G_n + H_n + \dots$$

It is to be noted that the terms involve only the dimensions of the cable. The terms can be calculated with a slide rule. As there is a considerable number of these terms, the method cannot be said to be a short one.

The formula for a two-conductor cable has been used to check one of the values of geometric factor in Mr. Simons' paper within

less than one per cent. For $t/T = 1$ and $\frac{T+t}{d} = 1$ the formula gives 1.730 to compare with 1.718 given by the graphical method.

R. Notvest: In connection with the Hayden-Eddy paper, it was very interesting to note the behavior of composite dielectrics under high direct as well as alternating-current potential stresses. The authors investigated practically all important commercial insulation materials from mica, oil, glass to paper and I regret that they have not extended the scope of their investigations upon slate, for slate, a composite dielectric of great commercial importance, is the classical example of the variation of the dielectric strength ratio of a given material between direct and alternating-current potentials. Slate has a rather high insulation value for direct current, but may show considerable leakage under alternating current of such low potentials as from 1500 volts up.

I have made a number of tests which plainly showed that as far as slate is concerned, leakage under high a-c. potentials cannot be ascribed to ionization of the dielectric, but is distinctly an impedance or condenser effect. This is due to the fact that slate contains among other ingredients also around 4 per cent of metallic oxides such as ferric and ferrous oxide as well as pyrites which to all practical purposes are distributed uniformly in almost molecular form throughout the otherwise electrically inert substances. Each such particle of metallic oxide is capable of assuming a definite capacity charge under alternating potentials and is interconnected with the others through an ohmic resistance of relatively high value, the 0.2 to 0.5 per cent of carbonaceous matter which slate contains. Impedance leakages actually measured on a number of various samples which were afterwards chemically analyzed, showed that variations of the metallic oxide content, that is, the capacity effect or the ohmic resistance, that is, the content of carbonaceous substances in graphitic form, corresponded very closely to estimated results based on Dr. Steinmetz formulas of a condition of a circuit having capacities and ohmic resistances in series. I am convinced that additional research on slate would produce valuable data and would give an insight of the stress distribution in composite dielectrics and the very pertinent problem of insulation in general.

Mr. Davis: Mr. Simons' paper and the formulas contained therein will undoubtedly be of inestimable value to engineers in calculating current capacities. His errors of twenty per cent of the approximate formula (I think he said twenty) and the errors published in the JOURNAL of the Institute of Electrical Engineers can hardly be considered serious when we think of the possible errors we have in the thermal resistance of this material.

I merely wanted to call attention to the fact that thermal resistivity as published by the Institute showed variations of approximately from 350 to 1250 watts per centimeter cube, per degree centigrade. Tests that we have made but not completed showed variations running from 300 watts per centimeter cube per degree centigrade to 1800. In other words, we have a variation there of about six hundred per cent. Now, the application of any of these formulas for calculation of temperature rises depends absolutely upon the use of some of those constants which really have wide variance. Consequently it gives an error of twenty per cent. That is small when the amount of thermal resistance varied about six hundred per cent.

C. F. Hanson: Referring to Table I of the paper by Hayden and Eddy the data given for impregnated cable paper are very interesting, particularly the data given for a rate of voltage rise of 5 per cent per second. The dielectric strength ratio of one paper at 25 deg. cent. is 1.343 when the rate of voltage rise is 5 per cent per second whereas the ratio of one paper at the same temperature is 2.470 when the rate of voltage rise is 20 per cent per second. One ratio is twice the other. This difference indicates that a cable of good dielectric qualities

Consider the influence of thickness on the ratio. Take dry cable paper, four layers, 20 per cent per second voltage rise, the ratio is 1.790 and for 32 layers 1.085, a drop of 39.4 per cent in terms of 1.790 for a change in wall thickness from 0.8 mm. (31.4 mils) 6.4 mm. (252 mils). As we test thicknesses greater than 6.4 mm. (252 mils) it appears we may get ratios less than one for the greater thicknesses and again 1.773 is unfair.

Referring to the rate of voltage rise, we note that a rate of increase of 0.1 per cent per second gives the lowest values for the dielectric strength ratio. This rate is equivalent to taking 16.7 minutes to bring the voltage up to cause breakdown. This is a slow rise and is almost comparable to a constant voltage test. Some of the values of the ratio for dry cable paper are slightly above but the average of all values shown give a value below 1.

When we study the results obtained for impregnated cable paper we find values of ratio above and below 1.773 not consistent, the range being from 2.775 to 1.238. In view of the wide range in value of ratio it doesn't seem possible we have a right to average all values and take this average as representing the ratio for impregnated cable paper because it is the average of several variables for which the ratio itself is quite a variable.

Tables II and III also show that the ratio is different for each kind of insulation and departs considerably from 1.773.

As the paper shows that in the data reported the ratio of direct voltage breakdown to maximum value of alternating voltage breakdown is different for each kind of insulation, we should not establish a general value of direct voltage in terms of alternating voltage for insulation testing but give a value of each type of insulation.

Aside from considering that in some cases much greater value of direct voltage than alternating voltage is necessary to cause breakdown on constantly rising voltage, let us consider the effect of the long time application of the high direct voltage on the possibility of weakening the insulation.

Referring to the Fig. 2, $A B C D E$ is one cycle of an alternating voltage sine wave. Let us assume that the insulation is under effective electric stress, for one fortieth of the time each side of the maximum, that is we will consider the insulation as being stressed for test purposes as soon as the voltage reaches the instantaneous value corresponding to 99.7 per cent of the maximum value and lasts until the voltage again reaches this value when decreasing. This is shown by the curve $b B c$. The line $F B G$ represents a direct voltage equal to the maximum value of alternating voltage. The line $H K$ represents a direct voltage 1.773 times as great as the maximum value of direct voltage. The area $a b c d$ represents the product of alternating voltage and time of application and may be taken as a measure of the stress under alternating voltage. Likewise the areas $A F G C$ and $A H K C$ represent the product of direct voltage and time of application for the respective voltages.

These areas are a measure of the relative stresses which the insulation is subject to. Although we cannot say, two equal areas, one having twice the voltage of the other, give the same effective stress, still on a time basis for the sake of discussion we can say the net effect is the same. Taking this viewpoint and calling the area $a b c d$ unity, then the area $A F G C$ is 12.73 and the area $A H K C$ is 22.6. This means the voltage time stress is 12.73 times greater for a direct voltage equal to the maximum value of alternating voltage and 22.6 times as great for a direct voltage 1.773 times the maximum value of alternating voltage. Referring to the results which have been obtained by Messrs. Hayden and Eddy this may be a serious problem for some kinds of insulation and result in weakening of the insulation.

Another source of possible weakening of the insulation is the value of dielectric stress resulting from the high direct voltage test. The stress equivalent to the maximum value of alternating voltage is not great enough to permanently weaken the insulation without chance of recovery. It may so happen that the stress equivalent to the direct voltage will be sufficiently great to permanently damage the insulation, yet not cause it to breakdown and the usefulness of the insulation greatly lowered as a

result. If a lower value of voltage had been used, possible sources of weakness would have been found, and yet the insulation have a high factor of safety.

I am a believer in direct voltage testing of insulation and look forward to the time when manufacturers and users of insulating materials will consider it as the routine method of test. However, today this method of test is purely in the formative stage and all the above questions should be seriously considered before we attempt to establish standards for the testing of insulation with direct voltages.

W. N. Eddy: Mr. Hanson brings out two points on which we would like to comment. He thinks that the increase of ratio caused in one case by increased rate of voltage application, indicates that a cable of good dielectric qualities might be damaged by the application of direct voltage at too slow a rate. We feel that such a change of the ratio rather indicates that the ratio of an insulation should not be specified without including the rate of voltage application. In fact, one of the principal points we tried to bring out in the paper was that a d-c.—a-c. ratio is meaningless unless accompanied by such factors as the rate of voltage application, the temperature, the type and shape of the insulation, etc.

He also attempts to draw definite conclusions from a comparison of two breakdown voltages and two ratios. In view of the well known difficulty of obtaining consistent breakdown data on insulation, we believe that such a practise should be avoided, and that in analyzing a collection of breakdown tests, the various values should be considered together, weighed against each other, and only general tendencies noted.

D. M. Simons: I am particularly gratified if I have been in any way instrumental in inducing Mr. Dwight to develop his formulas for the geometric factors of multi-conductor cables. When his formula for the geometric factor of three-conductor cables is available, this phase of cable engineering will apparently have received its final answer.

Several very interesting papers on the subject of the carrying capacity of cables have been published abroad at about the same time as the present paper. The Second Report on the Research on the Heating of Buried Cables¹ is an exceedingly important contribution to our knowledge of most phases of this subject. It is noted incidentally that the errors in the calculation of thermal resistivities in the first Report mentioned in Appendix C have been corrected. It is also very interesting to see that the geometric relationships of three-conductor cables were investigated both experimentally and by a graphical method. The graphical method, which is entirely different from the present one, checks my values about as closely as can be determined from the large scale graph on which the English data is plotted.

Another interesting contribution is "The Heating of Paper-Insulated Power Cables" by Sacchetto². I believe that there should be some word to express the form factor or geometric modulus to take care of the dimensions of the cable in numerical calculations. I have suggested the term "geometric factor" for this purpose. I was not entirely sure that this was the best term, although it seemed sufficiently appropriate and was certainly more concise than some expressions that have been used, such as "number equal to the capacity if the S. I. C. were unity," etc. Sacchetto confirms my choice by calling a similar term a *fattore geometrico*. His geometric factor is $2/n$ times the writer's. Sacchetto also mentions the fact that Picou³ called a corresponding factor in cable formulas the *facteur geometrique*.

I am very glad that Mr. Halperin has emphasized the possibility of errors due to the duct rise in calculating the allowable current. There is undoubtedly a great deal to be done on this section of the thermal path before we can accurately calculate in advance the temperature rise of cables.

Some Engineering Features of the Weymouth Station of The Edison Electric Illuminating Co. of Boston

BY I. E. MOULTROP

Member, A. I. E. E.
Edison Electric Ill. Co., Boston

and

JOSEPH POPE

Stone & Webster, Inc.

Review of the Subject.—The new power station of The Edison Electric Illuminating Company of Boston, now under construction on the Weymouth Fore River is expected to have an ultimate capacity of about 300,000 kw. The present construction covers the installation of two 32,000 kw. generating units with three 1974-h. p. boilers, operating at 375 lb. steam pressure and 700 deg. Fahr. In addition, a single boiler to carry steam at pressures up to 1200 lb. is to be installed. This boiler will have about the same heating surface as the normal pressure boilers. The steam generated by it will pass through a pressure reducing turbine developing about 2000 kw., and will be exhausted at 375 lb. pressure. After being reheated to the original temperature of 700 deg. the steam will be piped to the main header and used in the large turbines. If satisfactory results are obtained from the higher-pressure boiler-turbine units more of them will be installed. Three will be required to furnish sufficient steam to operate one of the 32,000-kw. units.

The maximum steam temperature was fixed at 700 deg. in consideration of the properties of materials at the higher temperatures. While the theoretical gain from higher pressure increases up to the maximum for which any data are available, the full benefit of the thermodynamic possibilities are not at present obtainable in practice without reheating the steam at some point intermediate between the throttle and the condenser. Without reheating, the most advantageous steam pressure, both practically and economically considered, seems to be about 375 lb. gage. With reheating, it appears that about 1200 lb. is a practicable initial pressure, and that 375 lb. is an entirely satisfactory pressure at which to reheat. Accordingly a combination of these two pressures with intermediate reheating has been adopted; the higher pressure with a view to developing its possibilities, the lower pressure with the feeling that it represents the best practice in the single expansion cycle and that operation solely at that pressure will give highly economical results. The character of the future development of the plant will depend upon the relative performance of the two classes of equipment.

Feed water is to be heated by two-stage bleeding of the main units and by economizers. All normally running auxiliary equipment is to be driven by alternating-current motors. Power for

driving the essential auxiliaries is to be supplied from a 2300-volt alternator of 2500 kv-a. capacity connected directly to each 30,000-kw. main generator shaft, and thus driven by the main turbine, which will have sufficient capacity for driving both generators at full load. This arrangement is expected to give a combination of greater economy and security than any heretofore used.

The switch house will be a separate structure, four stories and basement. The upper floor will carry the switchboard and the switch operating mechanism. The three lower stories will house the bus structures, oil circuit breakers and reactors, each phase being isolated to a single floor. The basement will serve as a cable vault and all incoming and outgoing circuits will pass through it. There will be two main ring busses and a transfer bus. The ring busses will be divided into sections, each section fed by two generators and with current-limiting reactors between sections. All circuits will be connected to the busses through two oil circuit breakers in series.

No prediction is made of the expected operating performance of the station, but it is calculated that under ideal conditions, acting solely as a 375-lb. single-expansion nonreheating plant, it could produce a net kw-hr. for 15,100 B. t. u. in the fuel and as a 1200 lb. compound reheating plant, it could produce a net kw-hr. for 13,600 B. t. u. These figures show the advance in heat economy that modern developments in steam engineering have made possible and the advantage which the very high-pressure reheat cycle possesses over the more conventional design. The actual plant performance will depend among other things upon the character of the load which it is found possible to put on Weymouth Station and the relative proportion of high and normal pressure equipment that may be operated.

GENERAL FEATURES

The selected site on the Fore River in Weymouth contains about 63 acres. It is on deep water, readily accessible by large ocean going coal carriers, and has all other advantages necessary to give entire freedom in the design of a large modern station.

Fig. 1 shows the general cross-section of the station. The turbine room is to be located adjacent to the water front so that the condensing water tunnels will be direct and short. These tunnels are designed to give the same ease of flow as though they were to serve hydraulic turbines. The boiler room adjoins the turbine room on the land side and lies between the latter and the isolated building for the busses and electrical control.

The initial main generating equipment will consist of two 32,000-kw. turbines each driving a main 30,000-

IN common with many of the other public service companies serving our larger communities, The Edison Electric Illuminating Company of Boston has found its existing power stations and sites developed to their economical limits. Faced with a rapidly growing demand for service and with a broad vision into the future, it is constructing, on an entirely new site, the initial development of a station expected to have an ultimate capacity of approximately 300,000 kw.

The scope of this paper is limited to a brief description of this station and its equipment, with an interspersed discussion of such engineering features as are thought to be of more timely interest.

Presented at the Annual Convention of the A. I. E. E., Swampscott, Mass., June 26-29, 1923.

kw. generator and a 2000-kw. auxiliary generator direct-connected to the shaft of the main generator. These units will be supplied with steam at a nominal pressure of 375 lb. and a total temperature of 700 deg. fahr. There will also be one 2500-kw. high back pressure turbo-generator taking steam up to 1200 lb. pressure and exhausting into the 375-lb. system. All station auxiliaries are to be driven by alternating-current motors.

The boiler installation will include three boilers each containing 19,743 sq. ft. of heating surface, with additional superheater and economizer surface, designed for 375-lb. working pressure. There will also be one boiler, of approximately the same heating surface, which will be designed to operate at a maximum of

bridge is to carry a man trolley with bucket for reclaiming from the storage pile. A Bradford breaker will be used for crushing the coal on its way to the station.

Current will be generated at 14,000 volts, three phase, 60 cycles. It will be distributed from the station through underground circuits partly at generator voltage and partly at 25,000 volts through an adjacent outdoor transformer substation. Future transmission by overhead lines at 115,000 volts will also be provided for. The bus and switching arrangement is described later in this paper.

SELECTION OF STEAM CONDITIONS

The important bearing which the operating steam

FIG. 1—CROSS-SECTION, WEYMOUTH STATION

1200 lb. It will likewise be provided with a superheater and an economizer, and also a steam reheater to restore the temperature of the exhaust steam from the high back pressure turbine to 700 deg. before it passes into the 375-lb. system. All boilers will be fired with underfeed stokers.

The coal handling equipment will consist of two electric unloading towers, a traveling bridge spanning the storage pile, and a system of belt conveyors for transporting the coal to or from the main storage or directly from the unloading towers to the station bunkers. The conveyor for delivering the coal to the station will be about 700 ft. in length. The traveling

pressure and temperature have upon the possible maximum fuel economy of a station naturally called for an extended study of these features before reaching a decision in regard to them. When suitable economizers are employed the influence of steam pressure and temperature upon the efficiency of steam generation is negligible, but the influence of these factors upon the efficiency with which the heat in the steam can be utilized is in any case of definite importance.

The selection of the temperature at which the steam should be supplied to the turbine is almost entirely a problem of materials, as the beneficial effect of superheat, although largely indirect, continues in worth-

easier these become. For the particular situation under discussion, it was desirable to have the lower pressure portion of the plant able to function as a complete and highly economical station, so that the same considerations which control the selection of an initial pressure for the single expansion cycle were allowed to govern the choice of a reheat pressure in this case. Although it appears from Curve 5 of Fig. 2, that about 600 lb. is the most efficient pressure for a single expansion unit, cost influences make a somewhat lower pressure more economical to use. For Weymouth Station the pressure selected is 375 lb.

FIG. 2—EFFECT OF STEAM PRESSURE ON TURBINE THERMAL EFFICIENCY

HIGH PRESSURE INSTALLATION

The high-pressure boilers will normally deliver steam at approximately 1000 lb. pressure and 700 deg. total temperature, corresponding to about 153 deg. of superheat. The entire steam output of each boiler, which under the usual operating conditions will be about 110,000 lb. per hour, will pass through a simple three-stage turbo-generator where it will be expanded down to a pressure of 375 lb. The steam will then be reheated to 700 deg. in a reheater installed in the same boiler setting, and finally be discharged into the 350-lb. header serving the main turbines. It may be noted from the quantity of steam passing through each of the high-pressure turbines that three such boiler-turbine units will be required to supply one of the main 32,000-kw. turbines at the higher loads. Operating under the conditions outlined each of the high-pressure tur-

bines will generate about 2000 kw. Thus, a total of 6000 kw. will be generated in reducing the pressure of the steam required by one of the main units.

The high-pressure boilers will have tubes 2 inches outside diameter and 15 feet long. The tubes will be arranged in two banks with sufficient space between for the superheater and reheater. The drum will be a hollow steel forging 48 inches inside diameter with walls 4 inches thick. In order to maintain suitable drum strength the tubes and nipples, which commonly enter the drum in lines parallel with its axis are turned in pairs through an angle of 90 deg. so that the two enter the drum on a common circumference. Fig. 3 shows a cross-section of this boiler.

The generator of the pressure reducing units rated at 3000 kv-a. is to be of the induction type, if a suitable design can be worked out. This would avoid the necessity of separate excitation and careful synchronizing when being placed in service.

There are many new problems involved in the design, construction and operation of this high-pressure and reheating installation, but their nature is such that their solution may be confidently expected. It is recognized, however, that a considerable amount of development work will have to be done. It has therefore been decided to employ proven types of equipment for the larger part of the initial installation, confining the use of equipment which is as yet lacking commercial demonstration to a comparatively small supplemental installation of one high-pressure boiler with its turbine unit. This installation will afford an opportunity to demonstrate the general practicability of using very high-pressure steam in a re-heat cycle.

The ratio of high-pressure equipment and normal pressure equipment to be installed in the future will depend upon the results obtained from this initial installation and upon the experiences of others who are working along similar lines, or who are employing other methods for the utilization of high-pressure steam and the re-heat cycle.

Any estimate of the improvement in heat utilization to be expected from the use of very high steam pressure, is necessarily based on assumed properties of steam obtained by extrapolation of existing steam tables and diagrams, which may be subject to some correction. The calculated savings are so large, however, that it is felt that any probable error in these assumptions as to the properties of steam will have a relatively unimportant bearing.

BOILER PLANT AND FEED WATER HEATING

The normal pressure boilers, which are to deliver steam at 375 lb. and a final temperature of 700 deg. will be of the cross drum design, 48 tubes wide and 17 tubes high, with the superheaters between the tube banks. The exit gases will be further cooled by straight steel tube economizers which, with the induced draft fans, will be located above the boilers. The furnace arrange-

FIG. 3—SECTION OF 1200-LB. BOILER

ment provides for firing from the low end of the boilers. The stokers are to be of the underfeed type, with clinker grinders, there being 16 retorts per boiler. The boilers will be set with the bottom of the uptake headers 25 feet above the firing floor. They will be arranged in parallel rows with the uptake ends facing a common center aisle from which all firing operations will be controlled. The stokers, which will thus be in the side aisles, will be supplied with coal from overhead longitudinal bunkers. This general arrangement of the boiler room is the same as that of the newer portion of the Edison Company's "L Street" Station, where it has proved highly satisfactory. It provides well lighted, clean and cool working quarters for boiler room operators and locates the stokers where abundant side light and ventilation are readily obtainable.

Except for the necessary modification in details, the boiler designed for operation at 1000 lb. pressure, and previously described, will be installed in accordance with the same general plan employed for the lower pressure boilers. The stoker and furnace installation will be practically the same and no attempt is to be made to isolate this installation.

Make-up water is to be provided by evaporators and the entire supply will be deaerated.

Economizers with a heating surface equivalent to about 55 per cent of the boiler surface were chosen. This selection was preceded by a study of the following influential factors:

1. The temperature at which the feed water should leave the bleeder heaters and enter the economizers.
2. The most advantageous division of the total heating surface between the boiler and the economizer.

The capacity of the feed water to absorb heat is theoretically limited by the range between two fixed temperatures,—that of the condensate and that of the saturated steam in the boiler. The practicable range of heating is, of course, somewhat narrower. The heat consumption of the main turbine, when credited with all heat returned to the system, is unquestionably the lowest when all of the heating is done by extracted steam. On the other hand, the efficiency of the boiler plant is highest when all of the heating is done in the economizer. The best over-all plant efficiency must therefore lie in some compromise between these opposing considerations. The calculations made for the Weymouth Station indicated that the most advantageous temperature to change the method of heating was between 210 deg. and 220 deg. fahr. Practically considered this is a most desirable temperature, also, for it avoids the use of superheated steam in the extraction heaters, diminishes the possibility of external corrosion of economizers and permits adequate deaeration of the feed water.

Considering the boiler and economizer in common, it is evident that for heating the water through a given total temperature range, and with a given outlet gas temperature, there will be less total heating surface

required as the proportion arranged as counterflow economizer surface is increased. The relative cost of the two kinds of surface, however, exerts an opposing influence and necessitates a compromise. As to the boiler, its width is largely determined by the number of stoker retorts required, so its heating surface varies with its height. For the Weymouth Station the various considerations indicated that a boiler 17 tubes high and with 55 per cent additional economizer surface would provide the most satisfactory proportion, and that the resulting economy would justify the installation of this total amount of surface.

Decision to fire the boilers with stokers was reached only after a very careful study of the relative merits of using pulverized coal. The conditions surrounding this problem for the Weymouth Station were such that the probable savings in fuel through the use of powdered coal represented a relatively low percentage of the total fuel cost. This estimated saving was further reduced by the additional carrying charges to a margin which was too narrow to clearly call for the use of the powdered coal system. It was accordingly decided to adhere to the present practise of the Edison Company and employ stokers, at least for the initial boiler installation.

AUXILIARY DRIVE

All of the normally operating station auxiliaries are to be electrically driven, using alternating-current motors throughout. Motors of 25 h. p. and less will, in general, be served at 550 volts, and those of greater capacity at 2300 volts. Any necessary speed regulation is to be obtained through the use of brush shifting and slip-ring motors.

Power for all auxiliaries upon which the continuity of operation of the main units depends, will be supplied from auxiliary generators driven by the main turbines through direct connection to the shafts of the main generators. These auxiliary alternators will have a rating of 2500 kv-a. and will generate at 2300 volts, 3 phase. They will be mechanically in phase with the main generators so that although they will normally operate independently, they may be connected to the main bus through suitable transformers when desired. In starting up a main unit all of the auxiliaries will be started from the main bus but after the unit is in operation the important auxiliaries will be transferred to the auxiliary bus of that unit and thus be supplied from the auxiliary generator independently of the main circuits. The less important auxiliaries will be regularly operated from a 2300-volt bus fed through transformers from the main bus. A separate steam driven auxiliary turbo-generator will be provided to permit starting the station from cold in emergency.

Each generator will be excited by a 175-kw. motor generator set, consisting of a 2300-volt induction motor and a 250-volt direct-current generator. This set will be operated from the direct-connected auxiliary generator. A spare motor generator exciter and also a spare

steam driven exciter are to be installed for emergency excitation and for battery charging. A storage battery will float on the exciter bus. The 2300-volt auxiliary generators will have direct-connected exciters but in an emergency may be excited from the 250-volt busses.

The auxiliary generators, being driven by the main turbines, will produce electrical energy with the highest obtainable economy, practically equal to that of the main units themselves. It is therefore expected that the use of this system will permit the attainment of higher plant efficiency with greater security, than would be possible with any other method of auxiliary power supply which presented itself.

The complete avoidance of auxiliary exhaust steam permits the preliminary heating of the feed water to be accomplished entirely by multi-stage bleeding of the main turbine. It is well recognized that this method of heating results in greater efficiency than by the use of exhaust steam from individual auxiliary turbines, "house turbines," or any combination of them. In most other possible arrangements for heating the feed water entirely by bleeding the main units the supply of auxiliary power must be taken from the bus and thus be subject to the effects of external electrical disturbances. Even the use of separate house turbines usually involves a connection with the main bus, either directly, with its attendant hazard to continuity of service, or through a motor generator set with attendant lowered efficiency,—this connection being required to secure the proper feed water temperature while carrying an auxiliary load which does not necessarily bear a direct relation to the feed heating requirements.

SWITCHING ARRANGEMENT

Figs. 4 and 5 show in diagram a plan and cross-section of the isolated switch house as it is expected to develop, consisting of four stories and a basement. All incoming and outgoing circuits enter or leave through the cable room in the basement.

In the layout of the cable room the following have been the guiding principles:

Proper segregation of the cables in the ducts.

Facility for taking any feeder circuit into any outgoing duct line without the need of further crossovers in outside manholes.

Means for testing any cable at any time at suitable high voltage, and for complete protection of men working on cables, through potential indicating and grounding devices.

Suitable space and handling facilities for cables.

The three floors above are occupied by the busses, switch gear and reactors, each phase being isolated on a separate floor. Fig. 5 shows a different equipment section on each floor,—on the first floor is represented a feeder section, on the second a generator section and on the third a bus tie section.

On the fourth floor are located the oil circuit breaker and disconnecting switch operating mechanisms, which

FIG. 6—MAIN SWITCHING CONNECTIONS

transformer circuits which may connect with other power systems are guaranteed to rupture 58,000 amperes at this same potential.

The generators and their cable connections to the busses will be protected by balanced relays arranged to automatically disconnect any unit from the bus in the event of a ground or short circuit on the machine side of the circuit breaker. The generator leads are to be single-conductor cables carried on insulators from the machines to the switch house, through closed corridors. No cables carrying a higher potential than 2300 volts will be carried in ducts within the station.

On account of the relatively low capacity of the generators which are to be driven by the 1200-lb. pressure turbines, the expense of providing the necessary

bay between the boiler room and turbine room. Truck type switch gear will be used.

PLANT EFFICIENCY

In what has gone before the discussion has centered for the most part around the efficiency of particular apparatus, conditions or methods. Of even greater interest to engineers in general is the efficiency of the whole plant as being indicative of the care and skill with which the various components have been proportioned and assembled, and the necessary compromises made between conflicting requirements.

It has been shown that in what, for purposes of differentiation, has come to be called the "Normal Pressure" part of Weymouth Station, steam pressures comparable with the highest now employed in America

FIG. 7—AUXILIARY SWITCHING CONNECTIONS

switching equipment and building space, for their direct connection to the main bus is not warranted. It is planned, therefore, to connect each group of three of these units to a separate bus through low-capacity oil circuit breakers. The group bus, will in turn, be connected to the main bus in about the same manner as a feeder.

A wiring diagram of the system for driving the station auxiliaries is given in Fig. 7. The auxiliary generators will be controlled from the main switchboard and the operator there will be responsible for keeping the 2300-volt busses constantly energized. The 2300-volt busses will be located in separate substations, one for each two units, to be provided in the auxiliary

are to be used. In addition pressures higher than any that have been used heretofore for similar purposes are to be thoroughly tried out in conjunction with the re-heat cycle.

Feed water heating is to be accomplished both by steam extraction from the main turbines and by the use of economizers. To obtain the maximum of benefit from the steam extraction method of heating motor driven auxiliaries only are to be used, supplied with power from a most efficient direct-connected auxiliary alternator. The auxiliary apparatus itself has been selected with a view to obtain the highest efficiency in both the driving and driven members.

Fig. 8 shows, in the upper diagram, an analysis of

the performance which could theoretically be realized in the operation of the normal pressure (375 lb.) portion of the station of the design as described. The lower diagram shows a similar analysis for such a station operating exclusively on the reheat cycle, with the entire steam supply generated at 1000 lb. Both diagrams are based upon ideal operating conditions, *i. e.*—a constant station load of such amount and

energy, which is equivalent to 15,100 B. t. u. per kw-hr. net generated, or approximately 1.05 lb. of coal of a heat value of 14,400 B. t. u. per lb.—while the corresponding figures for the high-pressure reheat plant are 25.1 per cent, 13,600 B. t. u. per kw-hr. and approximately 0.945 lb. of coal.

They above calculated results represent only the ultimate possibilities under ideal load conditions. It

FIG. 8—HEAT BALANCE DIAGRAM

character as would permit the main units to operate at their point of best efficiency and at 100 per cent load factor. The estimated efficiency of each individual piece of equipment is that guaranteed by the manufacturer.

From these diagrams it will be observed that the normal pressure straight condensing plant will transform 22.6 per cent of the heat in the fuel into electric

is, of course, impossible to predict what the results of actual operation will be as this will be influenced considerably by the extent to which a constant base load can be allocated to the Weymouth Station and the extent to which it is found advisable to employ the high-pressure equipment in making future extensions to the station.

A power plant boiler under the present conditions of service must be arranged so that it can be thoroughly cleaned both inside and out. The use of 2 in. tubes, such as will be supplied for the boiler gives a convenient size for internal cleaning, whereas it is difficult, if not impossible to properly clean tubes, say, 1 in. in diameter and smaller. Were it possible to maintain at all times absolutely tight surface condensers, it would then be unnecessary to clean the interior of the boiler tubes and the art of boiler design would be considerably simplified and smaller diameter tubes could be used provided they were arranged so that they could be thoroughly cleaned on the outside. For years The Babcock & Wilcox Co. believed that it was ready to put out a B & W boiler for any desired pressure for power plant service through using the Marine B & W boiler, in fact, the test boiler of drumless construction that has been referred to was built with 2 in. tubes for a pressure of 750 lb. per sq. in. The difficulties that were experienced at some plants in maintaining the outer surface of boiler tubes clean from slag and soot when run at high ratings convinced operators of power plants that it would be a mistake to install the 2 in. tubes in groups of four as in our marine boilers, because with the tubes so arranged there are no diagonal lanes available between the tubes for cleaning the outer surface of the tubes. A new forged steel header was therefore designed and constructed where the tubes are staggered and arranged with horizontal and diagonal lanes between all of the tubes, thereby making it possible to clean the outer surfaces of the tubes through the diagonal lanes from above and below the tubes. All B & W boilers for the higher pressures are now fitted with this new form of header. The case is different from marine boilers, which have a relatively narrow width and where all of the tubes may be cleaned on the outside by opening the side casing doors, and brushing the tubes through the horizontal lanes between the rows of tubes, which would be an impractical method for the wider boilers and settings used for power plant work.

Attention is called in the paper to the use of the forged steel drum of seamless construction for the 1200 lb. boiler and to the bending of the ends of the horizontal circulating tubes which enter the drum so that they enter at circumferential lines which are twice as far apart as the distance between the horizontal circulating tubes where they enter the headers, thereby greatly increasing the efficiency of the ligaments between the tube holes. There are two circulating tubes running from the top of each uptake header to the steam and water drum and the ends of the tubes which enter the headers are bent in such a way that the tubes enter all of the headers at the same height, thereby making the circulation the same in each header. The boiler is built of A. S. M. E. Code material throughout to meet all of the requirements of the Code.

The boilers for 375 lb. pressure first considered were 14-high and 48-tubes wide with the two lowermost rows of tubes exposed for their full length to the furnace, with a horizontal baffle above the second row of tubes exposed from the downtake headers to the bottom of the inclined baffle between the first and second passes, the superheater being placed in the first pass above six rows of tubes. A change was made to a boiler 17-tubes high and 48-tubes wide with the six lowermost rows of tubes exposed to the furnace, with the superheater in the same position. This was done in order to secure the following operating advantages:

1st: The furnace temperature will be somewhat lower with the six lowermost rows of tubes exposed than with only two rows exposed for their full length to the heat of the furnace and with a high furnace of the sort that will be used this would tend to reduce the cost for brickwork maintenance. 2nd: In case a coal is burned which will cause an undue amount of slagging on the outside of the tubes exposing six rows of tubes for their full length will lead to less slagging difficulties than exposing the two rows for their full length. 3rd: In case of tube troubles due to impure feed water the tube loss would be less for a given

amount of steam evaporated per hour from the boiler with six rows of tubes exposed both on account of causing the hot gases on striking the boiler tubes to be diffused over a longer length of tube surface and through providing a greater amount of boiler surface for a given amount of steam generated.

The flue gas temperatures for a given weight of steam evaporated per hour by the 17-high boilers with the six lowermost rows of tubes exposed will be but slightly lower than would be secured with the 14-high boilers with only the two lowermost rows of tubes exposed. A 16-high boiler with the six lowermost rows of tubes exposed would give about the same flue gas temperatures for a given weight of steam evaporated per boiler as a 14-high boiler with only the two lowermost rows of tubes exposed. The choice of the 17-high boilers with the six lowermost rows of tubes exposed was not therefore on the basis of the flue gas temperatures or the efficiencies, but on the broader basis of selecting a boiler which would give the best service under the conditions for use in connection with the economizers. If the 17-high boilers were fitted with a system of baffling that was considered for the 14-high boilers with the two lowermost rows of tubes exposed, the efficiency of the boilers for the same steam output under the average service conditions would be slightly more than one per cent higher than with the six lowermost rows of tubes exposed, and should no economizers be employed, this difference of efficiency would offset a considerable increase in cost of maintenance of brickwork and difficulties of operation.

P. Junkersfeld: Five considerations are stated on the third page of the paper. The third, "The probable effect of increased pressure upon reliability of operation and its flexibility in meeting anticipated load conditions with high over-all economy," and the fifth, "The economic balance of carrying charges and operating costs over a long period," are more or less inter-related. Under reliability of operation I assume that the authors have included maintenance. Apparatus of this sort naturally involves more maintenance or replacement than apparatus that has been tried out for a longer period of service. With the particular apparatus operating at 1200 lbs. steam pressure some troubles must be expected to develop during the early years, which means outages and units available less hours of the year.

Such outages do not reduce the total carrying charges per year, but will increase the carrying charges per kilowatt hour because if the turbine unit or boiler unit is out, for example, twice as many hours as a more seasoned piece of apparatus, it would double the carrying charges per kilowatt hour due to that particular apparatus. On the other side of the balance, if such turbine or boiler unit is running only half as many hours as a more seasoned unit in a year, the savings expected from the better fuel economy are much reduced. I take it, however, that these matters have been considered under considerations three and five, and the foregoing is submitted as a matter of emphasis on these two very important points in the paper.

Curve 1 Fig. 2, shows a very interesting and not usually appreciated fact, namely, that the total heat at 700 deg. fahr. decreases with increasing pressure. That is contrary to our ordinary expectations. Of course, after the careful analysis that the authors have made, we can see why it is so. However, considering Curve 1 and Curve 2 together, we see that after all, the heat available does increase with the pressure.

Curve 5 indicates that six hundred pounds should give the highest thermal efficiency. It is not clear to me whether this represents the expected performance from all types of turbines or only the particular type of turbine used in Weymouth Station.

On the third page it is stated that 1200 lb. was selected for the one new extra high pressure boiler. It would be interesting to know why 1200 lb. instead of say, 1000 or 1500 lb. was selected. There must have been some reason that led to the adoption of 1200 instead of something a little higher or a little lower.

There is frequently a tendency for too much standardization in power plants. It is a fact that the elements that go into a power plant like the elements that go into a suit of clothes,—the cloth, the thread and the buttons, should be thoroughly standardized, but you can never hope in my judgment to so far standardize power plants that they will fit every condition any more than you can hope to make a suit of clothes to fit every size of man. There would be a lot of misfits. There are a great many things that will be a good solution for one set of power plant conditions and one location, that might be a poor solution for another set.

The two most outstanding conditions that affect the proper design of plant for a given set of conditions are price of fuel and load factor. When I say price of fuel, I mean per thousand or million B. t. u., or some other equivalent that shows steaming value. Differential in price of fuel is usually a fairly definite thing. There is a substantial difference between the price of coal say in Boston, and price near the coal mines, over a long period of years. The price of coal on comparable basis may be two or three times as much in one locality as in another, and the same plant will not properly fit both localities.

Load factor, however, is a very elusive thing. It depends upon the general character of the business in the community. If every station were operated at exactly the natural consumption of power within its proper area, it would be one thing, but we are no longer operating stations,—we are operating systems, and that means one, two, three, four or even more stations in parallel. These stations on the same system are in competition with one another. The better load factor is allocated to the station with the lowest operating cost, and to an extent depending on how much lower that station operates than the other stations. Operating cost, not fixed charges, govern this allocation, because fixed charges are established when you build the station. I am assuming now that such transmission and distribution handicaps as might exist between the various stations are all taken into account in allocating load between stations.

During the life of the equipment and just as any new station is usually lower in operating cost than older stations or units on the system, so may another new station five years later be still lower. Therefore future load factor on a station or unit is a very difficult question to decide, requiring judgment and experience and the very best attention and study.

Two other points in the paper would be interesting if amplified. First,—how is it proposed to protect the reheater from overheating should the turbine load be suddenly discontinued? Second,—In view of the fact that we can so effectively heat feed water by bleeding turbines, is there much to be gained with economizers?

The final results from the Weymouth Station are very promising, indeed, as given in the paper under ideal conditions, which are the only conditions under which they can be given at this time.

L. L. Elden: The Weymouth Station now under construction will be operated in conjunction with the rest of the system substantially as follows: The area served by the Boston Edison Company resembles a square looking at it from the water side, with L Street Station located substantially at the centre of the base line. The new Weymouth Station is located at the southern terminus of the base line about eleven miles from L Street. The present area served by the company is supplied from some 85 substations.

The ultimate growth of the system may be estimated broadly from the fact that the connected load is increasing yearly at the rate of about 100,000 kw. With this growth in view, it is conceived that eventually in the interest of economy another large generating station will be required north of the city, assuming, of course, that a suitable site can be found for the purpose.

To provide a suitable link between the new station and the remote points of the present system, it is proposed to construct

a 110,000-volt ring around the system, starting from Weymouth and terminating at some desirable location on the north. Lines from L Street are serving all intermediate territory and will in the end be interconnected with lines from the Weymouth Station as business requirements may dictate.

Another project now being seriously considered is the introduction of hydro power in large quantities from the St. Lawrence district. The projected point of contact is at Framingham on the westerly side of our territory where it will intersect the 110,000-volt ring previously referred to. The route of this proposed ring will be exceptionally favorable for connection on the southerly side with the proposed superpower system developed by Mr. Murray and his associates during the war period.

We also find the location of the new station favorable to the supply of service to the New Haven and Boston and Albany Railroads in the event that the electrification of these roads becomes a reality in the future. With favorable conditions as regards coal, water and distribution facilities, we feel that it is conceivable that the entire proposed development of 300,000 or more kilowatts will be easily absorbed in the near future if all of the projects now in view actually eventuate.

Operating methods to which Col. Junkersfeld referred have not as yet been fully worked out, it being evident that to determine the best method of relaying and handling the two generators comprising each unit, when connected to the main system, will require considerable study. This has not yet been completed hence it is impossible at this time to indicate the reliability factor which will be developed in actual service. It would appear from studies made up to this time that the small 1000 pound unit may prove the only unreliable element in the whole development since all other equipment is standard and already in extensive use. When, however, it is realized that the capacity of the high-pressure unit is only of the order of 2500 kw., its importance becomes negligible in a large system like ours, where many interconnections and emergency arrangements provide means for instant absorption of loads of far greater magnitude than would be involved in the event of failure of the unit in question. Under these conditions the question of fixed charges on spare capacity at this station to meet emergencies is not important since the reserves for the system as a whole will not be carried at any one location.

H. P. Liversidge: The details of the Weymouth plant which have been presented before this Convention, indicate the very practical consideration which has been given to its design in order that the generated power may be produced at lowest over-all cost.

In the consideration of new plant layouts, there is prone to be a tendency toward maximum operating efficiency with the possible sacrifice of other factors which have a decided bearing on investment costs and over-all operating costs. It is quite evident that these various factors have all been given primary consideration in this station layout.

I believe that while this plant incorporates some radical departures from standard design, it would seem to be a very safe change. It is evident that the high-pressure section, which embodies very special features, has been so arranged in its relation to the rest of the plant that if an unforeseen complication should arise, no financial penalty will be imposed even if it becomes necessary to radically change or eliminate this special part of the equipment. This, in my opinion, is a most important consideration, and in the development of large central stations, I believe we should place ourselves in the position of doing not what we might like to do from the standpoint of highest efficiency alone, but what from a business standpoint is the safe thing to do,—investment and earnings being considered.

In designing a plant, another question to be considered is reliability—the plant must operate. We are in the position to-day where departures which involve radical changes from

standard design must be so planned as not to penalize the high order of service which must be rendered to-day.

I believe that this plant design presents a combination of equipment which marks a step in advance in the application of high steam pressures, and, at the same time, eliminates the possibility of complications which may have their effect in either the lowering of reliability of service or increasing maintenance costs.

G. L. Knight: There is one point I think which has not been touched on and that applies particularly to those of us who were compelled to make our decisions, especially on steam conditions, somewhat before these later developments in boiler and steam turbine designs were made available. We are not going to suffer altogether thereby, I think, but can take advantage of some of these developments by using high-pressure turbines in stations where we have adopted lower steam pressures, installing some of our new boilers at 1000 or 1200 lb. pressure and exhausting the high-pressure turbines into our present steam lines at the line pressure.

H. W. Eales: Attention was called by Mr. Liversidge to the feature of the design at this station which permitted of the elimination of the high-pressure portion and of the substitution of the more standardized methods of design in the event of any difficulties with the design. Being connected with a power station development which is utilizing pulverized fuel, I may say that the same factors have been carried out there. The design of the boiler house as laid out will permit of the substitution of any other form or method of burning coal which experience or advance in the art may direct.

Reference was made in the paper to the calculations of the Weymouth Station with reference to the choice of fuel combustion. It seems to the speaker that much of the discussion on the relative merits of pulverized fuel or stoker firing of coal in these super stations is still of the conjectural type. It is my opinion, therefore, that very little is to be gained by further discussion of the matter at this time. I would personally much prefer to delay comments until after experience with our particular station has demonstrated the results obtained.

The paper, on the sixth page pointed out two methods of securing power supply for station auxiliaries. It referred to the securing of power from the main station bus with attendant disaster to the auxiliaries in the event of general system trouble and the means of preventing that by using motor-generators floating between the house turbine bus and the station bus.

I wish to mention a third method, namely, that of using a saturated core reactor between the house turbine bus and the main station bus.

As a matter of purely experimental interest the speaker is greatly interested in the development of the Weymouth Station which uses an auxiliary alternator on the same shaft as the main generator. It may be pertinent to inquire if it is possible to go a step further and use a double-current generator, thereby deriving the excitation in auxiliary power by the same means.

F. Samuelson: Your plans are very bold and should give some really valuable information with regard to economy and reliability of extra high-pressure steam plant. It is very fortunate that it is relatively easy to ascertain the efficiency of the high-pressure end of the plant as the steam will be superheated on leaving the high-pressure turbine. With known inlet and outlet pressure and temperature of the steam it is readily found how much of the energy is converted into work. It is of course essential that the temperature measurements should be very carefully taken. There may be a slight error owing to want of exact knowledge of the specific heat of superheated steam at such high pressure of 1000 to 1200 lb. per sq. in., but this error will be small.

A very important matter in connection with the construction of steam plant at extra high pressures and temperatures, is the fact that the true elastic limit of most steels is lowered seriously

as the temperature is increased. At a temperature of about 750 deg. Fahr. the elastic limit may drop to half of that obtained at ordinary room temperature, and it is therefore very important that this loss of strength is understood when the factor of safety is settled upon.

As the strength of steel is so much affected by heat, I am strongly of the opinion that the temperature of the superheated steam should be controlled in some way. I have come across cases where the steam temperature has been above 800 deg. Fahr. at the turbine stop valve, and where it has been necessary to lower the temperature by removing some of the superheater tubes, entailing increased drop of pressure across the superheater. I would advocate that the superheater be located in a chamber or compartment, preferable within the boiler itself, and provided with water cooled dampers, or other means which will control the flow of the hot gases. Where a reheater element is used this should be put in the same compartment as the steam passes through both these in series, and they ought therefore to be subjected to the same control. The temperature control should be automatic, regulated by some simple servo motor and pilot valve, which in turn is actuated by the temperature of the steam leaving the superheaters.

The arrangement you have adopted for providing power for the auxiliaries in the station is very economical and commendable. A somewhat similar arrangement is in use in the Birmingham Corporation power station on some 18,750-kw. sets, but in this case the auxiliaries are driven by direct current. A double unit d-c. generator set is driven direct from the main turbine, one unit provides excitation, the other supplies power for the auxiliaries.

With regard to the high-pressure turbine and its separate generator, I am not sure that this is the best ultimate arrangement. It would seem simpler to run both turbines at the same speed, putting them in tandem and connecting the two mechanically by a shaft having the usual claw coupling element at both ends. There need be no fear from out of alignment with this arrangement, and it does away with the generator, its losses, and some switching gear. The high-pressure turbine would in this case have more wheels than is indicated in the paper, but I think this would be in favor of economy, as with very high steam densities low steam speeds are desirable.

The design of the high-pressure turbine casing will no doubt present some difficulties with 1200 lb. initial and 375 lb. exhaust pressure, the mean internal pressure being in the neighborhood of 750 lb. It may be impracticable to split such a casing horizontally. The turbine set may preferably be placed at right angles from that shown on your plan with the high-pressure end nearest to the boiler house to shorten the steam pipes.

I see no reference in your paper to pre-heating the combustion air by the combustion gases on their way to the chimney. I believe this practise will be more and more taken up as it affords a means of cooling the combustion gases before they escape to the atmosphere, and also at the same time enables feed water to be heated to a higher temperature by bleeding before going to the economizer section of the boiler. With the higher feed water temperature the size of the economizer can be considerably reduced—part of this relatively expensive element is substituted for a cheaper air heating element.

There are some plants in this country in which air heating has been tried, but full information is still lacking. I think, however, that the system is right, and will eventually be successful.

I have not had an opportunity to check the curves giving the effect of steam pressure on the turbine thermal efficiency, but in general, I would say that they agree closely with similar investigations I have made, though not at such high pressures. I would, however, refer to curve No. 4. which gives the efficiency ratio of a turbo-generator under different steam pressures, and believe that the slope of this curve is somewhat greater than it

ought to be. In other words, that the efficiency of the turbine will be relatively greater at the higher pressures than indicated by this curve, which is to the good.

In conclusion, I would emphasize the great importance of proper control of the superheat in large stations such as yours at Weymouth. If such control is established the steam temperature may be raised some 50 deg. Fahr. without any more risk than with a fluctuating temperature aiming at a lower temperature.

Joseph Pope: Answering the questions which Colonel Junkersfeld has asked, Curve No. 4 and consequently Curve No. 5, were prepared from data relating to the type of turbine to be installed in Weymouth Station. The manufacturers of the turbines, however, are not responsible for the high pressure end of these curves. Mr. Samuelson has also referred to Curve No. 4 suggesting that the slope is somewhat greater than he would anticipate. It is interesting to investigate the effect upon the problem in hand if the high pressure end of Curve No. 4 is raised as much as 5 per cent of its present indicated value, that is, from 72.5 per cent efficiency ratio at 1000 lb. abs. pressure to 76.0 per cent and if instead of being convex upward the curve is made a straight line of uniform slope between 300 lb. abs. and 1000 lb. abs. A table shows the result of this change most conveniently:

Abs. Press	Eff. Rankine Cycle Curve 3	Eff. Ratio Curve 4	Thermal Eff. Curve 5	Eff. Ratio as Modified	Thermal Eff. as Modified
100	30.75	83.30	25.61	83.30	25.61
200	33.75	82.80	27.92	82.80	27.92
300	35.30	82.10	28.99	82.10	28.99
365	36.20	81.49	29.48	81.50	29.49
400	36.60	81.15	29.68	81.22	29.73
500	37.50	80.00	30.00	80.35	30.12
600	38.27	78.80	30.12	79.48	30.40
700	38.83	77.45	30.07	78.61	30.50
800	39.40	75.90	29.90	77.74	30.60
900	39.77	74.28	29.52	76.87	30.52
1000	40.00	72.51	29.00	76.00	30.40

These are all slide rule figures, but sufficiently accurate for the purpose. Under the new conditions, the peak of efficiency comes at 800 lb. absolute, but this maximum is only 3.8 per cent higher than the efficiency at 365 lb. absolute, the throttle pressure actually selected, as against 2.1 per cent difference between the selected pressure and the maximum efficiency shown by Curve 5 in the paper, an amount clearly insufficient to justify the added expense. Although Curve 4, as stated, is based on data for the Weymouth machines, similar information was obtained concerning other turbine types, but the conclusions to be drawn from them were in nowise different.

The second question is "Why was 1200 lb. selected for the high-pressure equipment?" It was principally because of the equipment available, and because the curve of cycle efficiency is

rapidly approaching the horizontal at that pressure. In actual operation the boiler pressure will vary with the steam output and consequently with the load on the pressure reducing turbine. It is probable that the normal operating steam output will be such that the boiler pressure will be about 1000 lb. although the safety valves are to be set at 1200 lb.

The third question "How is it proposed to protect the reheater from overheating should the turbine load be suddenly discontinued?" At the time this paper was prepared there had been no opportunity to completely investigate matters of this nature and the cut of the high-pressure boiler as shown is practically as it was first offered by the manufacturers. After suitable performance data were available, more thorough study of the interaction of the boiler, superheater, turbine and resuperheater at varying loads indicated some difficulty in controlling the reheat. With an initial temperature of about 700 deg. the exhaust temperature from the turbine at light loads is also very high. In consequence the temperature leaving the reheater would be considerably above what is commonly held to be safe. A change was therefore made in the design and location of the reheater in order to give the necessary control of the reheating, but as the regulation of the initial superheat is quite satisfactory the superheater was left substantially unchanged. It is purposed now to locate the reheater above the first two passes of the tube bank with the tubes running across the boiler. The reheater tubes are in two groups separated by a vertically sliding damper forming in effect an extension of the front boiler gas baffle. By varying the vertical position of the damper the combustion gases may be made to pass over more or less of the reheater surface, and the outlet steam thereby maintained at the desired temperature. It will be understood that this same arrangement effectually takes care of the situation which may arise from sudden loss of load on the high-pressure turbine.

The fourth question "Is there much to be gained by the use of economizers, since feed water can be effectively heated by bleeding turbines?" If it be granted, and we presume that it will be, that large commercial air heaters are still decidedly experimental and without practical demonstration of economic justification sufficient to warrant their general use, a combination of feed heating by extracted steam and by economizers seems to be the best arrangement. It is realized that economizers cost money, but surface type water heaters are by no means inexpensive. The heat reclaimed from flue gases is practically net gain, whereas that saved in bled steam is partially offset by the extra live steam that has to be supplied at the turbine throttle on account of the extraction.

Mr. Eales inquired if it is possible to use a double-current generator on the same shaft as the main unit and thereby derive the excitation and auxiliary power by the same means. Mr. Samuelson calls attention to a case in Birmingham where a double unit d-c. generator set is used in this manner. The use of a direct-connected exciter in conjunction with the auxiliary alternator was considered for Weymouth and while feasible enough was abandoned in favor of the present arrangement.

The Cooling of Electric Machines

BY GEORGE E. LUKE

Associate, A. I. E. E.
Westinghouse Electric & Mfg. Co.

Review of the Subject.—The elevation in temperature of the windings of any electric machine due to the internal heat losses is usually the dominating factor in limiting the rating of the machine. This limitation found in the heating, is primarily due to the effects of high temperatures on the various types of insulation used in such machines. The American Institute of Electrical Engineers Standards specify the maximum permissible operating temperatures for the various grades of insulation. The temperature of the windings in the machines then, must be kept below this maximum permissible temperature.

The heat losses produced in a machine are the results of electrical and mechanical losses. These losses must be transferred from the source of generation to the cooling medium. The first step of the heat flow path is by conduction through the copper, iron or insulation to the ventilating or cooling surfaces. The second step in the transfer of the heat may be called the liberation or dissipation of the heat from these surfaces to the cooling medium. This portion of the heat flow may be divided into two or more stages by the use of an intermediate cooling medium, such as oil, in an oil-insulated transformer.

This paper deals with some of the more common types of ventilating and cooling systems used in the electric machines and particularly with the laws governing the flow of heat from the cooling surfaces.

Considerable data have been published in the past giving the rate at which heat can be liberated from a surface by radiation and natural air convection currents. This is always a factor in the cooling of a machine and may be the sole means for cooling some small types of electric apparatus. Some new experimental data as well as a summary of the old data are given regarding this heat loss by natural ventilation and radiation. Tests are given for several types of surfaces, such as plane, cylindrical and corrugated surfaces.

A survey of the technical press will reveal very little accurate data regarding the rate of heat dissipation from the surfaces of electric machines by forced air convection currents. Thus, an experimental investigation was initiated for the purpose of determining some of the principal factors governing the rate at which heat can be dissipated from various types of surfaces by forced ventilation.

The results of many tests on the dissipation of heat from axial ducts are given. These tests show the influence of the air velocity, shape and surface of the air duct upon the rate of cooling. The rate of heat transfer is shown to be approximately proportional to the average air velocity, and not to the square root of the velocity as has been previously published. Another unexpected result was that the unit rate of cooling of the small circular ducts tested was practi-

cally the same as that found for the larger ducts over a considerable air velocity range. The effectiveness of the radial ducts in cooling a machine is shown by tests on ducts of several widths. The rate of heat dissipation does not differ materially from that found for axial ducts, also there is no great difference between the heat liberated from the narrow or from the relatively wide ducts.

Some interesting results were found in the cooling of a rotor. The heat loss with self-ventilation, due to its own rotation, is not proportional to the peripheral velocity. The heat dissipation curves for the rotor during rotation with separate ventilation along the periphery or air gap are very complicated being influenced by both the peripheral velocities and the forced air velocities.

The great value of proper ventilation of the end windings in electric machines is shown by the rate at which heat can be dissipated from the surfaces with forced air ventilation. Tests were made on a rotating and a stationary model with various ventilating spaces between the coil sides.

The rate of heat dissipation from cylindrical surfaces is also given with forced ventilation. The tests were made with the air flow at right angles to the cylinder or tube and the results show a much higher rate of heat flow than was found from axial or radial duct surfaces.

A summary of some miscellaneous tests is given for the heat dissipation constants found with water and oil cooling. These constants given for liquids are several fold greater than can be obtained with gases. Water, particularly, is a cooling medium with a very high rate of heat transfer coefficient.

THE disposal of the heat resulting from the electrical and mechanical losses in any electric machine is always an important item to the designer as well as to the operator of the machine. These losses appearing all in the form of heat must be transferred from their source with a temperature gradient not to exceed the maximum safe operating temperatures. These maximum temperatures are limited by the insulation necessary to insulate the windings.

In the early days of machine design the generators, being principally of the engine type, were slow in speed and hence large in size. Due to the large surfaces, it

was comparatively easy to liberate the heat with a low temperature rise. In fact with these old machines it was usually unnecessary to provide for additional ventilation other than that due to natural ventilation and windage of the rotating element. The ratings on many of these earlier machines were limited not by the temperature rise but by the performance such as commutation or regulation.

The development of the high-speed turbo-generator and the hydroelectric generator resulted in a machine of greater rating, hence greater losses, with a physically smaller machine than was used with the direct engine drive. This concentration of losses in a smaller space was possible only by greatly improving the ventilation.

Presented at the Annual Convention of the A. I. E. E., Swampscott, Mass., June 26-29, 1923.

Today the commutation and regulation limitations of a machine have been practically removed so that the temperature limitation is usually the dominating factor in setting the maximum rating of electric machines. Thus to design the most economical machine, full consideration must be given to the temperature obtained at its rating. A machine with temperatures above the maximum permissible temperatures will not have a long life; on the other hand, a machine with temperatures too low mean an economic waste of material.

DISPOSAL OF THE HEAT LOSSES

The heat resulting from the internal losses of an electric machine must eventually be transferred from the machine to the air, water or the earth. This transfer of heat may be accomplished by many means. A direct system of cooling can be used such as the circulation of air or water over the heated surfaces with the heated air or water discharged at a point remote from the intake supply. An indirect system is often used for cooling a machine, such a system utilizes a fluid such as air, oil or water to "ferry" the heat from the surfaces of the machine to the outside supply of air or water. This transfer of heat may be made in several stages. Thus in an oil-insulated water-cooled transformer the heat "picked up" by the oil is transferred to the water in the cooling coils. This water then carries away the heat and distributes it either in the earth or in a body of water.

The most common system of cooling used with electrical apparatus is the direct air system. This system is especially adapted to rotating machines due to the mobility of the air. For high-voltage apparatus, such as transformers, oil is used for insulation purposes, so that the indirect system of cooling must be used. The oil merely acts as a "heat ferry" and carries the heat to the water-cooling coils in the case of a water-cooled transformer or to the ventilating surfaces in the case of a self-ventilated transformer.

Hence, one of the principal factors in the cooling of electrical apparatus is the determination of the temperature differences necessary to transfer the heat from the surfaces of the machine to the cooling fluids and from one fluid to another. The purpose of this paper is to give a summary of the various rates of heat transfer necessary for the predetermination of the machines operating temperature. Since air is the most common cooling agent it is given the greater consideration. The data given, unless noted to the contrary, are the results of experimental tests under the writer's direction and much of the data have been hitherto unpublished.

COEFFICIENT OF HEAT TRANSFER

The rate at which heat is transferred between a surface and a gas or liquid is called the coefficient of heat transfer or the heat dissipation constant. Throughout this paper the coefficient is defined in terms of watts per square inch of surface per deg. cent. difference between

the surface and the fluid. This heat transfer constant is the same for a heat flow from a surface to the fluid or from the fluid to the surface, the direction of flow being dependent only upon the temperature gradient.

This coefficient is often expressed in other units; the relation of some of these constants is approximately:

1 B.t.u. / sq. ft. / deg. Fahr. / hr.	= 0.00366 Watts/sq. in./deg. cent.
1 Calorie / sq. cm. / deg. cent. / sec.	= 27.0 Watts/sq. in./deg. cent.
1 Kilo-calorie/sq. meter/deg. cent./hr.	= 0.00075 Watts/sq. in./deg. cent.
1 Watt / sq. cm. / deg. cent.	= 6.45 Watts/sq. in./deg. cent.

FIG. 1

$$T_s = \frac{W}{S K} \left(1 + \frac{1.765 S K}{V} \right)$$

where T_s = Max. temperature rise of ventilating surface, deg. cent.
 W = Total watts loss
 S = Total ventilating surface, sq. in.
 K = Coefficient of heat transfer in watts/sq. in./deg. cent.
 V = Air Volume in cu. ft. per min. at 25 deg. cent.

The application of this heat dissipation constant to the cooling of electrical machines is illustrated in Figs. 1 and 2 for two conditions of heat flow.

The first condition is similar to that found in the cooling of a stator core with axial air ducts. In this case, Fig. 1, the loss is assumed to be uniformly generated along the axial ducts and the heat flow to be radial towards the ventilating surfaces. This is practically the condition found with the axial system of ventilation

FIG. 2

$$T_s = \frac{1.765 W}{V \left(1 - \epsilon \frac{1.765 S K}{V} \right)}$$

for laminated cores, since the resistance to the flow of heat is very much less in the radial than in an axial direction.

With a radial duct system of ventilation the ventilating surfaces of the ducts can be taken as having approximately a constant temperature; in this case the iron temperature rise will take a different form as shown on Fig. 2.

When the losses must be transferred from one liquid or gas to another, such as is found in the water cooling

of oil-insulated transformers, it can be shown¹ that the relation given in Fig. 3 will hold regardless of the directions of fluid or heat flow.

DISSIPATION OF HEAT BY NATURAL VENTILATION AND RADIATION

The liberation of heat from electrical apparatus by natural ventilation and radiation is always a factor in limiting the operating temperatures. Many small industrial machines are operated totally enclosed, in which case all the heat must be dissipated by natural ventilation and radiation, also transformers, wires, cables and bearings are quite commonly cooled by this same agency.

A. Radiation.

The law governing the heat loss from a hot body by radiation has been thoroughly investigated by many

FIG. 3—HEAT TRANSFER BETWEEN FLUIDS OR BETWEEN A FLUID AND A SURFACE

T_i is initial temp. differences, deg. cent.

T_f = Final temp. difference, deg. cent.

Let W = Total watts transferred

S = Total cooling surface in sq. in.

K = Coefficient of heat transfer in W/sq. in./deg. cent.

T_m = Integrated mean temp. difference, deg. cent.

Hence $W = S K T_m$ where

$$T_m = \frac{T_i - T_f}{2.3 \log_{10} T_i/T_f}$$

authorities. It can be conveniently expressed as follows:

$$W = 36.9 e \left[\left(\frac{T_1 + 273}{1000} \right)^4 - \left(\frac{T_0 + 273}{1000} \right)^4 \right]$$

Where W = Watts radiated per square inch of surface.

e = Relative emissivity coefficient.

T_1 = Deg. cent. temperature of surface radiating heat.

T_0 = Deg. cent. temperature of surrounding objects or air.

The emissivity coefficient (e) depends upon the color of the radiating surface and is unity for a perfect radia-

tor, that is a dull black surface. The values of (e) for other surfaces are approximately:

Surface	Value of (e)
Lamp black.....	1.00
*Oils, varnishes, insulating materials.....	0.80 to 0.90
*Copper oxidized.....	0.74
*Cast iron freshly machined.....	0.25
*Cast iron oxidized.....	0.65
*Silver polished.....	0.03
Tinned surface.....	0.50
Steel surface oxidized.....	0.75

*By Langmuir².

FIG. 4—HEAT LOSS BY RADIATION FROM A BLACK SURFACE

FIG. 5 HEAT LOSS BY NATURAL CONVECTION IN STILL AIR FROM A STEEL OR ALUMINUM PLATE 3 FT. SQUARE

The values of the heat loss radiated at various temperatures are shown plotted on Fig. 4. These curves show a considerable difference in the unit heat loss depending upon the room wall temperatures, also the rate of heat radiation increases considerably with increase in temperature rise.

B. Natural Convection.

The liberation of heat from a hot surface by natural convection is probably both by conduction and convection. That is the heat for a short distance from the surface is

conducted through a thin layer of dead or stagnant air, the outer surface of this air film is set into motion by the expansion of the heated air particles and from here on the heat is ferried away by these convection currents.

Tests made by the English National Physical Laboratory³ on the convection losses from a plane surface (3 ft. square) with different positions of the heated surface are shown in Fig. 5. As shown the heat loss by natural convection is proportional to the 5/4 power of the

FIG. 6—HEAT LOSS FROM SURFACE OF VERTICAL PLATES BY NATURAL CONVECTION AND RADIATION

temperature rise above the ambient temperatures. These tests were made on both smooth steel and aluminum plates with the same results as shown.

C. Radiation and Convection.

1. *Plane Surfaces.* The heat loss by radiation and convection from a plane vertical surface is given on Fig. 6. This surface was 3 feet square and was painted a dull black color. The heat loss from a 9-in. square heater⁴ is also shown on Fig. 6 for a black plate and a brass plate.

The heat loss from a plane surface by natural ventilation and radiation can be put in the approximate form of

$$W = aT + bT^2$$

Where a and b are constants

T = Deg. cent. temperature rise.

W = Watts loss per square inch.

For approximate calculations with average temperatures common to electrical apparatus the natural heat loss can be taken as below:

Surface	Watts/sq. in./deg. cent. rise
Smooth plane.....	0.006
Cast iron.....	0.008
Enveloping machine.....	0.010 to 0.015

This enveloping surface of a motor or generator is calculated by figuring the surface of a cylinder whose general outline dimensions are approximately the same as the machine in question.

2. *Corrugated Surfaces:* The use of corrugated surfaces is quite common for oil-insulated transformer tanks. It is thus possible to increase the actual surface several fold over that obtained with the plane tank surface. The increased heat dissipating capacity due to the corrugations is principally due to the action of natural convection currents. The heat actually radiated will not be appreciably increased by the corrugations. The effective radiating surface is the minimum enveloping surface and not the actual surface. Thus the so called "radiators" used for heating a room or of a type used for cooling the oil in a self-cooled transformer function mainly by convection and not by radiation. The equation for the unit heat loss by natural ventilation and radiation, is:

$$W = a(T_1 - T_0)^{1.25} + 36.9re \left[\left(\frac{T_1 + 273}{1000} \right)^4 - \left(\frac{T_0 + 273}{1000} \right)^4 \right]$$

Where W = watts loss per square inch of actual surface.

FIG. 7—HEAT DISSIPATION FROM WIRES OR CYLINDRICAL SURFACES BY NATURAL VENTILATION AND RADIATION IN STILL AIR BASED ON ROOM TEMPERATURE OF 20 DEG. CENT.

a = convection constant.

e = emissivity or radiation constant.

r = ratio of the enveloping surface to the actual surface. (Note — $r = 1$ for a plane surface).

T_1 = deg. cent. temp. of hot surface.

T_0 = deg. cent. ambient temperature.

3. *Cylindrical Surfaces:* The dissipation of heat from a cylindrical surface* by natural ventilation and

* The total surface is taken as $\pi D L$, where (D) is the diameter and (L) the length in inches.

radiation is a function of the diameter of the cylinder or wire.⁵ This is shown on Fig. 7. These tests were made with the wires or cylinders suspended horizontally in free air in a large room and no attempt was made to reduce the natural air convection currents found. Thus the smaller diameter wire can liberate the heat at a greater rate per unit surface than the larger wire. This is due to the fact that the relative thermal resistance to the flow of heat from the surface of the small wire through the encircling dead air film is less than that resistance found with the large wire. The effect of high surface temperature rise is to increase the coefficient of heat loss as shown.

DISSIPATION OF HEAT BY FORCED AIR STREAMS

In order to improve the rating of electric machines, it has long been the practise to use forced air ventilation. Radiation plays very little part in dissipating the heat from the internal motor surfaces. Most of these surfaces are at the same temperatures, hence, the heat interchanged by radiation will be small if any. Thus the cooling action obtained with forced air convection is due almost entirely to the transfer of heat to the air by conduction and convection.

These forced air streams may be produced either by the fanning action of the rotating parts on the rotor, by an external fan or by a combination of the two.

A. AXIAL DUCTS

The cooling of a machine by forcing air to flow through axial ducts in the core is a type of ventilation that is used in many machines especially in railway motors and turbo-generators. Some advantages of this system of ventilation are:

1. The heat may flow radially through the iron to the ventilating surfaces without passing through the laminations. This is an advantage since the resistance to heat flow across the laminations is from 30 to 50 times that along the laminations.
2. The air flows through the ducts at a uniform velocity since the cross-section is constant. This gives a minimum air pressure for a given average air velocity.
3. Due to the rough surface obtained, a high rate of heat transfer is secured.
4. The core length of a machine will be a minimum for a given magnetic flux.

Some disadvantages of the axial system of ventilation are:

1. A fan or blower is necessary to force the air through the ducts.
2. The axial ducts must be placed in the core where the loss per unit volume is a minimum. This will give a fairly long heat flow path from the tooth zone where the maximum losses are found to the ventilating surfaces of the ducts.
3. Due to the space required by the ducts, the over-all diameter of the core will be increased.
4. The maximum iron temperature will usually be

found adjacent the hottest air, that is near the end of the ducts.

The heat dissipated from the ventilating surfaces of axial ducts is influenced by the air velocity, size and shape of ducts, and the roughness of the duct surface.

DESCRIPTION OF EXPERIMENTAL APPARATUS

A diagrammatic sketch of the experimental model used in determining the heat transfer (K) from the surfaces of axial ducts is shown on Fig. 8. The first series of tests was made on smooth brass tubes of various sizes and shapes. The tubes were 36 in. long and the wall thickness was 0.063 inches. Around each tube the heater was wound consisting of 400 turns of 0.072 inches square asbestos covered copper wire. This duct was then placed in the center of an 8-inch micarta tube with the tubes held in position by two 2-inch wood end plates. The space between the duct and the outer casing was filled with mineral wool for heat insulation. The temperature of the tube was obtained by seven copper-advance thermocouples placed equal distances apart along the tube and the hot junctions of each were soldered to the outside surface of the tube. The thermal drop of the heat flow through the tube wall was

FIG. 8—APPARATUS FOR DETERMINING THE HEAT DISSIPATED FROM AXIAL DUCTS

very small, being a maximum of $1/5$ deg. cent., so that for all practical purposes the thermocouples gave the true temperature of the ventilating surface.

The ventilating air was supplied by a blower driven by a variable speed d-c. motor. A maximum of $4\frac{1}{2}$ in. of water, static pressure, could be obtained in the intake pipe. To obtain the total average air temperature rise five thermocouples were connected in series opposition. That is, the five hot junctions were placed in the outlet chamber with the five cold junctions in the inlet chamber and so connected that the voltage reading obtained was proportional to five times the average air temperature rise. It was necessary to thoroughly mix the air in the outlet pipe in order to obtain the average temperature. This was done by allowing the air to expand and forcing it to pass a brass gauze screen before coming in contact with the distributed thermocouple junctions.

The heater, which had terminals at each end of the duct, was supplied with current from a separate motor generator set. Potential taps were provided at each end of the heater, also two taps were taken off of a central portion of the heater. All the constants obtained were based upon the heat loss in this central

portion since the temperatures there were affected very little by the stray heat loss from the ends of the tube.

METHOD OF TEST AND THEORY

The model was first calibrated for stray loss through the casing and end plates. This was done by circulating a given current and reading the final average heater temperature rise as given by the change in resistance of the heater with the corresponding heater input in volts and amperes. During this test no air was forced through the heater. It was found that the stray loss was approximately proportional to the heater temperature rise so that only one such run was necessary for each tube. This loss was small in all cases ranging from 15 to 30 watts which was an average of 5 per cent of the total watts involved, so that the value of the stray loss did not have to be known to a high degree of accuracy.

After the stray loss was obtained, runs were made with forced ventilation. The blower was run at a certain constant speed and the heater input was adjusted so as to give a surface rise ranging around 50 deg. cent. After thermal equilibrium had been established the heater amperes and potential taps were read, together with all thermocouple readings. The temperatures corresponding to the thermocouple readings were taken from a calibration curve for the thermocouple wire used.

The total cubic feet of air per minute was obtained by knowing the watts input to the air and the resulting average air rise. The watts absorbed by the air equals the total watts input minus the stray loss as given by the calibration curve corresponding to that particular heater temperature. The average temperature rise of the air was obtained from five thermocouples with the junctions in the outlet and intake pipes, hence:

$$V = \frac{1.765 W}{T_a}$$

Where V = cubic feet of air per minute (25 deg. cent. temperature)

W = watts absorbed by air.

T_a = resulting air rise deg. cent.

The constant (1.765) is the degrees centigrade one cubic foot of air will rise with the storage of 1-watt-minute of energy. This is based upon air as weighing 0.074 lb. per cubic foot and a specific heat of 0.2418, all at 25 deg. cent. and standard atmospheric pressure (29.92 inches of mercury).

The average air velocity (v) through the duct then, is:

$$v = \frac{254 W}{A T_a}$$

Where v = average air velocity in feet per minute.

A = cross-sectional area of duct in square inches.

The surface dissipation constant then is:

$$K = \frac{W}{S T_s}$$

Where K = dissipation constant in watts/square inch deg. cent.

W = watts input to the air from the middle section of the heater.

S = ventilating surface of the middle duct section in square in.

T_s = average surface temperature of the middle duct section minus the average air temperature.

For each particular duct tested, five or more tests were made at various air velocities and heater inputs so as to obtain sufficient points for plotting the curves.

RESULTS AND DISCUSSION

(a) Circular ducts of various diameters, smooth surface.

FIG. 9—WATTS DISSIPATED FROM INTERIOR SURFACE OF SMOOTH AXIAL DUCTS SHOWING EFFECT OF CHANGE IN DIAMETER

The heat transfer constant (K) plotted against air velocity for smooth brass tubes, diameters 5/8 to 1 3/4 inches, is shown on Fig. 9. There is little difference in this value of (K) for the various diameters, except for the higher velocities. The 7/8 inch duct gives the highest values and the 1 3/4 inch duct the lowest.

Fig. 10 gives the distribution of the air velocities across the 1 1/4 inch diameter duct also the temperature distribution for the same air conditions. An empirical equation for (K) for the 1 1/4 inch diameter duct is:

$$K = \frac{0.0154 v}{1 + 0.048 v} \quad \text{where } v = \text{average air velocity in 1000's feet per minute.}$$

The curves show practically a linear relation between (K) and (v) for air velocities up to 4000 feet per minute.

Tests made by the U. S. Bureau of Standards⁶ on aeroplane radiators with $\frac{1}{4}$ and $\frac{11}{32}$ inch diameter air cells show a heat transfer of,

$$K = \frac{0.0139 v}{1 + 0.0135 v}$$

This equation checks Fig. 9 rather closely up to an air

FIG. 10—DISSIPATION OF HEAT FROM AXIAL DUCTS. TRANSVERSE DISTRIBUTION OF AIR VELOCITIES AND TEMPERATURES

FIG. 11—WATTS DISSIPATED FROM INTERIOR SURFACE OF A SMOOTH AXIAL DUCT, SAME PERIPHERY

velocity of 4000 feet per minute.

Tests made by H. P. Jordan⁷ give the following results:

Diameter of copper tube

0.506 inches.....	$K = 0.0125 v$.
1.236 inches.....	$K = 0.0108 v$.
1.968 inches.....	$K = 0.0102 v$.

The results were obtained by subtracting the stray loss at zero velocity from the losses given. The velocities tested ranged from 0 to 20,000 feet per minute. His tests show that the unit heat transfer (K) increases slightly with the temperature of the surface and air, but tests by the writer show that for all practical purposes the unit heat transfer is independent of the temperature over the range of 20 to 100 deg. cent.

(b) Effect of change in shape of duct cross-section.

Fig. 11 gives the value of the heat transfer constant for three different shapes of ducts. All three have the same periphery. These curves show that the oblong duct has a better heat transfer than the triangular or circular duct also the watts dissipated are more nearly proportional to the air velocity.

(c) Effect of change in air flow through duct.

FIG. 12—WATTS DISSIPATED FROM INTERIOR SURFACE OF SMOOTH AXIAL DUCT, SHOWING EFFECT OF CHANGE OF AIR PATH

A piece of 0.020-inch fullerboard, $1\frac{1}{4}$ inch wide and 36 inches long, was placed in the $1\frac{1}{4}$ inch diameter duct and given a twist of two turns in its full length. This twist forced the air to take a helical path through the duct. Fig. 12 gives the results of this upon the heat liberated. It shows that the air was forced to mix more thoroughly and to scour the tube surface so as to give a greatly increased heat transfer over that obtained with the smooth tube.

(d) Effect of change in nature of surface.

Axial ducts in machines are formed by stacking the laminations in which holes are punched so as to form a continuous system of ducts through the core. The surface of such ducts will not be smooth, due to slight variations in the punchings and in their stacking. To study the effects of this upon the heat dissipated, a series of tests was made with a laminated duct.

Punchings of 0.017-in. iron in the form of washers $1\frac{3}{4}$ inches outside diameter and $1\frac{1}{4}$ in. inside diameter were forced in the $1\frac{3}{4}$ -in. tube forming a duct $1\frac{1}{4}$ inches in diameter and 36 inches long. Thermocouples were placed at equal intervals along the duct between the laminations so as to obtain the surface temperatures.

Fig. 13 gives the values of the heat transfer constant for the smooth and laminated $1\frac{1}{4}$ -in. diameter ducts. The value of (*K*) for the laminated duct is appreciably higher than that for the smooth surface duct and is almost proportional to the air velocity. This shows that a rough surface sets up eddies in the air stream, disturbing the uniform air path found in the case of the ducts with smooth surfaces. This tends to prevent a flow of relatively cool air through the center of the duct.

The surface of such ducts in actual machines may be considerably rougher (due to greater irregularities in the stacking) than the surface in this model duct. Hence, in practise, the heat dissipation constant may exceed the values shown.

(e) Effect of dust deposits upon the dissipation of heat. Ventilated machines operating in dirty air will in time have a layer of dust deposited upon the ventilating surfaces. To show the detrimental effects of this dust upon the heating of the machine, the $1\frac{1}{4}$ -in. diameter

FIG. 13—WATTS DISSIPATED FROM INTERIOR SURFACE OF AXIAL DUCT, SHOWING EFFECT OF SURFACE

laminated duct was given a 0.030-in. coating of fine coal dust. To obtain a permanent coating of this dust in a short time, it was necessary to put a thin coating of varnish upon the surface and then to blow the coal dust through before the varnish dried. The coat of dust deposit, Fig. 14, shows a very great reduction in the heat dissipated especially at high air velocities.

The dust deposit introduced an additional temperature drop which is independent of the air velocity, depending only upon the watts per square inch which must be conducted through this deposit. The dust coating also reduced the velocity of air passing through the duct for a given static air pressure. Thus for a static air pressure of $1\frac{1}{2}$ inches the unit dissipation

FIG. 14—EFFECTS OF COAL DUST DEPOSITS ON THE DISSIPATION OF HEAT FROM AXIAL DUCTS

constant was reduced from 0.066 to 0.031 watts/sq. in./deg. cent. by the dust coating.

(f) Static Air Pressures

The pressure required to drive the air at a given velocity through the axial ducts is an important factor in the cooling of electric machines by this system. Pressures were measured in the experimental model as shown in the sketch. Due to the relatively low velocity of the air in the intake and exit pipes attached to the duct, the static pressure measured is the resultant of the intake, exit and frictional losses.

The values of these pressures obtained were:

Type of duct		$p = Cv^2$
Smooth circular	$1\frac{1}{4}$ in. and $1\frac{3}{4}$ in. Dia.....	$= 0.086 v^2$
"	" $\frac{7}{8}$ in. Dia.....	$= 0.132 v^2$
"	" $\frac{5}{8}$ in. Dia.....	$= 0.227 v^2$
"	" $1\frac{1}{4}$ in. Dia. with paper helix.....	$= 0.177 v^2$
Laminated "	$1\frac{1}{4}$ in. Dia.....	$= 0.128 v^2$
"	" $1\frac{1}{4}$ in. Dia. with dust deposit....	$= 0.171 v^2$
Smooth triangular	3.93 in. periphery.....	$= 0.097 v^2$
" oblong	3.93 in. "	$= 0.140 v^2$

Where *p* = the total static pressure drop in inches of water with an air temperature of 25 deg. cent.

v = average air velocity through the duct in 1000's ft. per minute.

Where p = the total static pressure drop in inches of water with an air temperature of 25 deg. cent.

v = average air velocity through the duct in 1000's ft. per minute.

The intake opening to the ducts was designed so as to give practically no loss at intake so that the above pressures are composed of the static pressure due to friction losses along the duct and the static pressure necessary to raise the air from zero up to the average air velocity in the duct. With no frictional losses, $p = 0.0615 v^2$, so that the difference between the pressures given above and this pressure is approximately the static air pressure drop due to friction in the 3-ft. ducts.

There is seen to be some relation between the heat transfer and the static air pressure drop for ducts of the same size. Thus, the heat transfer for a given air velocity was greater with the laminated $1\frac{1}{4}$ -in. diameter duct than for a smooth surface duct of the same size, also the static air pressure required was greater for the laminated duct. Likewise, the insertion of the paper helix in the smooth duct increased both the heat transfer and the static air pressure required to force through a given quantity of air.

B. RADIAL DUCTS

The most common method of cooling the cores of rotating machines is with the use of radial air ducts. Some advantages of the radial duct system are:

1. Radial ducts on the rotating element act as blowers, hence are self-ventilating.
2. Maximum air velocities are found where the losses are most concentrated; that is, in the tooth zone.
3. The air reaches the above tooth zone before it has become appreciably heated and the maximum air temperature is found where the iron losses per unit volume are a minimum.
4. Parallel ventilation of the end windings and the radial ducts is very simply accomplished.

Some of the disadvantages of the radial air duct system are:

1. On rotors having low peripheral speed the fanning action of the radial ducts is small, since the volume of air forced through is directly proportional to the peripheral speed for any given machine.
2. The majority of the heat due to the iron losses in the interior of the iron packet between two ventilating ducts must be conducted to these ducts through the intervening laminations. Since the resistance to the flow of heat across the laminations is 30 to 50 times the resistance to the heat flow along the laminations, it is thus necessary to limit the length of the heat flow path by close spacing of the radial ducts.
3. On high-speed machines especially induction motors, the windage noise may be excessive for certain applications.
4. On machines using small widths of teeth, the

duct opening may be too small for effective ventilation and may become closed in service by duct and lint deposits.

5. On small diameter machines the air intake to the radial ducts in the rotor spider is apt to be restricted.

6. The radial ducts increase the gross core length and hence the distance between bearings.

DISSIPATION OF HEAT FROM RADIAL DUCTS

The experimental determination of the heat transfer constants from the surfaces of radial ducts is rather difficult due to the erratic disturbance set up in the air stream by the irregular separating spacers or fingers and to the conductors traversing the air flow path. Also the cross-section of the air path is constantly changing due to the changing diameter.

On machines of large diameter and shallow core depth the air velocity does not change much in passing

FIG. 15—HEAT TRANSFER FROM THE SURFACE OF PARALLEL PLATES FOR VARIOUS SEPARATION

through the main portion of the core. These conditions can be imitated by two hot plates spaced a definite distance apart with air forced through the separating duct. This air duct varies from $\frac{1}{4}$ to $\frac{1}{2}$ in., the average radial air duct being $\frac{3}{8}$ in. thick.

The results of tests made by the U. S. Bureau of Standards⁶ on copper plate type of radiators with three different air separations between them are shown on Fig. 15. There is not a great difference between these three curves and it is probable that the differences shown for the low velocities are within the range of experimental error.

Some preliminary tests⁴ made on two smooth parallel hot iron plates separated a distance of $\frac{7}{16}$ in. are also shown on Fig. 15. These values are lower than those found above. It should be noted that in all these tests the heat dissipation constant is almost directly proportional to the average air velocity. Comparison of the

figures given for the 7/16-in. parallel duct with those given in Fig. 9 for the circular axial ducts will show almost the same values.

In the above experimental tests the air flow through the ducts was more uniform than that found in actual radial ducts. The tests given on Fig. 12 show a large increase in the heat transfer by a disturbance or mixing of the air flow in the ducts. Thus it is probable that the heat transfer constants given for the model radial ducts should be increased from 25 to 50 per cent for the actual values obtained in a machine due to the presence of the conductors and the ventilating fingers.

The fingers or ventilating spacers used in the radial ducts are effective not only in mixing up the air flow streams but they also increase the ventilating surfaces. Calculations will show that on the average machine the average temperature of the ventilating spacers is at least 90 per cent of the main duct surface temperatures. This additional ventilating surface on some machines will increase the effective duct surface as much as 30 per cent.

On machines of small diameter where the air velocity

FIG. 16—APPARATUS FOR DETERMINING THE HEAT DISSIPATION FROM ROTORS

through the radial ducts is changing continuously, the average heat dissipation can be taken on the basis of the average air velocity. This is justified by the fact that the heat dissipation constant is practically proportional to the air velocity.

C. DISSIPATION OF HEAT FROM A ROTATING ELEMENT

The tests previously given show that for all practical purposes the transfer of heat from the surfaces of axial or radial ducts is almost proportional to the average air velocity forced through these ducts. Experience, however, on the removal of heat from a rotating armature, for example, does not exactly agree with the above observed law. Also no definite data were available regarding the effects of forced air convection currents along the surface of a rotating element. For these reasons this phase of the cooling problem was experimentally investigated on a model rotor.

DESCRIPTION OF EXPERIMENTAL APPARATUS

A sketch of the experimental rotor is shown on Fig. 16. The rotor proper was made of micarta tubing and

plate, supported on a 4-in. shaft which in turn was supported between two pedestal bearings. The heating element (0.057 in. $\times$ 0.875 in. monel metal strap) was wound on the outside of this drum. The temperature of this winding was obtained by the change in resistance of a copper search coil wound in between this monel metal heater and the micarta drum. The heater straps were insulated from each other and from the copper temperature coil by a 0.005 in. paper sleeve. The outer surface of the heater, however, was bare. The heating element was connected to two slip rings also the copper search coil was connected to two other copper slip rings. Care was taken to minimize contact drop by using copper leaf brushes. Also separate brushes were used for current and for potential taps. The copper temperature winding was made of 0.005 in. $\times$ 0.250 in. copper strap and had a resistance of approximately 3 ohms.

The drum as shown is surrounded by a tin housing. This was used in investigating the cooling of the rotor with forced ventilation. For self-ventilation tests this housing could be removed. For forced ventilation the air flow was axial along the air gap surface of the rotor. The air was supplied from an adjustable speed blower. The rise of air temperature due to the absorption of the loss was measured by a series of ten thermocouples distributed across the air inlet and outlet.

PROCEDURE OF TESTS

The first series of tests was made with self ventilation, with the tin housing removed, allowing the rotor to rotate in free air. With the drum rotating at a fixed speed the current was thrown on so as to give a temperature rise ranging from 30 to 75 deg. cent. The current and rotor speed were held constant until thermal equilibrium was reached after which all readings were taken.

The power was supplied by a d-c. generator. The watts dissipated were found from the product of the current and the voltage drop as measured by two pairs of copper leaf brushes on the slip rings.

The temperature of the surface was found by the resistance reading of the copper temperature winding. This method of getting the temperature was accurate since there was no flow of heat in towards the center of the rotor after steady condition had been reached, and the temperature difference between the two sides of the monel strap did not exceed $\frac{1}{2}$ deg. cent.

With forced ventilation a series of tests was made with the drum stationary. During each run the blower speed as well as the heater input were held constant. With the drum rotating at a definite speed a series of runs was taken with various blower speeds and heater inputs. This way 5 series of runs were made with rotor speeds of 60, 200, 600, 1000 and 1300 rev. per min. Under these different conditions the static air pressures were measured.

DISCUSSION OF RESULTS

Fig. 17 gives the rate at which heat is dissipated for self-ventilation and forced ventilation. Under self-ventilation the ordinate is obtained by dividing the total watts dissipated by the total surface (2470 sq. in.) and by the rise in deg. cent. of the surface above room air temperature. With forced ventilation the deg. cent. rise used is the rise of the heater strap above the average air temperature. This is equivalent to

FIG. 17—DISSIPATION OF HEAT FROM THE SURFACE OF A ROTOR, 25 IN. DIA., 36 IN. LONG

the temperature of the surface minus the adjacent air temperature in the air gap.

For self-ventilation the abscissa is expressed as the peripheral speed of the rotor in 1000's ft./min. For the curve with forced ventilation the abscissa represents the average air velocity through the air gap with the drum stationary.

The cubic feet of air per minute was obtained from the watts absorbed and the corresponding rise in air temperature.

$$\text{hence } V = \frac{1.765 W}{T}$$

where V = cu. ft. of air per minute.

where W = watts absorbed by air.

T = rise in air temperature deg. cent.

The curve with self-ventilation bends over with high rotor speeds. This indicates that some of the hot air is carried around with the rotor. With forced ventilation, however, the air is forced to pass through the duct. The dissipation of heat is proportional to the number of air molecules passing a given surface, and to the temperature difference between the surface and those air molecules. This is shown by the dissipation constant being roughly proportional to the air velocity with forced

ventilation. The curve gives 0.004 watts/sq. in./deg. cent. with zero air velocity. This is due to the fact that there was some air leakage caused by convection currents. With self-ventilation about 0.008 watts/sq. in./deg. cent. is dissipated with the drum stationary due to convection and radiation.

The curve obtained with forced ventilation and drum stationary agrees very closely with the curve shown on Fig. 13 which gives the corresponding values for an axial duct through punchings.

By extending the curve shown for natural ventilation it is estimated that with a peripheral velocity such as is obtained in turbo-generators of 20,000 to 25,000 feet per minute the dissipation constant will have reached its maximum value of about 0.10 to 0.12 watts per sq. in. per deg. cent. rise. With forced ventilation under the conditions shown, there seems to be no limit to the amount of heat which can be dissipated. In practise, however, there are several factors which limit to a certain extent the maximum air velocity, such as friction and windage or blower input.

Curves given on Fig. 18 were all obtained with forced ventilation and the drum rotating at various speeds including the stationary run.

It is seen that with a high rotor speed (1300 rev. per min.) the heat dissipation constant is practically constant for air velocities ranging from 2000 to 6000 ft./

FIG. 18—WATTS DISSIPATED FROM THE SURFACE OF A ROTATING ROTOR (25 IN. DIA., 36 IN. LONG), WITH FORCED AXIAL VENTILATION THROUGH A $\frac{1}{2}$ -IN. SINGLE AIR GAP.

min. Conversely it is seen that with the rotor stationary this dissipation constant is practically proportional to the air velocity through the air gap. With a rotor speed of 600 rev. per min. an intermediate condition is shown.

It has been explained before that the curve on Fig. 17 found with natural ventilation indicates that particles of hot air are carried around the rotor when under rotation which causes the curve to bend over with high rotor speeds. This same condition happens with the

drum rotating in a stator and with forced ventilation through the air gap. In addition to this the rotating surface of the drum at high speeds with its film of rotating air particles offers a very high resistance to the axial flow of air through the air gap.

Although these results show that with respect to the rotor the heat dissipation is by no means proportional to the average air-gap velocity yet with respect to the stator the conditions are entirely different and a heat dissipation roughly proportional to the air velocity is to be expected. With the high rotor speeds a high dissipation constant is obtained with low average axial air velocities. This indicates thorough mixing of the air and good scouring action of the rotor surface. However, under these conditions with a long core the temperature of air would rise to an excessive value which would also mean an excessive iron temperature unless other means of ventilation of the core were used.

Thus it is seen that under certain conditions more heat can be dissipated from the rotor stationary than when rotating with the same temperature rise and with the same quantity of air through the air gap per minute.

The air resistance along the stator is comparatively low so that under these conditions, high axial air velocities are found adjacent to the stator while the axial air velocity adjacent to the rotor is small. Thus with a rotor speed of 1300 rev. per min. doubling the quantity of air through the air gap changed the axial air velocities adjacent to the stationary air conduit while the effective air velocity sweeping across the rotor surface was unchanged.

STATIC AIR PRESSURE

The disturbing influence of the rotating drum upon the flow of air through the air gap is shown by the static air pressure curves, Fig. 19. Thus an average air velocity of 3000 ft./min. through the air gap requires a total static pressure of 0.9 in. of water with the drum stationary. With the drum rotation at 1300 rev. per min. or a peripheral speed of 8550 ft./min. requires 1.97 in. of water static pressure to force through the same amount of air. Also for an average air velocity of 5000 ft. min. through the gap requires a pressure of 2.5 in. with the rotor stationary and 4.34 in., with a rotor speed of 1300 rev. per min.

The empirical equation for these pressure-velocity curves is:

$$p = (0.0152 v^{3/2} + 0.1 V) V$$

where p = total static air pressure drop.

v = rotor peripheral velocity in 1000's ft./min.

V = average air velocity through air gap in 1000's ft./min.

From the equation it is seen that the factor $(0.0152 V v^{3/2})$ represents the additional static air pressure required to overcome the disturbing influence of the rotor. The factor $0.1 V^2$ represents the pressure required with the rotor stationary.

With a rotor peripheral speed of 20,000 ft./min.,

such as found in turbo-generators, and an average air-gap velocity of 5000 ft./min. the total static air pressure which would be required for the apparatus tested amounts to 9.3 inches of water.

In machines using small air gaps such as induction motors it is seen that very little, if any effective ventilation or cooling can be obtained by trying to force air through the air gaps. The resistance of the air path is too high for the static air pressures usually available.

With the drum rotating at 1000 rev. per min. and with no forced ventilation the watts dissipated due to the natural fanning action of the rotor amounted to only 0.008 watts/sq./in./deg. cent. rise of rotor windings, which is a negligible quantity.

FIG. 19—TOTAL STATIC AIR PRESSURE REQUIRED TO FORCE AIR THROUGH A 1/2-IN. SINGLE AIR GAP, 36 IN. LONG WITH ROTOR AT VARIOUS SPEEDS. ROTOR DIAM. 25-IN.

D. DISSIPATION OF HEAT FROM END WINDINGS

The designer of rotating electric machines tries to reduce the length of the heat flow path in the windings to a minimum. Thus the end windings of these machines are usually ventilated so that the copper loss can be liberated after having been conducted through the insulating material. Due to the great surface available in these ventilated end windings their temperatures are usually lower than the imbedded windings, in fact many short core machines can be cooled almost entirely by these ventilated windings⁸. The tests described below were made for the purpose of investigating the rate of heat transfer from these windings as affected by air velocities and coil arrangement.

(a) *Description of Experimental Apparatus:* For investigating the cooling of a rotating end winding due to its own fanning action an experimental rotor was

made as shown on Fig. 20. This was a 600-volt, Class A insulated winding in which the core length was reduced to a minimum. Thus the armature coil can be considered as two end windings connected together. The ventilating space between the coils was approxi-

FIG. 20—EXPERIMENTAL MODEL FOR DETERMINING THE DISSIPATION OF HEAT FROM ROTATING END WINDINGS

mately 1/8 in. and a minimum of banding wire was used so as to obtain the maximum ventilation.

The determination of the heat transfer constants from such a winding was subject to difficulties due to the irregular air flow through the windings. The irregularity was due to the unevenness of the coil

FIG. 21—DISSIPATION OF HEAT FROM SURFACES OF ROTATING END WINDINGS

separations also part of the coils, on the diamond portion, crossed each other forming a checker-board effect, while the remainder of the coil sides were parallel to each other. For these reasons tests were made on this model with self-ventilation only.

The windings were all connected in series and direct current was circulated for heating the windings. The average temperature of the copper was obtained by the change in resistance method.

TESTS AND DISCUSSION

The results of the tests obtained are shown on Fig. 21. The ventilation surface of the end coil was taken at its mean length of turn times the outside periphery. Tests were also made with the winding non-ventilated, that is, with the intake air cut off. The great differences shown by the two curves bring out clearly the importance of ventilating the winding. These two curves given for the insulated windings show a bending over of the curves with increasing speed due to the thermal drop through the insulation.

The similarity of the curves given for the ventilated winding to that given on Fig. 17 for the heat transfer from a rotating cylinder in free air should be noted.

The curve shown in dotted lines is for the surface heat transfer and gives the values with no drop through the insulation, or with the insulation removed.

FIG. 22—EXPERIMENTAL MODEL FOR TESTING THE HEAT DISSIPATION FROM END WINDINGS

(b) *Test with Separate Ventilation.*⁴ In order to investigate more fully the ventilation of end windings, an experimental model was made as shown in Fig. 22. This model consisted of a wood frame holding the coils to be tested with the proper clearance between them. The coils were 1 in. by 2 1/4 in. by 12 in. long. They were wound with a special wire heater and insulated with cotton tape, treated as in practise. The average surface temperatures of the coils were obtained by the change in resistance of a fine copper wire distributed over the surface of the coils. Two frames containing the sample coils were used. These could be arranged with the coils parallel and in line with each other, or by rotating one frame 90 deg. the coils in the two separate frames would cross each other, forming the checker-board effect such as is formed on the diamond portion of the end windings.

The air volume passing through the ventilating space of these coils was measured by the electric method

previously described. The average air velocities were obtained by dividing the volume by the cross-sectional area of the ventilating spaces.

TESTS AND DISCUSSION

The results of these tests are shown on Fig. 23. The values given for the 1/8-in. and 1/4-in. air spaces are a mean value for all the curves. This one curve is not only common for both of these ventilating spaces but is also common for both coil arrangements.

That is, the heat transfer coefficient is the same with

FIG. 23—DISSIPATION OF HEAT FROM END WINDINGS BY FORCED VENTILATION

the coil axes parallel and at right angles to each other. The values given for the 3/8-in. and 1/2-in. air spaces with the coils parallel lie below this mean curve while the values for these spacing with the coils at right angles are above the mean curve. It should be noted that the rate of increase of the heat transfer per 1000 foot air velocity is practically the same as that given for the laminated axial ducts, Fig. 13. The curves for the end windings do not pass through zero for zero air velocity. This ordinate represents the heat dissipated by natural convection and radiation.

E. DISSIPATION OF HEAT FROM CYLINDRICAL SURFACES

(a) *Plain Cylindrical Surfaces.* The current capacity of wires or cables either bare or insulated placed in a given air velocity stream will depend upon the rate of heat liberation from the ventilating surface. Tubular type of air coolers are also used for cooling the ventilating air in the closed circuit system of ventilation. Another application where heat is transferred from cylindrical surfaces is in the tubular type of air-oil coolers.

The transfer of heat from cylindrical surfaces with forced air convection at right angles to the cylinder axis is much greater than the coefficient previously given. For example, Kennelly and Wright,⁹ found the

following equation to hold for wires placed at right angles to an air stream:

$$K = \left(\frac{1.21}{d} + 595 \right) \frac{\sqrt{1 + 20.3v}}{10^4}$$

where K = heat transfer in watts/sq. in./deg. cent.

d = diameter of wire in inches.

v = air velocity in 1000's ft./min.

These tests were made on small wires of 0.0045 in. to 0.0272 in. diameter. The above equation does not hold for wires larger than these. With a 0.0201-in. diameter wire (No. 24 B & S gage), the heat transfer on the basis of a 1000 foot per minute air velocity will be 0.303 watts/sq. in./deg. cent.

Hughes¹⁰ tests on the heat transfer from the outside surfaces of copper tubes by forced air convections currents at right angles to the tubes are plotted on Fig. 24. These tests show a great variation of the constants with the tube diameter.

(b) *Cylindrical Surfaces with Fins.* In the tubular type of cooler or heat interchanger where a liquid is forced through the tube bore and the air flow is external at right angles to the tube, it will be found that the limiting resistance to the heat flow will be on the air side, due to the high rate of heat transfer on the liquid side. Hence it is usually advisable to increase the

FIG. 24—DISSIPATION OF HEAT FROM THE OUTSIDE SURFACE OF COPPER TUBES BY FORCED AIR CONVECTION AT RIGHT ANGLES TO TUBE.

effective air-ventilating surface by fastening metal fins on the outside of the tube. In this way the effective ventilating surfaces can be increased several fold.

Tests on such a cooler with 5/8 in. outside diameter copper tubes, equipped with 5 fins per inch of tube, are shown on Fig. 25. The heat transfer given is figured on the basis of the total ventilating surfaces composed of the outside tube surface and the total fin surfaces. The fin surface was six times the outside tubular surface yet the average heat transfer coefficient is much

investigation on particular elements that go into the heating problem.

Especially in connection with the ventilation of machinery we are going ahead quite rapidly. We are realizing that there is a distinct connection, for instance, between the character of flow of water and that of air, and since we use air almost exclusively for cooling, we can take the results of the work of hydraulic engineers, or apply them directly to some of our problems in connection with the flow of air.

For the most part the engineer who has worked with air problems has considered air to be highly compressible whereas water is not, and therefore air could not be considered in the same manner as water. Now, as a matter of fact, the compression to which air is subjected in electric machinery is ordinarily of the order of one or two per cent or even less of the total pressure. Atmospheric pressure corresponds to approximately 407 inches of water, and it is seldom we run more than ten or twelve inches, which is less than three per cent.

Now, considering that very fact means that we can take the work of the hydraulic engineers and use their formulas for computation of such things as pressure drops in our machines, when they can be applied. We can use their method of attack in many cases and build up models of parts of machines and cause air to flow through them (or water, if it can be more readily used), and determine our constants, so we are better able to compute the air pressure drops as we can compute the electric pressure drops in our external networks, although, of course, the computation is far more difficult in the case of the air circuit than in the electric circuit. Then if we determine experimentally the characteristics of the generator of pressure, that is the fan, we have solved a very large part of the ventilating problem, if the air circuit is in an enclosed chamber such as in the high-speed turbine generators. Once we have determined how the air flows through the machine, and the volume and pressure, we have gone a long ways toward solving this very complex problem.

One more thing in connection with Mr. Rice's paper; electrical engineers have seldom used the method of dimensions for solving their problems. It is a method which is quite foreign to most of their methods of attack. I might suggest that they look into that a little further, but in using that method of dimensions great caution must be observed because some item might be overlooked and the solution will in consequence be entirely in error.

V. M. Montsinger: In Fig. 6 Mr. Luke gives some curves for the dissipation of total loss from large vertical plates. According to these curves and from 0 to 120 deg. cent. rise the loss varies approximately as the temperature rises raised to the powers of 1.3 and 1.36. For temperature rises used in practise I have found that the exponent is somewhat less than these values.

Suppose we consider rises from 20 to 70 deg. cent. and calculate the exponent considering both radiation and convection. If we differentiate the radiation formula we can calculate the exponential values for different values of rises for any given room temperature as follows:

$$k(T_2^4 - T_1^4) = (T_2 - T_1)^n k$$

$$\log(T_2^4 - T_1^4) + \log k = n \log(T_2 - T_1) + \log k$$

Differentiating, we get

$$n = \frac{4 T_2^3}{(T_2 + T_1)(T_2^2 + T_1^2)}$$

The following gives the values of n for a room temperature of 20 deg. cent. ($T_1 = 293$ deg.)

$(T_2 - T_1)$	n
10	1.051
20	1.104
30	1.150
40	1.200
50	1.245
60	1.292
70	1.339
Average 1.197	

Since approximately one-half the loss from a plain black surface is dissipated by convection and the other half by radiation and since the exponent is 1.25 for convection the general average exponential value should be about 1.225. This I find checks fairly closely with test results within this range of rises.

In second column on the fourth page, Mr. Luke gives a formula for the total loss from an irregular surface. For corrugated surfaces I have found that it is necessary to introduce a correction factor, say R , in the convection part of the formula to take care of restricted air circulation in deep corrugations. For instance, if we should have a corrugation 12 in. deep and with an air space 1 in. wide the value of R is about 0.5. In other words the convection is only about one-half as effective within this corrugation as for a plain surface. This reduction is a function of the width divided by the depth of the air space in the corrugation.

I hope to publish in the near future an article dealing with dissipation of loss by radiation and convection from plain and irregular surfaces and in which will be given a formula that will hold for any reasonable shape of corrugation, etc.

G. E. Luke: Mr. Montsinger has given some data indicating that the dissipation of heat from large vertical plates by radiation and convection should vary approximately as the temperature rise raised to the 1.225 power or $W = a T^{1.225}$ where (W) is watts loss per square inch of surface and (a) is a constant.

This equation is approximate for a given temperature range. The values of 1.30 to 1.36 given in the paper were averages for a temperature rise of 20 to 120 deg. cent. The exponents of (T) based on temperature rises of 20 to 70 deg. cent. would be reduced and would not differ materially from the above value given by Mr. Montsinger.

The exact value of this exponent is not well established, for example, Frank and Stephens¹ give data which result in a value of approximately 1.31 for this exponent based on a temperature rise up to 70 deg. cent. To determine the exact value of this equation will require exceedingly accurate tests and will probably be dependent upon the conditions of test such as size and position of plate and upon the natural air convection currents found in the room used for the tests.

There is no doubt but that the heat loss from a unit surface of a radiator or corrugated surface by natural convection will be less than that found from a plane surface so that a factor (R) as suggested by Mr. Montsinger would be desirable in the general heat loss equation from such surfaces. This constant will not only vary with the depth of the corrugations but will depend upon the height of the vertical surfaces and also upon the degree of freedom the air has in flowing through the radiator.

Free and Forced Convection of Heat in Gases and Liquids

BY CHESTER W. RICE

Associate, A. I. E. E.
Research Laboratory, General Electric Co.

Review of the Subject.—The general problem of heat transfer requires a knowledge of the laws of conduction, radiation and convection. In 1822, Fourier gave us the first thoroughly scientific definition of conductivity and reduced the problem of heat conduction to an exact science, with a power and completeness which left little room for extension or improvement even to the present day. The law of radiation was first suggested by Stefan in 1879 as a result of an analysis of some experiments made by Tyndall. In 1884 Boltzman deduced the law theoretically from the principles of thermodynamics and electromagnetics. Thus the laws of conduction and radiation have been accurately known for a long time, while the problem of convection has received relatively little study. This fact is surprising when we consider the important part played by convection in almost all cases of heat transfer. A complete mathematical solution of a convection problem would require a knowledge of the hydrodynamic laws of viscous fluids for stream line and turbulent motion, combined with the Fourier equations of heat conduction in a moving medium. At present our lack of the hydrodynamic laws for turbulent motion renders a rigorous solution impossible. Therefore in most of the theoretical work so far attempted the simplifying assumption of an inviscid fluid has been found necessary. The theoretical results obtained when viscosity is neglected are in general far from the experimental facts. Langmuir's study of the problem showed that the viscosity is a factor of first importance which cannot be neglected. He therefore adopted a film theory as an approximation. The reason for the existence of a film around a hot body may be seen as follows: Consider a horizontal wire maintained at a given temperature in a fluid, the fluid adjacent to the wire will become heated and rise while the cooler fluid of greater density will flow into its place. Thus a convection current is set up by the difference in density between the hot and cold fluid. This condition is usually referred to as free convection. At the surface of the wire the fluid is stationary due to viscosity. As we proceed from the surface of the wire the velocity of the convection currents increase until a distance is reached at which the critical velocity conditions in the fluid are exceeded and the stream line flow bursts into turbulent motion. The discontinuity between

the stream line and turbulent motion constitutes the outer boundary of the film. At the inner boundary the fluid has the temperature of the hot surface and at the outer boundary the temperature of the ambient fluid. The actual configuration of the outer boundary is unknown. As an approximation we might assume that it was an eccentric ellipse or cylinder, etc., and determine the size and eccentricity so as to best fit the experimental results. For ease of calculation Langmuir adopted the simplest approximation and assumed that the outer boundary of the relatively stagnant film was a cylinder concentric with the wire. He thus reduced the hopelessly complex problem of convection to one of conduction in the steady state.

The question of how the film thickness varies with the size and shape of the body and properties of the ambient fluid is determined by the method of dimensions plus experiments. Raleigh has frequently pointed out the great power of the **method of dimensions** in obtaining the solution of physical problems. He says—"It often happens that simple reasoning founded upon this principle tells us nearly all that is to be learned from even a successful mathematical investigation, and in numerous cases where such a mathematical investigation is beyond our powers, the principle gives us information of the utmost importance." As already stated the problem of convection is at present beyond our reach and therefore we have to be content with the information which we can obtain from the **method of dimensions**.

Recently Davis has attacked the problem by dimensional methods starting from certain general hydrodynamic considerations which do not take into consideration the existence of a film. In the present papers on Free and Forced Convection Langmuir's film theory has been extended by dimensional analysis and it is felt that the results obtained give a clearer insight into the mechanism of convection, as well as more useful equations. An attempt has also been made to bring together the available data and correlate them as far as possible. A striking example of the practical results which may be expected from a thorough understanding of the laws of conduction, radiation and convection is found in Langmuir's gas filled lamps. His study and application of these laws allowed him to more than double the efficiency of the incandescent lamp.

FREE CONVECTION OF HEAT

I. Introduction

A RIGOROUS mathematical solution of a problem in free convection would require an exact knowledge of the hydrodynamic laws of viscous fluids for stream line and turbulent motion, combined with the Fourier equations of heat conduction in a moving medium. The problem of turbulent fluid motion has been attacked by Stokes, Kelvin, Rayleigh, Reynolds and others without as yet having reached a satisfactory solution. A summary and discussion of their work may be found in Lamb's *Hydrodynamics*.¹

1. Horace Lamb, *Hydrodynamics* Camb. Univ. Press 3rd Edition, p. 591.

Presented at the Annual Convention of the A. I. E. E., Swampscott, Mass., June 26-29, 1923.

In most of the theoretical work so far attempted on convection the simplifying assumption of an inviscid fluid has been found necessary. A summary of this theoretical work on heat transfer, with numerous references, may be found in Russell's² valuable paper. Langmuir³ preferred to retain the idea of viscosity as a factor of first importance and therefore adopted a film

theory as his approximation. More recently Davis⁴ has attacked the problem of convection by the method of dimensions starting from certain hydrodynamic considerations.

II. Langmuir Film Theory of Convection

When a horizontal wire is maintained at a given temperature in a fluid, the fluid adjacent to the wire becomes heated and rises while the cooler fluid of greater density flows into its place. Thus a convection current is set up by the difference in density between the hot and the cold fluid. At the surface of the wire the fluid is stationary since the viscosity requires that there is no slip at the boundary between the wire and the fluid. As we proceed from the surface of the wire the velocity of the convection currents increase until a distance is reached at which the critical velocity conditions in the fluid are exceeded and the stream line flow bursts into turbulent motion. The discontinuity between the stream line and turbulent motion constitutes the outer boundary of the film. At the inner boundary of the film the fluid has the temperature of the hot surface and at the outer boundary the temperature of the ambient fluid. In order to simplify this picture for purposes of calculation Langmuir assumed that the outer boundary of the relatively stagnant film of fluid was a cylinder concentric with the wire, and of a definite diameter. He thus reduced the complex problem of free convection to a problem of conduction in the steady state.

The general equation for the conduction of heat after the steady state has been reached is

$$W = (A/L) k \Delta t \quad \text{watts} \quad (1)$$

where W = watts of heat flow

A = Area of cross-section of heat flow path in square cm.

L = Length of heat path in cm.

k = Heat conductivity of medium expressed in watts per cm. per deg. cent.

Δt = Temperature difference causing the heat flow in deg. cent.

For the case of free convection from a wire, we substituted the problem of conduction between concentric cylinders as illustrated in Fig. 1, the inner cylinder being at the temperature of the wire and the outer cylinder having the temperature of the ambient fluid. Applying equation (1) to the element dr we obtain for the total heat flow for a length of L cm.

$$W = - \frac{2 \pi r L}{dr} k dt \quad \text{watts} \quad (2)$$

4. a. A. H. Davis, *Phil. Mag.*, Vol. 40, p. 692, 1920. (Paper dealing with Free and Forced Convection).

b. A. H. Davis, *Phil. Mag.*, Vol. 41, p. 899, 1921. (Paper dealing with Forced Convection for Cylinders and a relation to mechanical resistance to flow).

c. A. H. Davis, *Phil. Mag.*, Vol. 43, p. 329, 1922. (Paper Free Convection from Cylinders).

d. A. H. Davis, *Phil. Mag.*, Vol. 44, p. 920 and p. 940, 1922. (Papers on Free and Forced Convection).

This can be written

$$\frac{W}{2 \pi L} \frac{dr}{r} = - k dt \quad (3)$$

Integrating between limits $r = D/2$ and $r = b/2$ and $t = T_2$ and $t = T_1$

$$\frac{W}{2 \pi L} \int_{r=D/2}^{r=b/2} \frac{dr}{r} = - \int_{T_2}^{T_1} k dt \quad (4)$$

If the heat conductivity k is independent of temperature we obtain

$$\frac{W}{2 \pi L} \log_e b/D = (T_2 - T_1) k \quad (5)$$

$$\text{or} \quad W = \frac{2 \pi L k \Delta t}{\log_e b/D} \quad \text{watts} \quad (6)$$

Now if k is a function of the temperature as is the

FIG. 1—FREE CONVECTION IN GASES AND LIQUIDS

case in all real fluids we go back to equation (4) and obtain after integrating the left hand side and interchanging the limits of integration for T

$$W = \frac{2 \pi L}{\log_e b/D} \cdot \int_{T_2}^{T_1} k dt \quad \text{watts} \quad (7)$$

$$\text{or} \quad W = \frac{2 \pi L}{\log_e b/D} \left[\int_0^{T_2} k dt - \int_0^{T_1} k dt \right] \quad (8)$$

Langmuir has used the following abbreviation for the thermal conduction

$$\varphi = \int_0^T k dt \quad \text{watts per cm.} \quad (9)$$

where

T = Absolute temperature of fluid in deg. K.

k = Heat conductivity in watts per cm. per deg. cent.

If the heat conductivity k is given in calories per second per cm. per deg. cent. then we have

$$\varphi = 4.19 \int_0^x k dt \quad \text{watts per cm.} \quad (10)$$

Langmuir has also put

$$S = \frac{2 \pi L}{\log_e b/D} \quad \text{cm.} \quad (11)$$

write equation (8) in the following abbreviated form

$$W = S (\varphi_2 - \varphi_1) \quad (12)$$

or putting $\varphi_2 - \varphi_1 = \Delta \varphi$

$$W = S \Delta \varphi \quad \text{watts} \quad (13)$$

CALCULATION OF "SHAPE CONDUCTANCE"

Langmuir has pointed out that all problems in steady heat flow can theoretically be reduced to the form given by equation (13).

This "shape conductance" is the same as the "shape capacity" in electrostatics or "shape permeance" in the magnetic circuit, provided Heaviside units are used, or as the "shape conductance" in the electric circuit. In brief, the shape conductance has the same value for that large class of problems which are governed by the divergence theorem and the Fourier-Ohm law. The combination of these two laws results in Laplace's

and called it the "Shape Factor." The factor S might also be termed the "Shape Conductance" since it measures the ease with which heat is conducted through a body of given form without reference to the intervening medium.

By the definitions of equations (11) and (9) we may

FIG. 4—FREE CONVECTION ON TESTS IN OVEN

equation and therefore to determine the shape conductance we require the solution of Laplace's equation so as to fulfill the boundary conditions imposed by the problem. It is not in general possible by known mathematical methods to obtain the required solution except for a relatively few simple geometrical forms. These will be found in works on Electricity and Magnetism, Hydrodynamics, Heat and Sound. Some further useful shapes have been calculated by methods of approximation in a paper by Langmuir,⁴ Adams and Meikle. Reference may also be made to a paper⁵ by the present writer in which an experimental method of obtaining the solution of any flow problem is discussed.

$$S = A/t \quad \text{cm.} \quad (14)$$

FIG. 5

FIG. 6

where A = Area of surface in sq. cm.
 t = thickness of material between surfaces in cm.

II. Concentric cylinders

$$S = \frac{2\pi L}{\log_e b/D} \quad \text{cm.} \quad (15)$$

where L = Length of cylinder in cm.
 b = Diameter of outer cylinder in cm.
 D = Diameter of inner cylinder in cm.

III. Concentric Spheres

$$S = \frac{2\pi}{1/D - 1/b} \quad \text{cm.} \quad (16)$$

where D = Diameter of inner sphere in cm.

b = Diameter of outer sphere in cm.

CALCULATION OF THE THERMAL CONDUCTION ϕ

To calculate the function ϕ for different absolute temperatures it is necessary to express the heat conductivity of the gas or liquid as a function of the absolute temperature.

Due to the meager amount of experimental data available on the heat conductivity of gases as function of temperature compared with that available on the variation of viscosity with temperature, Langmuir^{3a} preferred to calculate the heat conductivity k from the following relations supplied by the kinetic theory of gases

$$k = M \mu c_v \frac{\text{cal.} \times \text{cm.}}{\text{cm}^2 \times ^\circ\text{C} \times \text{sec.}} \quad (17)$$

where M = constant depending on the number of atoms forming the gas molecule.

μ = Viscosity of gas in c. g. s. units

c_v = Specific heat per gram at constant volume.

For the variation of viscosity with temperature he used Sutherland's equation which is

$$\mu = \frac{K T^{1/2}}{1 + C/T} \frac{\text{dynes} \times \text{cm}}{\text{cm per sec.} \times \text{cm}^2} \quad (18)$$

Where K and C are constants which depend on the nature of the gas

T = Absolute temperature of gas in deg. K

For the variation of the specific heat with temperature he used the values given by Pier⁶ of the form

6. M. Pier, *Z. f. Electrochem* 15, p. 536. 1909 and 16, p. 899, 1910.

$$c_v = F (1 + \alpha T) \quad \text{cal. per gram per deg. cent.} \quad (19)$$

Where F and α are constants of the gas

T = Absolute temp. deg. K

For air $F = 0.1614$; $\alpha = 0.0002$

H_2 $F = 2.21$; $\alpha = 0.0002$

Substituting $A = 4.19 M F K$ we obtain

$$k = A (1 + \alpha T) \frac{T^{1/2}}{1 + C/T} \quad \text{Watts per cm. per deg. cent.} \quad (21)$$

which is the relation in the form used by Langmuir in

FIG. 7

CO_2 $F = 0.124$; $\alpha = 0.00095$ (Below 1100 deg. K.)

Substituting (18) and (19) in (17) he obtained for the heat conductivity of the gas as function of temperature.

$$k = M F (1 + \alpha T) \frac{K T^{1/2}}{1 + C/T} \quad \text{Cal. per sec. per cm per deg. cent.} \quad (20)$$

calculating the values of the function φ . We have from equations (9) and (21)

$$\varphi = \int_0^T k dt = A \int_0^T \left[(1 + \alpha T) \frac{T^{1/2}}{1 + C/T} \right] dT \quad (22)$$

and since it is only for large values of T that the temperature coefficient α is important it can be shown that

FIG. 8

From which we obtain

$$\varphi = A (1 + 0.6 \alpha T) (2/3 T^{3/2} - 2 C T^{1/2} + 2 C^{3/2} \tan^{-1} \sqrt{T/C}) \quad (24)$$

The values of the constants taken and the corresponding values of φ have been tabulated for air, hydrogen, mercury vapor, nitrogen, carbon dioxide by Langmuir.^{3d} His values for air, hydrogen and carbon dioxide have been used in the present work and have been reproduced here in Figs. 9, 10 and 11.

Instead of equation (17) we could use the more complete form given by Jeans.⁷

$$k = 1/4 (9\gamma - 5) \mu c_v \text{ Cal. per sec. per cm. per deg. cent} \quad (25)$$

where $\gamma = c_p/c_v$ ratio of specific heats.

For the variation of viscosity with temperature we could use the simpler expression given by Jeans⁷ page 302.

$$\mu = \mu_0 (T/273)^n \quad (26)$$

Where μ_0 = viscosity at 0 deg. cent.

n = exponent depending upon the gas.

For air $n = 0.754$; H_2 , $n = 0.69$; CO_2 , $n = 0.98$.

If we now substitute equations (26) and (19) in (25) we obtain.

$$k = 1/4 (9\gamma - 5) \mu_0 (T/273)^n F (1 + \alpha T) \quad (27)$$

If we place

$$N = 4.19 \times 1/4 (9\gamma - 5) \times F \times (1/273)^n \times \mu_0$$

We obtain

FIG. 9

(22) may be written with sufficient approximation as

$$\varphi = A (1 + 0.6 \alpha T) \int_0^T \frac{T^{1/2} dT}{1 + C/T} \quad (23)$$

$$k = N (1 + \alpha T) T^n \text{ watts per cm. per deg. cent.} \quad (28)$$

7. Jeans. Dynamical Theory of Gases, Camb. Univ. Press, Second Edition, p. 318, 1916.

From which

$$\varphi = \int_0^T k dT = \frac{N}{n+1} \left(1 + \frac{n+1}{n+2} \alpha T \right) T^{n+1} \quad (29)$$

For the purposes of approximation we may assume $n = 1$ in the parenthesis and obtain

$$\varphi = \frac{N}{n+1} (1 + 2/3 \alpha T) T^{n+1} \quad (30)$$

For air we have the following values

- $\mu_0 = 0.0001705$ c. g. s. units
- $F = 0.1614$
- $\gamma = 1.40$
- $n = 0.754$
- $\alpha = 0.0002$

Substitute these values in eq. (29) we obtain for air $\varphi_{air} = 1.825 \times 10^{-6} (1 + .0001275 T) T^{1.754} \quad (31)$

This curve is parallel with Langmuir's between 300 deg. K. and 1000 deg. K. and gives approximately 5

per cent higher values. In this range the maximum variation in $\Delta \varphi$ is approximately 4 per cent.

Above 1000 deg. K. the two curves diverge slowly and at 2500 deg. K. this value of φ is approximately 18 per cent greater than Langmuir's. Jeans' points out that Kamerlingh Onnes finds very definitely that the viscosity of helium between -258.1 deg. cent. and 183.7 deg. cent. cannot be represented by Sutherland's formula with anything like the accuracy given by the simple relation of equation (26). More data on the viscosity of gases at very high temperatures will be required before any definite conclusion as to the best form of equation can be settled. In the following work we have adhered to Langmuir's values of φ .

Langmuir³ found that this very simple assumption of a film theory enabled him to obtain excellent agreement with his experiments made on small wires over a very wide range in temperature and in different gases. He found that the film thickness in a given gas was independent of the wire temperature and merely depended upon the ambient temperature and pressure.

E. Q. Adams and Langmuir^{3a} then developed the following relation to connect the film diameter with the wire diameter:

$$\log_e b/D = \frac{2 B_o}{b} \quad (32)$$

where b = outer diameter of film in cm.

D = wire diameter in cm.

B_o = The film thickness in cm. for a plane surface in the same gas having the same ambient temperature and pressure. For air at 20 deg. cent. and 76 cm. Hg, $B_o = 0.43$ cm.

Langmuir's experiments on small wires were not suitable for obtaining a definite answer to the question of the variation of film thickness with the properties of the ambient gas.

III. Film Thickness by the Method of Dimensions

Let us now see what the method of dimensions can tell us about the variation of film thickness with the shape of the object and properties of the ambient fluid. Rayleigh⁸ has frequently pointed out the great power of the method of dimensions or the effect of scale upon physical phenomena, in obtaining the solution of physical problems. He says—"It often happens that simple reasoning founded upon this principle tells us nearly all that is to be learned from even a successful mathematical investigation, and in numerous cases where such a mathematical investigation is beyond our powers, the principle gives us information of the utmost importance."

The most complete discussions of the principle of

dimensions which the writer has seen are those of Buckingham.⁹

Assume that the film thickness depends on the viscosity of the gas and the density, for it is the viscosity that causes the existence of the film and it is the motion set up by the action of gravity on the difference of density between the hot and cold gas that keeps the film from becoming indefinitely large. Obviously the motion will also depend upon the shape of the hot body. If these factors are all which have an influence on the film thickness B in free convection, the method of dimensions tell us that

$$B = (g, \mu, \rho, D, r_1, r_2 \dots) \quad (33)$$

where B = Film thickness (L)

g = Accelerating force of gravity ($L T^{-2}$)

μ = Viscosity of fluid ($L^{-1} M T^{-1}$)

ρ = Density of fluid ($M L^{-3}$)

D = A linear dimension in terms of which all shape factors may be expressed (L).

r_1, r_2 = Numerical ratios describing the form of the hot body in terms of D and condition of fluid in terms of μ and ρ .

In the case of a wire we might select the diameter as reference linear dimension D and then express the roughness as one tenth of the diameter. The form of the stream lines or tubes of flow around the cylinder will also be expressed in terms of D . Other ratios will state the relation between the density or viscosity near the wire surface to that at a great distance.

The method of dimensions now states that the film thickness may be written in the following form in which all of the numerical ratios have been lumped in the single constant K since the method of dimensions cannot tell us anything about numerical multipliers

$$B = K g^x \mu^y D^z \rho^n \quad (34)$$

Substituting the dimensions of the various factors in equation (34) we obtain

$$(L)^1 = (L T^{-2})^x (L^{-1} M T^{-1})^y (L)^z (M L^{-3})^n \quad (35)$$

If this is to be a true physical equation the dimensions on the two sides must be the same. Therefore

$$\left. \begin{array}{l} \text{By } L; \quad 1 = x - y + z - 3n \\ \text{By } M; \quad 0 = y + n \\ \text{By } T; \quad 0 = -2x - y \end{array} \right\} \quad (36)$$

Solving equation (36) as simultaneous equations in terms of n , we obtain

$$\left. \begin{array}{l} x = n/2 \\ y = -n \\ z = \frac{2+3n}{2} \end{array} \right\} \quad (37)$$

Substitute these values of the exponents in (34) and obtain

$$B = K g^{n/2} \mu^{-n} D^{\frac{2+3n}{2}} \rho^n \quad (38)$$

9. E. Buckingham, *Journ. Wash. Acad. Sci.*, Vol. IV, No. 13, p. 347, July 1914.

Buckingham, *Phy. Rev. N. S.*, Vol. IV, No. 4, p. 345, Oct. 1914.

Buckingham, *Phil. Mag.* Vol. 42, No. 251, p. 696, Nov. 1921.

8. Nature, Vol. XXXII, p. 314, 1885 or *Sci. Papers*, Vol. II, p. 424, 1881-1887.

Since we know from physical considerations that the film thickness will increase with μ and decrease with ρ , n must be negative or substitute $n = -m$ and get

$$B = K (\mu/\rho)^m D^{\frac{2-3m}{2}} / g^{m/2} \text{ cm.} \quad (39)$$

This is the general equation for the film thickness. Let us now see the effect of trying certain special values of m in this equation and substituting them in the general heat flow equation (1) which is

$$W = (A/B) k \Delta t \quad (40)$$

$$\text{If } m = 0 \quad B = K D \quad (41)$$

Here we may associate D with the spacing between parallel surfaces and putting $K = 1$ obtain the condition for a problem in pure conduction or,

$$W = (A/D) k \Delta t \quad (42)$$

$$\text{If } m = 1/2, B = K \sqrt{\mu/\rho} \sqrt[3]{D/g} \quad (43)$$

If we associate D with the diameter of a cylinder of length L we obtain

$$W = \frac{\pi g^{1/4} D^{3/4} L}{K} \sqrt{\rho/\mu} k \Delta t \quad \text{watts} \quad (44)$$

which is a possible relation for the free convection from a cylinder in which the film thickness is small compared with the diameter and for small temperature differences.

If we associate D with the diameter of a sphere in equation (43) we would write $A = \pi D^2$ and obtain

$$W = \frac{\pi g^{1/4} D^{7/4}}{K} \sqrt{\rho/\mu} k \Delta t \quad \text{watts} \quad (45)$$

Here we have a possible relation for the free convection from a sphere in which the film thickness is small compared with the diameter and the temperature differences are small.

$$\text{If } m = 2/3, B = (K/g^{1/3}) (\mu/\rho)^{2/3} \quad (46)$$

$$W = \frac{g^{1/3} A}{K} (\rho/\mu)^{2/3} k \Delta t \quad \text{watts} \quad (47)$$

Here the film thickness is independent of the size of the body. This is the relation which we might expect to hold for a plane surface provided considerations of stability permit.

$$\text{If } m = 1 \quad B = K (\mu/\rho) \left(\frac{1}{g D} \right)^{1/2} \quad (48)$$

Here we see that the greater the size of the object, the thinner the film. This looks more like a "draught effect" than ordinary free convection. We might associate D with the diameter of a short vertical tube whose length is a constant C times the diameter. We would then have

$$A = \pi D \times C D \quad (49)$$

and obtain

$$W = \frac{\pi C g^{1/2} D^{5/2}}{K} (\rho/\mu) k \Delta t \quad (50)$$

This is a possible relation for the convection in a short

vertical tube of limited length under the conditions that the film thickness is small compared with the diameter and for small temperature differences.

For large temperature differences and thick films we obtain the following for the case of long cylinders from equation (8)

$$W_c = \frac{2 \pi L \Delta \varphi}{\log_e \frac{2B+D}{D}} \quad \text{watts convection} \quad (51)$$

Similarly for spheres we obtain from equation (16)

$$W_c = \frac{2 \pi \Delta \varphi}{1/D - \frac{1}{2B+D}} \quad \text{watts convection} \quad (52)$$

In these relations the film thickness has the form given by equation (39). To determine the exponent m and the constant K it is necessary to appeal to experiment. For convenience in determining the exponent from the experimental data equation (39) may be put in the following non-dimensional form

$$B/D = K \left(\frac{\mu}{\rho g^{1/2} D^{3/2}} \right)^m \quad (53)$$

By substituting the experimental data for the free convection from cylinders in equation (51) we can solve for the film thickness B .

The boundary of the film occurs at the point in the fluid where the velocity of the stream line motion exceeds the critical velocity in the fluid. Osborne Reynolds¹⁰ has shown that the critical velocity is governed by the properties of the fluid. For the case of pipes he obtained

$$V_c = M \frac{\mu}{\rho D} \quad \text{cm. per sec.} \quad (54)$$

Where M = numerical constant (approximately 2500).

μ = viscosity of fluid c. g. s. units

ρ = density of fluid grams per cu. cm.

D = Diameter of pipe in cm.

Since the fluid is practically at the ambient temperature when it bursts into turbulent motion, it seems reasonable to assume that it is the ambient temperature and not the wire temperature which is the controlling factor. Langmuir's work appears to amply confirm this assumption. We may now plot the non-dimensional relation

$$B/D \text{ vs. } \frac{\mu}{\rho g^{1/2} D^{3/2}} \quad (55)$$

on log log paper for all of the available data and should find that the points fall on a single curve. The exponent m for a certain range is the slope of the curve in the range considered. Having determined the exponent m the value of the constant K is determined from equation (53).

IV. Experimental

FREE CONVECTION FROM LARGE HORIZONTAL CYLINDERS IN AIR

The following tests on the free convection from large horizontal cylinders were undertaken to extend the available data into the region where the film thickness is small compared with the cylinder diameter. Under this condition the law of variation of the film thickness can be most accurately tested. The cylinders used consisted of heavy wall, polished, silver plated copper tubes provided with internal electric heating units. The units were constructed by first winding two layers of mica paper tape on a brass tube of proper size and then winding it with nicrome ribbon, after which, two more layers of mica paper tape were applied. This brought the outside diameter up to a point where it was a snug fit into the copper tube. The spacing between the turns of the nicrome ribbon was approximately 1½ mm. Four nicrome-ideal thermocouples were provided to measure the cylinder temperature. The couples were silver soldered into small copper pipe plugs which were later screwed into holes which had been tapped in the copper tube. Three of the couples were situated along the top of the tube, one in the middle and one about 10 cm. from each end, the fourth was at the bottom of the cylinder in the middle. The dimensions of the cylinders were as follows:

1. Large cylinder, 11.35 cm. outside diameter, with a wall thickness of 0.635 cm. and 152.5 cm. long.
2. Medium cylinder 5.56 cm. outside diameter with a wall thickness of 0.476 cm. and 122 cm. long.
3. Small cylinder, 4.28 cm. outside diameter with a wall thickness of 0.635 cm. and 122 cm. long.

FREE CONVECTION TESTS IN CASK USING AIR

The effect of reduced air pressure was studied by placing one of the cylinders a little below the axis of a large wooden cask arranged for evacuation. The cask was built of paraffin-treated wood and was 1.8 meters inside diameter by 2.1 meters long. The inside of the cask was lined on all sides, except the ends with water pipes for the purpose of controlling the ambient temperature. A heavy pressboard lining was placed inside of the cooling coils. The ambient temperature was measured by specially calibrated copper resistance detectors of the three lead type. The normal resistance of the detectors was approximately 10 ohms. A differential meter was used in connection with the detectors which read the temperature directly in deg. cent. The location of the detectors and cylinder in the cask is shown in Fig. 2. Fig. 3 is a photograph of the set-up. Power was supplied to the heater from a direct-current source through small bare copper wires (approx. 0.075 cm. diam.). A similar pair of small wires was provided for measuring the voltage drop across the heater. The ammeters and voltmeters used in the tests were carefully calibrated. The potential differences developed by the nicrome-ideal thermocouples on the cylinder were measured by a portable potentiometer. The pressure difference between the air in the cask and the outside was measured with a mercury U-tube. A standard barometer on the same floor of the building was used to reduce the pressures in the cask to absolute values.

Tests were made on the large and small cylinders in the cask. Table I is a sample data sheet from which an idea of the duration of the tests, variations in tem-

E = Relative emissivity of surface
T = Absolute temperature of hot body deg. K
T₀ = Absolute temperature of surroundings deg. K.

An emissivity of three per cent was assumed for the polished silver surface of the cylinders. This is the mean value given by Langmuir^{3d} between 325 deg. K and 900 deg. K.

Table III is a summary of the data obtained with the small cylinder in the cask.

FREE CONVECTION TESTS IN OVEN USING AIR

The effect of ambient temperature on free convection was studied by placing the medium cylinder in a large oven which was provided with heating units at the top and bottom. The units could be operated together or separately. Fig. 4 is a skeleton view of the oven set up and Fig. 5 is a photograph of one of the ovens. Preliminary tests showed that large convection currents were set up in the oven which vitiated the results, when both heating units were operated. Subsequently all tests were made using the top unit only. Another point observed in the preliminary tests was that the radiation from the heating unit seriously affected the readings of the copper wire temperature detectors. The writer therefore, resorted to a network of 0.010 in. diam. (0.0254 cm.) bare polished silver wire for the purpose of determining the ambient air temperature. One net work was placed about 20 cm. below, and another 20 cm. above the cylinder. A third on the level with the cylinder passed alternately over and under the cylinder. The silver wire was supported at the ends and in the middle on asbestos strings. Table IV is a sample record sheet. The resistance of the silver wire detectors was measured by a portable (Leeds and Northrup) bridge which was checked against a standard. The resistance of the detectors at 0 deg. cent. was determined from the relation

$R_0 = \frac{R_1}{1 + \alpha t_1}$ ohms (57)

where R₁ = observed resistance of detector at temperature t₁ deg. cent.
α = 0.00344 the temperature coefficient of a sample of the silver wire determined experimentally.

In determining the R₀ the oven was left closed over night without heat and the ambient temperature t₁ determined as the average of the ten copper resistance detectors. The temperature for another value of resistance was then obtained from the relation

$t = \frac{R_t - R_0}{\alpha R_0}$ deg. cent. (58)

Table V is a summary of the R₀ determinations. Table VI is a summary of the data obtained in the oven.

V. Analysis of Experiments

EFFECT OF CYLINDER TEMPERATURE

In Fig. 6 the watts convection for the small cylinder have been plotted against the corresponding values of $\Delta\phi$. Here the ambient temperatures are approximately constant and therefore if the film thickness is independent of cylinder temperature a linear relation between W_c and $\Delta\phi$ is to be expected from equation (51). Fig. 6 shows this to be the case for the three low temperature points. The high temperature points show too large values of W_c for the values of $\Delta\phi$. Fearing trouble from oxidation all the low temperature points were taken first and the high temperature points last. After the test was completed and the cylinder inspected, it was found to be badly tarnished. This undoubtedly greatly increased the radiation which accounts for the higher points being considerably off the curves.

EFFECT OF AIR DENSITY

To determine the relation between air density and free convection the watts convection per cm. of length per deg. cent. temperature difference have been plotted against the air pressure on log log paper in Fig. 7. If equation (44) applied strictly the convection loss would be proportional to the square root of the air density, since from the kinetic theory of gases, we know that both the heat conductivity and viscosity are independent of density. For small temperature differences the appropriate value of heat conductivity may be taken as the average value of the heat conductivity for the fluid at the cylinder temperature and the ambient temperature, since for small temperature differences we have

$$k_{avg} \Delta t = \Delta\phi \quad (59)$$

Fig. 7 shows that equation (44) is approximately fulfilled. To see the variation of the film thickness with the air density the small cylinder points have been calculated from equation (51) assuming the film thickness determined by the air density for the ambient temperature. The straight lines in Fig. 7 drawn to represent the mean values of B as function of air density are square root lines. These lines are not the best average lines, but do not depart more than about 10 per cent from the worst points.

EFFECT OF AMBIENT TEMPERATURE

In Fig. 8 the watts convection per deg. cent. for the high and low temperature points obtained from the oven tests have been plotted against the ambient air temperature. We see from this that the convection increases with the ambient temperature. The equation for the film thickness on the assumption that $m = 1/2$ is

$$B = K \sqrt{\mu/\rho} \sqrt{D/g} \quad (60)$$

The density of a gas as function of the absolute temperature is

$$\rho = \rho_0 (273/T) \quad \text{grams per cu. cm.} \quad (61)$$

where ρ_0 = Density of gas at 0 deg. cent. and 76 cm. of mercury in grams per cu. cm.

T = Absolute temperature deg. K.

The viscosity is given by equation (26) with sufficient accuracy as

$$\mu = \mu_0 (T/273)^n \quad \text{c. g. s. units} \quad (62)$$

where μ_0 = viscosity of gas at 0 deg. cent. in c. g. s. units

T = Absolute temperature of gas deg. K.

n = Exponent depending on the gas.

From the above relations we obtain

$$\sqrt{\mu/\rho} = \sqrt{\mu_0/\rho_0} (T/273)^{\frac{n+1}{2}} \quad (63)$$

Using the following values for air,

$$\mu_0 = 0.0001705 \text{ c. g. s.}$$

$$\rho_0 = 0.00129 \text{ grams per cu. cm. at 76 cm. Hg.}$$

$$n = 0.754$$

we obtain for air

$$\sqrt{\mu/\rho} = 0.364 (T/273)^{0.878} \quad (64)$$

From the oven tests we have for the average ambient temperatures for the high and low points the following:

$$\text{High temperature, } T = 103.2 + 273 = 376.2 \text{ deg. K.}$$

$$\text{Low temperature, } T = 28.8 + 273 = 301.8 \text{ deg. K.}$$

By equation (60) and (64) the ratio of the film thickness as determined by the ambient temperature will be

$$\text{Calc. } B_{103\text{deg. cent.}}/B_{28\text{deg. cent.}}$$

$$= (376.2/301.8)^{0.878} = 1.21 \quad (65)$$

We may now compare this with the values of B determined from the experiments as calculated from equation (51).

For the low temperature point we have, from Fig. 9.

$$\text{Cylinder } 82.3 \text{ deg. cent.} = 355.3 \text{ deg. K. } \varphi_2 = 0.053$$

$$\text{Ambient } 28.8 \text{ deg. cent.} = 301.8 \text{ deg. K. } \varphi_1 = 0.039$$

$$W_c = 83.7 \text{ watts}$$

$$\Delta \varphi = 0.014$$

$$\log_e \frac{2B + D}{D} = \frac{2\pi L \Delta \varphi}{W_c}$$

$$= \frac{2\pi \times 122 \times 0.014}{83.7} = 0.128$$

The anti-log then gives

$$\frac{2B + D}{D} = 1.137$$

and

$$B_{28\text{deg. cent.}} = 0.37 \quad (66)$$

For the high temperature points we have

$$\text{Cylinder } 150.4 \text{ deg. cent.} = 423.4 \text{ deg. K. } \varphi_2 = 0.0747$$

$$\text{Ambient } 103.2 \text{ deg. cent.} = 376.2 \text{ deg. K. } \varphi_1 = 0.0152$$

$$W_c = 85.0$$

$$\Delta \varphi = 0.0152$$

from which we obtain

$$B_{103\text{deg. cent.}} = 0.41 \text{ cm.} \quad (67)$$

This gives as the experimental ratio

$$\text{Exp. } B_{103\text{deg. cent.}}/B_{28\text{deg. cent.}} = 1.11 \quad (68)$$

This value shows the right trend but is 9 per cent too low. The check, however, is considered satisfactory, considering the accuracy of the experiments.

VI. Summary of Available Data on Free Convection from Cylinders

GASES

The data used have been converted into watts convection per cm. length of cylinder. A radiation correction has been made where necessary, using the values of emissivity given by Langmuir³¹. The watts convection have then been plotted against $\Delta \varphi$ as in Fig. 6. By this means we obtain an average of all the points for a given wire size having the same ambient

conditions. The values of watts convection for a given value of $\Delta \varphi$ read off the curves are those given in Table VII. Langmuir's values of φ as given in Figs. 9, 10 and 11 have been used.

AVG.					5.300	4.651	4.583

The data by Langmuir³² were taken in practically open air, using small platinum wires. Wire temperatures up to 1600 deg. cent. were used with an ambient temperature of 27 deg. cent.

Ayrton and Kilgour¹¹ worked with small platinum wires in air at temperatures up to 300 deg. cent. with an ambient temperature in the vicinity of 10 deg. cent. In these experiments the wire was placed in the axis of a water jacketed cylinder having an internal diameter of 5.08 cm. diameter.

Petavel¹² worked with a platinum wire 0.1106 cm. diameter in the axis of a water cooled cylinder 2.06 cm. diameter. Wire temperatures up to 1100 deg. cent. were used with an ambient temperature of 16 deg. cent. His tests ranged from a pressure of 1/10 to 100 atmospheres in air, oxygen, hydrogen, carbon dioxide, nitrous oxide and some preliminary tests in liquid carbon dioxide and nitrous oxide.

Kennelly¹³ worked with small copper wires in a large tank with air pressures ranging from approximately 1/2 to 2 1/4 atmospheres. The wire temperatures were around 180 deg. cent. with an ambient of approximately 20 deg. cent. His data as studied and corrected for radiation by Langmuir³¹ have been taken.

Only a portion of the data by the various investigators has been worked out, but we believe that we have obtained a representative selection.

The collected data have been plotted in the non-dimensional form of equation (55) in Fig. 12, and are seen to lie on a single curve on log log paper within the probable experimental errors. The single straight line which seems best to fit the points has a slope of $m = 0.54$. The value of K found by averaging the K 's for all of the points as calculated from equation (53) assuming $m = 0.54$ is $K = 4.4$. The line of slope $m = 1/2$ has also been drawn in such a manner

FIG. 12

as to give most weight to the first 13 points because the accuracy of determining B/D is greatest for the small values, assuming equal accuracy in determining the watts convection.

To see the error involved in using the simple relation $m = 1/2$, we have for Langmuir's highest point

$$\text{Obs. } B/D = 27.4; \frac{\mu}{\rho g^{1/2} D^{3/2}} = 19.9 \quad (69)$$

$$\text{Obs. } W_c = 0.84; \Delta \varphi = 0.537; D = 0.00404 \text{ cm.} \quad (70)$$

For the same ambient condition on the square root curve, we have

$$B/D = 15.0; \frac{\mu}{\rho g^{1/2} D^{3/2}} = 19.9 \quad (71)$$

$$\Delta \varphi = 0.537 \quad D = 0.00404 \text{ cm.}$$

$$W_c = \frac{2 \pi L \Delta \varphi}{\log_e \frac{2B + D}{D}} = \frac{2 \pi \times 1 \times 0.537}{\log_e 31.0} = 0.985 \text{ watts} \quad (72)$$

Thus, the watts convection which would be obtained by using the simple square root relation is only 17 per cent higher than Langmuir's observed value.

If we now take Petavel's point for air at 100 atmospheres pressure which will be seen to lie about as far off the curve as any in the low range, we have

$$\text{Obs. } B/D = 0.142; \frac{\mu}{\rho g^{1/2} D^{3/2}} = 0.0013 \quad (73)$$

$$\text{Obs. } W_c = 11.3; \Delta \varphi = 0.450; D = 0.1106 \text{ cm.} \quad (74)$$

And for the same ambient condition on the square root curve

$$B/D = 0.120; \frac{\mu}{\rho g^{1/2} D^{3/2}} = 0.0013 \quad (75)$$

$$\Delta \varphi = 0.450; D = 0.1106 \text{ cm.}$$

$$W_c = \frac{2 \pi L \Delta \varphi}{\log_e \frac{2B+D}{D}} = \frac{2 \pi \times 1 \times .45}{\log_e 1.24} = 13.15 \text{ watts} \quad (76)$$

For this point the calculated value of watts convection is 16 per cent higher than Petavel's observation which is probably not far from the experimental error.

The value of the constant K , assuming $m = 1/2$, has been taken as $K = 3.4$ which is the average value for the first 13 points.

We may conclude that the simple square root relation can be used over the entire range of available data without exceeding the probable experimental errors, and is therefore preferable to a fractional exponent until such is definitely required by more precise data.

LIQUIDS

A few tests were made, in a light petroleum oil (No. 12 Transil Oil), on the free convection from a horizontal grid of 0.010 in. diam. (0.0254 cm.) silver wires. The spacing between the wires forming the grid was approximately 2.5 cm. and the total length of wire used was 1560 cm. The grid was submerged to a depth of 15 cm. in a large rectangular oil bath leaving 15 cm. of oil between the grid and the bottom of the

tank. The ambient oil temperature was measured by mercury thermometers and the temperature of the wire determined by the resistance method, using equa-

tions (57) and (58). Table VIII is a summary of the data obtained.

In Fig. 13 the watts convection per cm. length of wire

has been plotted against the temperature difference between the wire and the ambient fluid. Since heat conductivity data are not available the procedure adopted was to calculate the heat conductivity from the free convection data and compare the order of magnitude of the result with that obtained by Graetz¹⁴ for the heat conductivity of a certain petroleum oil which he used.

In these calculations we have assumed the relations

translated from second Saybolt to c. g. s. units using a chart given by N. MacCoull.¹⁵

The heat conductivity calculations are given in Table IX. The values of watts convection given in column five were read from the smooth curve of Fig. 13 at equal temperature intervals. In the fifth column and first line we have

$$\varphi_1 - \varphi_a = \int_0^{T_1} k dT - \int_0^{T_a} k dT$$

FIG. 16

which we have found to hold for gases as given by equations (59), (51) and (39) in which $m = 1/2$ and $k = 3.4$. We have also assumed that the film thickness merely depends upon the ambient properties of the liquid. Fig. 14 gives the density and viscosity taken from some available data on No. 12 transil oil as a function of temperature. The viscosity data were

and from the second line

$$\varphi_2 - \varphi_a = \int_0^{T_1} k dT - \int_0^{T_a} k dT$$

Taking the difference we have the value given in column six or

$$\Delta \varphi = \varphi_2 - \varphi_1 = \int_0^{T_2} k dT - \int_0^{T_1} k dT = \int_{T_1}^{T_2} k dT$$

14. Graetz Ann. der Physik, Vol. 25, p. 353, 1885.

15. N. Mac Coull Lubrication (Texas Co.), May, 1921.

For small values of $T_2 - T_1$ we may take k at the average of the two temperatures and write

$$\varphi_2 - \varphi_1 = \Delta \varphi = k_{avg} (T_2 - T_1)$$

or
$$k_{avg} = \frac{\Delta \varphi}{\Delta t}$$

as given in column eight. In Fig. 15 the calculated heat conductivity of No. 12 transil oil is compared with the following values obtained by Graetz¹⁴ for a certain petroleum oil

k at 12.7 deg. cent = 0.000355 cal. per sec. per cm.
per deg. cent.
 ρ = 0.79 grams per cu. cm.
 c = 0.5 calories per gram
 k at 22.7 deg. cent = 0.000395 cal. per sec. per cm.
per deg. cent.
 ρ = 0.784 grams per c. c.
 c = 0.5 calories per gram.

}

(77)

The general agreement between the two materials is considered satisfactory.

Davis^{4d} has recently published results on the free convection from horizontal platinum wires 0.0083 and 0.0155 cm. diameter in toluene, carbon tetrachloride, aniline, olive oil and glycerine for temperature differences up to 50 deg. cent. The ambient fluid temperatures are not given and it has therefore been necessary to estimate them from the values of viscosity which he assigns. This procedure appears to be satisfactory except in the case of olive oil where the widely different values of viscosity given by different observers leaves us in doubt. We have therefore adopted Davis' value of viscosity and assumed a constant ambient temperature of 18 deg. cent. In Table X we have calculated the non-dimensional expressions of equation (55) for the 10 deg. cent. temperature difference points. The results are plotted in Fig. 12 and are seen to fall as well as can be expected on the same curve as the gases.

It is now interesting to calculate the heat conductivities of the different liquids from the free convection test as we did for No. 12 transil oil and compare them with the available direct determinations of heat conductivity. For this purpose we have reproduced Davis' data for the 0.0155 cm. diameter wire in Fig. 16 and obtained from the smooth curves the points used for the calculations given in Table XI. The calculated heat conductivities are plotted in Fig. 17. In Table XII we have compared the calculated values with the experimental values by H. F. Weber (Landolt-Börnstein Tabellen).

The variation is not greater than 5 per cent and is therefore probably within the experimental errors. Thus free convection tests can be used as a convenient method of determining the heat conductivity of fluids when the viscosity and density are known.

For long cylinders we have obtained

$$W_c = \frac{2 \pi L \Delta \varphi}{\log_e \frac{2B + D}{D}} \quad \text{watts convection (78)}$$

where L = Length of cylinder in cm.

$\Delta \varphi$ = Thermal conduction in watts per cm.

D = Cylinder diameter in cm.

B = Film thickness in cm.

The film thickness for long horizontal cylinders is given by

$$B = K \sqrt{\mu/\rho} \sqrt[4]{D/g} \quad \text{cm. (79)}$$

where K = 3.4 a numerical constant determined by experiment.

μ = Viscosity of ambient fluid in c. g. s. units.

which he was able to obtain. We have calculated the watts convection from his data by the following relation

$$W_c = 4.19 C M (V_t - V_r) \quad \text{watts convection (80)}$$

where C = 0.0952 = specific heat of copper at the sphere temperature in calories per gram per deg. cent.

M = 38.54 = Mass of sphere in grams (value given by Compan)

V_t = Rate of cooling of sphere at temperature t in deg. cent. per second

V_r = Rate of cooling of sphere at temperature t in vacuum expressed in deg. cent. per sec.

The watts convection have then been plotted against $\Delta \varphi$ as in Fig. 6. By this means we obtain an average of the values for different sphere temperatures for a

FIG. 17

ρ = Density of ambient fluid in grams per cu. cm.

D = Diameter of cylinder in cm.

g = Acceleration of gravity (980) cm. per sec.²

VII. Free Convection from Spheres

There appears to be very little reliable data on the free convection from spheres. Compan¹⁶ made a careful study of convection from a lamp black covered copper sphere 2.0 cm. diameter, in spherical enclosures of 16 cm. 14.5 cm. and 8.3 cm. diameter. The range of pressures covered was from approximately 6 atmospheres to 1/1000 of a mm. Compan gives the rate of cooling in deg. cent. per second for different sphere temperatures. The radiation correction is obtained as the rate of cooling under the best vacuum conditions

16. Paul Compan, *Ann. de Chemie et de Physique*, VII, Series, Vol. 26, p. 488-574, 1902.

given ambient condition. For this work we have used the values obtained by Compan with the 2.00 cm. diameter sphere in the 14.5 cm. diameter metal sphere enclosure. His points all fall very accurately on straight lines as demanded by the theory. The values of watts convection for a given value of $\Delta \varphi$ as read off the curves are given in Table XIII.

TABLE XIII.
FREE CONVECTION FROM SPHERE 2.00 CM. DIAMETER AT 98.56 DEG. CENT.
ENCLOSURE 14.5 CM. DIAMETER SPHERE AT 0 DEG. CENT.

Air Pressure atmos.	Total Watts Convection W_c	$\Delta \varphi$ watts per cm.	B/D	μ	
				$\rho g^{1/2} D^{3/2}$ C.G.S units	Assuming $m = 2/3$ K
0.0737	0.143	0.0251	—	0.0202	—
0.530	0.424	0.0251	1.445	0.00281	72.3

2.03	0.805	0.0251	0.322	0.000735	39.3
4.13	1.142	0.0251	0.1905	0.000361	37.2
5.90	1.335	0.0251	0.1545	0.000253	38.7

For spheres equation (52) gives

$$W_c = \frac{2 \pi \Delta \varphi}{1/D - \frac{1}{2B + D}} \quad \text{watts} \quad (81)$$

From which

$$B/D = 1/2 \left(\frac{2 \pi \Delta \varphi D}{W_c - 2 \pi \Delta \varphi D} \right) \quad (82)$$

In Fig. 18 we have plotted the values of B/D against

$\frac{\mu}{\rho g^{1/2} D^{3/2}}$ on log log paper. The three high-

pressure points are seen to lie on a straight line of slope $m = 2/3$. For larger values of B/D the enclosure is probably too small to permit of free convection conditions. At low pressures the film entirely fills the

FIG. 18

enclosure and the problem is then one of pure conduction. This fact is useful for eliminating convection in determinations of the heat conductivity of gases.

If we assume that Compton's three high-pressure points accurately represent the conditions of free convection for spheres we have

$$B = (K/g^{1/3}) (\mu/\rho)^{2/3} \quad \text{cm.} \quad (83)$$

In the last column of the table are the values of K assuming this relation. The average value for the three high-pressure points gives $K = 38.4$. Here the film thickness is independent of the size of the body. More tests are needed before this conclusion can be definitely held.

VIII. Free Convection from Large Surfaces

For large surfaces the film thickness will usually be small compared with the dimensions of the body and therefore the "shape conductance" will have the simple form of equation (14) and the convection loss may be written

$$W_c = (A/B) \Delta \varphi \quad \text{watts} \quad (84)$$

The variation of the film thickness B with the size of the body and ambient fluid properties can be found by determining the values of m and K in the general equation (39) for the film thickness, from experiment on similar bodies of various sizes or, by variations of the ambient fluid properties.

Where such experiments are not available a good approximation can usually be obtained by substituting an equivalent cylinder or sphere, etc., for the desired object.

LARGE CYLINDERS

For large cylinders in which the film thickness is small compared with the diameter the convection loss will be given by

$$W_c = \frac{\pi g^{1/4} D^{3/4} L}{K} \sqrt{\rho/\mu} \Delta \varphi \quad \text{watts} \quad (85)$$

where g = Acceleration of gravity (980) cm. per sec.²

D = Diameter of cylinder in cm.

L = Length of cylinder, assumed long compared with the diameter, in cm.

K = 3.4 a numerical constant for horizontal cylinders

ρ = Density of ambient fluid grams per cu. cm.

μ = Viscosity of ambient fluid in c. g. s. units

$\Delta \varphi$ = Thermal conduction of fluid in watts per cm.

For gases we have from equations (61) and (62)

$$\rho/\mu = \rho_0/\mu_0 (273/T)^{n+1} \quad (86)$$

where ρ_0 = Density of gas at atmospheric pressure and 0 deg. cent. in grams per cu. cm.

μ_0 = Viscosity of gas at 0 deg. cent. in c. g. s. units

T = Absolute temperature of the gas in deg. K.

n = Exponent depending on the nature of the gas; values are given by Jeans.⁷

For air at atmospheric pressure (76 cm. Hg) and 0 deg. cent. we have

$$\rho_0 = 0.00129 \text{ grams per cu. cm.}$$

$$\mu_0 = 0.0001705 \text{ c. g. s. units}$$

$$n = 0.754$$

Substituting these values in equation (86) we obtain for air at atmospheric pressure

$$\rho/\mu = 7.56 (273/T)^{1.754} \quad (87)$$

$$\text{and } \sqrt{\rho/\mu} = 2.75 (273/T)^{0.877} \quad (88)$$

For small temperature differences of the order of 100 deg. cent. for air, we may take as a good approximation

$$\Delta \varphi = k_{avg. temp.} \times \Delta t \quad (89)$$

If we now take the value of the specific heat of air at 300 deg. K. and assume it constant, we may write equation (28) for air

$$k = 3.4 \times 10^{-6} T^{0.754} \text{ watts per cm. per deg. cent.} \quad (90)$$

If we now substitute equations (88), (89) and (90) in equation (85), we obtain the following for air.

$$W_c = 0.0067 D^{3/4} L p^{1/2} \frac{T_{avg}^{0.754}}{T_{amb}^{0.877}} \Delta t \text{ watts} \quad (91)$$

where D = Cylinder diameter in cm.
 L = Cylinder length in cm.
 p = Absolute air pressure in atmospheres
 T_{avg} = Average of cyl. and amb. temp. deg. K.
 T_{amb} = Ambient air temp. deg. K.
 Δt = Temperature difference deg. cent.

Let us now apply this relation to the large silver plated cylinder $D = 11.35$ cm. $L = 152.5$ cm. For the atmospheric pressure points we have for the average values

$$T_{amb} = 11.7 + 273 = 284.7 \text{ deg. K.}$$

$$\text{Cyl. Temp. } T = 98.7 + 273 = 371.7 \text{ deg. K.}$$

$$T_{avg} = 328.2 \text{ deg. K.}$$

$$\Delta t = 87.0 \text{ deg. cent.}$$

$$p = 1.0$$

$$W_c = 0.0067 \times (11.35)^{3/4} \times 152.5 \times 1.0$$

$$\times \frac{(328.2)^{0.754}}{(284.7)^{0.877}} \times 87 = 304 \text{ watts}$$

The observed experimental value is 323 watts. Thus, the experimental value is 6 per cent high, which is not far from the probable experimental error.

LARGE SPHERES

For spheres in which the film thickness is small compared with the diameter the convection loss is, assuming $m = 2/3$ as indicated by Compan's¹⁶ work,

$$W_c = \frac{g^{1/3} \pi D^2}{K} (\rho/\mu)^{2/3} \Delta \varphi \quad (92)$$

where g = Acceleration of gravity (980) cm. per sec.²
 D = Diameter of sphere in cm.
 K = 38.4 a numerical constant for spheres
 ρ = Density of ambient fluid in grams per cu. cm.
 μ = Viscosity of ambient fluid in c. g. s. units
 $\Delta \varphi$ = Thermal conduction of fluid in watts per cm.

From equation (87) we have for air

$$(\rho/\mu)^{2/3} = 3.85 (273/T)^{1.17} \quad (93)$$

If we now substitute equations (89), (90) and (93) in (92), we obtain for moderate temperature differences in air

$$W_c = 0.0024 p^{2/3} \frac{T_{avg}^{0.754}}{T_{amb}^{1.17}} \pi D^2 \Delta t \quad (94)$$

Here the significance of the symbols is the same as in equation (91).

CIRCULAR DISKS

For a circular disk 19.1 cm. in diameter, Langmuir^{3d} obtained, assuming equation (84), the following values for the film thickness in air at atmospheric pressure and a room temperature of 300 deg. K.

Horizontal, upper surface exposed $B = 0.41$ cm.

Vertical position $B = 0.45$ cm.

Horizontal, surface exposed downward $B = 0.92$ cm.

There are no data available to guide us in selecting the exponent m for this case. Tentatively we will assume $m = 1/2$ in equation (39) and associate the linear dimension with the diameter D of the disk. We then have

$$B = K \sqrt{\mu/\rho} \sqrt{D/g} \text{ cm.} \quad (95)$$

The diameter of the disk was 19.1 cm. and taking $B = 0.45$ cm., we obtain

$$K = 3.05$$

The average value of the K 's for cylinders was 3.4 and since it is probable that the K 's for the two cases should be practically the same we will use the K obtained from the large number of cylinder tests for convenience.

By substituting $K = 3.4$ in equation (95), we obtain

$$B = 0.485 \text{ cm.}$$

which is not far from Langmuir's values.

We will then write the convection as

$$W_c = \frac{\pi g^{1/4} D^{7/4}}{4 K} \sqrt{\rho/\mu} \Delta \varphi \text{ watts} \quad (96)$$

If we substitute equations (88), (89) and (90) in equation (96), we obtain for a disk in air, assuming $K = 3.4$,

$$W_c = 0.0017 D^{7/4} p^{1/2} \frac{T_{avg}^{0.754}}{T_{amb}^{0.877}} \Delta t \text{ watts} \quad (97)$$

Here the symbols have their usual significance.

INFINITE PLANE SURFACES

The problem of free convection from large or infinite plane surfaces involves many uncertainties. A horizontal surface exposed upwards involves questions of instability with the possibility of cyclonic action. Extended vertical surfaces will introduce "draught effects" which may require separate consideration. A horizontal plane surface exposed downward cannot produce convection. In spite of these objections it is interesting to study the case in which the free convection per unit area of surface is independent of the size of the body and apply it as a tentative approximation for the convection from large surfaces. To obtain this condition from our general equation for the film thickness we put $m = 2/3$ in equation (39), and obtain

$$B = (K/g^{1/3}) (\mu/\rho)^{2/3} \text{ cm.} \quad (98)$$

From which

$$W_c = (g^{1/3}/K) (\rho/\mu)^{2/3} A \Delta \varphi \text{ watts} \quad (99)$$

For air at atmospheric pressure we have

$$(\rho/\mu)^{2/3} = 3.85 (273/T)^{1.17} \quad (100)$$

Since no tests are available on large plane surfaces, we will have to assume a value of K from the data on other surfaces. For spheres Compan's work indicates $m = 2/3$ and $K = 38.4$. In view of the small amount of data and rather limited size of enclosure used by Compan, it seems best to take our K from the cylinder and disk tests. For convenience we will assume a film thickness

$B = 0.485$ which corresponds to $K = 3.4$ in equation (95). Substituting this value in equation (98) gives

$$K = 16.5$$

Substituting equation (89), (90) and (100) in (99), we obtain the following for air

$$W_c = 0.0056 p^{2/3} \frac{T_{avg}^{0.754}}{T_{amb}^{1.17}} A \Delta t$$

watts convection (101)

From all of these relations we see that for a constant ambient air temperature the watts convection per deg. cent. temperature difference increases approximately as the $3/4$ power of the average of the absolute temperatures of the surface and the ambient air. If we plot W_c v. s. Δt from these relations on log log paper, we find that for a constant ambient temperature the watts convection for temperature differences from 100 deg. cent. to 500 deg. cent. lie practically on a straight line of slope 1.21. This means that in this range the convection loss increases as the 1.21 power of the temperature difference. The equations of Dulong and Petit¹⁷ and Lorenz¹⁸ express the free convection loss as proportional to the 1.23 and 1.25 power respectively of the temperature difference.

The use of any of these expressions as approximations for the convection from large surfaces gives the same variation of the convection with the average absolute temperature of the surface and ambient air. The effect of ambient temperature and the air pressure depend on the assumed value of m . Further tests on large surfaces are needed to indicate the most suitable approximation for general work.

IX. Summary and Conclusions

1. The present work gives additional evidence in favor of Langmuir's film theory of convection which states that the loss of heat by free convection from a body takes place as if there were a film of relatively stationary gas around the body through which the heat is carried entirely by conduction and therefore if the film thickness is known the free convection loss can be calculated by the ordinary laws of heat conduction in the steady state.

17. Dulong and Petit, *Ann. de Chim. et de Phys.* 7 (1817). See discussion by Langmuir, (3d).

18. L. Lorenz, *Ann. Phys.* 13, p. 582, 1881. See discussion by Langmuir, (3d) p. 319 and 320.

2. The heat conduction between two surfaces in a fluid may be written

$$W = S (\varphi_2 - \varphi_1) \quad \text{watts} \quad (102)$$

Where S = "Shape conductance" of the heat flow path measured in cm.

$$\varphi_2 - \varphi_1 = \Delta \varphi = \int_{T_1}^{T_2} k dT$$

in watts per cm. (103)

Where k = Heat conductivity of the fluid in watts per cm. per deg. cent.

T_2 = Absolute temperature of hot body in deg. K.

T_1 = Absolute temperature of cold body in deg. K.

3. The method of dimensions gives the following general relation for the film thickness

$$B = K (\mu/\rho)^m \frac{D^{2-3m}}{g^{m/2}} \text{ cm.} \quad (104)$$

where K = Numerical constant to be determined by experiment.

m = Numerical exponent to be determined by experiment

μ = Viscosity of ambient fluid in c. g. s. units

ρ = Density of ambient fluid in grams per cu. cm.

g = Acceleration of gravity (980) cm. per sec.²

D = Linear dimension describing the body under consideration measured in cm.

4. In applying relation (102) to the film theory of convection the inner boundary of S is the body from which the convection is desired and the outer boundary is obtained by adding the film thickness to the body. Having thus determined the configuration of the corresponding conduction problem the value of S may be calculated or determined experimentally. Calculations of S are only possible in the simplest cases but fortunately the experimental method is simple and can always be applied.

5. For the case of free convection from long horizontal cylinders the available experiments include cylinders from 0.004 cm. to 11.35 cm. in diameter with temperatures up to 1600 deg. cent. and pressure ranging from 1/10 to 100 atmospheres. Tests in air, hydrogen, carbondioxide and several liquids show that the following simple relations hold within the probable experimental errors.

$$W_c = \frac{2 \pi L \Delta \varphi}{\log_e \frac{2B + D}{D}}$$

watts convection (105)

where L = Length of cylinder in cm.

$\Delta \varphi$ = Thermal conduction in watts per cm.

D = Diameter of cylinder in cm.

$$B = 3.4 \sqrt{\mu/\rho} \sqrt[3]{D/g} \quad \text{cm.} \quad (106)$$

The scanty data available indicate that the film thickness will be given by equation (115) from which the convection is

$$W_c = \frac{g^{1/3}}{K} \left(\frac{\rho}{\mu} \right)^{2/3} \pi D^2 \Delta \varphi \quad (120)$$

where $K = 38.4$ a numerical constant

The other symbols have their usual significance.

For moderate temperature differences *in air*, we may write equation (120) as follows

$$W_c = 0.0024 p^{2/3} \frac{T_{avg.}^{0.75}}{T_{amb.}^{1.17}} \pi D^2 \Delta t \quad \text{watts} \quad (121)$$

Here the symbols have their usual significance.

14. For circular disks in which the film thickness is small compared with the diameter, we will assume that $m = 1/2$ in the general equation (104) for the film thickness and write the free convection as

$$W_c = \frac{\pi g^{1/4} D^{7/4}}{4 K} \sqrt{\rho/\mu} \Delta \varphi \quad \text{watts} \quad (122)$$

here D = Diameter of disk in cm.

The other symbols have the same significance as in equation (117). For horizontal and vertical disks we may assume $K = 3.4$ with fair accuracy.

For moderate temperature differences *in air* we may write equation (122) as follows:

$$W_c = 0.0017 D^{7/4} p^{1/2} \frac{T_{avg.}^{0.764}}{T_{amb.}^{0.877}} \Delta t \quad \text{watts} \quad (123)$$

Here the symbols have the same significance as in equation (118).

15. If the free convection per unit area is to be independent of the size of the body, the method of dimensions tells us to put $m = 2/3$ in the general equation (104) for the film thickness and obtain

$$B = (K/g^{1/3}) (\mu/\rho)^{2/3} \quad \text{cm.} \quad (124)$$

If we apply this relation to convection from large surfaces in which the film thickness is small compared with the dimensions of the body we obtain

$$W_c = \frac{g^{1/3} A}{K} (\rho/\mu)^{2/3} \Delta \varphi \quad \text{watts} \quad (125)$$

where K = Numerical constant to be determined from experiment

A = Area of surface in sq. cm.

the other symbols having their usual meaning.

The value of K has been calculated on certain assumptions from which we obtain

$$K = 16.5$$

We may apply equation (125) as a tentative approximation for the convection from large surfaces. *For air* we then obtain for moderate temperature differences

$$W_c = 0.0056 p^{2/3} \frac{T_{avg.}^{0.764}}{T_{amb.}^{1.17}} A \Delta t \quad \text{watts} \quad (126)$$

16. The above equations for the free convection *in air* from large bodies show that for moderate tem-

perature differences with constant ambient air temperature the watts convection per deg. cent. temperature difference increases approximately as the $3/4$ power of the average of the absolute temperature of the surface and the ambient air.

17. Free convection tests constitute a convenient method of obtaining the heat conductivity of liquids when the viscosity and density are known. The following results (excepting water) have been obtained by this method.

No. 12	Water	$k = 0.00555 (1 + .00298 t)$	watts	cm^{-1}	deg. cent. ⁻¹

18. We have seen that the physical assumption of Langmuir's film theory combined with dimensional reasoning gives equations from which the free convection, from bodies of various shapes may be calculated in any gas or pure (non-plastic) liquid. It therefore seems certain that when a successful mathematical solution of the actual convection problem is obtained it will show the existence of the relatively stationary film with turbulent boundary as postulated by Langmuir's film theory.

The writer wishes to express his indebtedness to Mr. R. E. Doherty for the use of his equipment in connection with the tests on the large cylinders in the cask and to Mr. C. W. Cutler for his careful work in connection with these tests.

FORCED CONVECTION OF HEAT

I. Introduction

In a companion paper¹, Langmuir's film theory was applied to the calculation of the free convection from various bodies. The present work shows how it may be used to determine the forced convection.

The heat loss from any surface is the sum of two parts, the radiation and the convection. Thus the total heat loss is

$$W = W_r + W_c \quad \text{watts} \quad (1)$$

The heat loss by radiation, W_r , may be calculated from the Stefan-Boltzman equation

$$W_r = 5.7 A E [(T/1000)^4 - (T_0/1000)^4] \quad \text{watts} \quad (2)$$

where 5.7 = black body radiation constant (most recent value)

A = area of radiating surface in sq. cm.

E = relative emissivity of surface

T = absolute temperature of hot body deg. K.

T_0 = absolute temperature of surroundings deg. K.

1. Chester W. Rice, Free Convection of Heat in Gases and Liquids.

cussion of this subject will be found in the paper on Free Convection¹. We may now express any heat conduction problem in the following form

$$W = S \Delta \varphi \quad \text{watts} \quad (9)$$

In applying relation (9) to the film theory of convection, the inner boundary of S is the body from which the forced convection is desired and the outer boundary is obtained by adding the film thickness to the body.

III. Film Thickness by the Method of Dimensions

We will assume from physical considerations that the film thickness may be represented by an equation of the following form:

$$B = K \rho^x \mu^y D^z v^n \quad (10)$$

where K = A numerical constant

ρ = Density of fluid in grams per cc.

μ = Viscosity of fluid in c. g. s. units

D = Linear dimension, describing the form of body, in cm.

v = Velocity of fluid stream in cm. per sec.

Substituting the dimensions of the symbols in equation (10), we obtain

$$(L)^1 = (M L^{-3})^x (L^{-1} M T^{-1})^y (L)^z (L T^{-1})^n \quad (11)$$

In order to have this represent a true physical equation we must have the dimensions of the various quantities equal on both sides of the equation. We therefore write the following simultaneous equations:

$$\left. \begin{array}{l} \text{By } L, \quad 1 = -3x - y + z + n \\ \text{By } M, \quad 0 = x + y \\ \text{By } T, \quad 0 = -y - n \end{array} \right\} \quad (12)$$

Solving in terms of n we obtain

$$\left. \begin{array}{l} x = n \\ y = -n \\ z = n + 1 \end{array} \right\} \quad (13)$$

Substituting the values of the exponents in (10), we have

$$B = K \rho^n \mu^{-n} D^{n+1} v^n \quad (14)$$

Since it is evident that the film thickness will decrease with increasing velocity, we should change the sign of n or substitute

$$n = -m \quad (15)$$

and obtain for the general expression for the film thickness in forced convection

$$B = K D \left(\frac{\mu}{\rho D v} \right)^m \quad \text{cm.} \quad (16)$$

For large surfaces in which the film thickness is small compared with the dimensions of the body, the shape conductance may be written

$$S = A/B \quad \text{cm.} \quad (17)$$

and the watts convection will then be given by the following expression

$$W_c = (A/B) \Delta \varphi \quad \text{watts} \quad (18)$$

If we now substitute equation (16) in (18), we have

$$W_c = \frac{A}{K D} \left(\frac{\rho D v}{\mu} \right)^m \Delta \varphi \quad \text{watts} \quad (19)$$

This is our general expression for the forced con-

vection from large surfaces in which the film thickness is small compared with the size of the body. For small temperature differences we may write

$$\Delta \varphi = k_{avg. temp.} \Delta t \quad \text{watts per cm.} \quad (20)$$

and obtain

$$W_c = \frac{A}{K D} \left(\frac{\rho D v}{\mu} \right)^m k_a \Delta t \quad \text{watts} \quad (21)$$

For the case of cylinders or pipes we would associate D with the diameter and write

$$A = \pi D \times L \quad \text{sq. cm.}$$

Substituting this value in (21) we obtain

$$W_c = \frac{\pi L}{K} \left(\frac{\rho D v}{\mu} \right)^m k_a \Delta t \quad \text{watts} \quad (22)$$

This is the form of relation obtained by Davis⁴.

Davis has also shown that the relations derived by Boissinesq⁵ and Rayleigh⁶ may be thrown into this form. According to the present film theory this is the form of relation which should hold only for large cylinders or tubes in which the film thickness is small compared with the diameter and for small temperature differences.

From the kinetic theory of gases we have for the heat conductivity

$$k = M \mu c_v \quad (23)$$

where M = numerical constant depending on nature of gas

μ = Viscosity of gas in c. g. s. units

c_v = Specific heat of gas per gram at constant volume

We also have, for the ratio of the specific heats

$$c_p/c_v = \gamma \quad (24)$$

We may write

$$C = \rho c_p \text{ specific heat per cc. at constant pressure} \quad (25)$$

If we now substitute μ from equation (23) in equation (21) we obtain with the use of equation (24) and (25) the following

$$\frac{W_c}{A k \Delta t} = \frac{K}{D^{1-m}} \left(\frac{C_v}{k} \right)^m \quad (26)$$

This is the relation derived from dimensional considerations by Nusselt⁷ for forced convection in tubes.

As a matter of interest we may note that if we assume $m = 1$ in equation (26) and substitute

$$Q = A_v \quad \text{flow in cc. per sec.} \quad (27)$$

we obtain

$$W_c = K Q C \Delta t \quad \text{watts} \quad (28)$$

In this case the heat transfer is proportional to the rate of flow of material in cc. per sec., the specific heat per unit volume, and the temperature difference, which is a commonly used type of expression for forced convection.

IV. Forced Heat Convection from Cylinders

A representative portion of the data by the various

FIG. 1

FIG. 2

investigators has been converted into watts convection per cm. length of cylinder. For small wires the radiation is negligible. In Hughes' data on large cylinders his radiation corrections have been applied. Langmuir's² values of ϕ as given in Figs. 1, 2, and 3 have been used.

The data by King⁸ were taken in the open air, and the wire under test was mounted in a fork at the end

of a rotating arm. He worked with platinum wires of 0.0153 cm. to 0.00278 cm. in diameter. The velocity was varied from about 17 cm. to 800 cm. per second. Wire temperatures from 227 deg. cent. to 1004 deg. cent. were used. The ambient air temperature was approximately 17 deg. cent.

Kennelly⁹ investigated the forced convection from copper wires in the open air. As in King's work, a fork carrying the wire was mounted at the end of a whirling arm. Kennelly's data as summarized by Langmuir¹⁰ has been used. In this investigation the copper wires had diameters of 0.0101 cm., 0.0159 cm., and 0.0204 cm. Wind velocities from standstill to approximately 1800 cm. per second were studied. Wire temperatures up to approximately 300 deg. cent. were used. The ambient temperature was in the vicinity of 20 deg. cent. More recently Kennelly¹¹ has studied the effect of air pressure on forced convection from a platinum wire 0.0114 cm. diameter. The rotating arm device was installed in a large steel tank in which the air pressure could be con-

FIG. 3

trolled. Wind velocities from standstill to 1900 cm. per second were used and the pressure varied from approximately 0.4 of an atmosphere to 4 atmospheres. Wire temperatures of approximately 410 deg. cent. and 558 deg. cent. were employed. The ambient air temperature was in the vicinity of 18 deg. cent.

Hughes¹² studied the forced convection from copper tubes in a wind tunnel. The tubes were heated by steam at atmospheric pressure and the temperature of the tube surface was assumed to be 100 deg. cent. The ambient air temperature has been assumed to be 15 deg. cent. Wind velocities from zero to 1500 cm. per second were studied. The cylinders had diameters

10. Irving Langmuir, A. I. E. E., Vol. XXXI, Part 1, p. 1237, 1912.

11. A. E. Kennelly and H. S. Sanborn, *Proc. Amer. Phil. Soc.*, Vol. LIII, p. 55, 1914.

12. J. A. Hughes, *Phil. Mag.*, Vol. 31, p. 118, 1916.

8. L. V. King, *Phil. Trans. Roy. Soc. A.*, Vol. 214, p. 373, 1914.

of 0.43 cm., 0.81 cm., 1.93 cm., 5.06 cm., and 15.5 cm. The first four cylinders were approximately 100 cm. long. The 15.5 cm. diameter one was only 20 cm. long, and, from the experimental arrangement, it would appear to be subject to large end effects. The data on this cylinder have therefore not been considered.

Worthington¹³ and Malone studied the forces convection from a platinum wire 0.0256 cm. in diameter by rotating it at the end of an arm in a large tank of water. The experiments covered velocities from 0 to 16 cm. per second. Wire temperatures in the vicinity of 50 deg. cent. were used. The ambient water temperature is not given but has been assumed to be 20 deg. cent.

From the point of view of the film theory of forced convection we have obtained

μ = Viscosity of fluid in c. g. s. units

ρ = Density of fluid in grams per cc.

v = Velocity of fluid stream in cm. per sec.

m = Numerical exponent to be determined by experiment.

To determine the value of the exponent we plot the non-dimensional relation

$$B/D \text{ vs. } \frac{\mu}{\rho D v} \quad (31)$$

on log: log paper for the available data, and should find that the points all fall on a single curve. The exponent m for a certain range is the slope of the curve in the range considered. Having determined the exponent m , the value of the constant K is determined from equation (30).

FIG. 4

$$W_c = \frac{2 \pi L \Delta \varphi}{\log_e b/D} \quad \text{watts convection} \quad (29)$$

where L = Length of cylinder, assumed long compared with the diameter, in cm.

$\Delta \varphi$ = Thermal conduction in watts per cm.

D = Diameter of cylinder in cm.

$b = 2B + D$ = Outside diameter of film in cm.

For the film thickness we obtained

$$B = K D \left(\frac{\mu}{\rho D v} \right)^m = \text{Film thickness in cm.} \quad (30)$$

K = Numerical constant to be determined by experiment.

13. Worthington and Malone, *Journ. Franklin Inst.*, CLXXXIV, p. 115, 1917.

EFFECT OF CYLINDER TEMPERATURE ON FILM THICKNESS

Before we can correlate the data in the above manner for a cylinder at different temperatures it is necessary to decide on the particular temperature at which the viscosity and density are to be taken. In the case of free convection, Langmuir³ showed that the film thickness was determined solely by the viscosity and density of the ambient fluid irrespective of the wire temperature.

This was shown to be the case by plotting the watts convection against the thermal conduction $\Delta \varphi$ for different cylinder temperatures with constant ambient temperature conditions. The curves obtained were straight lines as required by equation (29), if b is to be independent of the cylinder temperature. King's⁸ data cover the widest variation in wire temperature,

We see that column VIII yields the most nearly constant value of K . We will therefore assume that the film thickness in forced convection is determined by the viscosity and density of the fluid at the geometric mean of the wire and ambient fluid temperatures. Data on larger wires at high temperature are, however, needed before the question can be definitely settled.

conductivity by Jakob¹⁴. Since the temperature difference is small we have written
$$\Delta \phi = k_{\text{average temp.}} \Delta t \quad \text{watts per cm.} \quad (34)$$
where $k_{\text{average temp.}}$ = Heat conductivity of water at the average of the wire and ambient temperature in watts per cm. per deg. cent.

SUMMARY OF COLLECTED DATA ON FORCED CONVECTION FROM CYLINDERS

In Table III we have given a summary of the collected data on the forced convection from cylinders in a stream of fluid normal to the axis of the cylinder. For the water point we have used the recent data on heat

Δt = Temperature difference between the wire and ambient water deg. cent.

In Fig. 6 the data have been plotted on log: log paper. From this we see that for small values of B/D

14. M. Jakob, *Ann. der Physik*, Vol. 63, p. 537, 1920.

in the companion paper on free convection¹. In Fig. 7 we have plotted the watts convection against $\Delta \phi$ for the different velocities. A decided curvature is apparent, showing that here also the film thickness is affected by the sphere temperature with constant ambient conditions. As in the case of cylinders we have assumed that the appropriate temperature at which the viscosity and density should be taken to give the film thickness is the geometric mean of the sphere

and ambient temperatures. It has been shown¹ that the convection from spheres on the film theory is given by

$$W_c = \frac{2 \pi \Delta \phi}{1/D - 1/b}$$

watts (37)

where $\Delta \phi$ = Thermal conduction in watts per cm.
 D = Diameter of sphere in cm.
 b = $2 B + D$ = Outer diameter of film in cm.

FIG. 7

FIG. 8

From the above we obtain

$$B/D = 1/2 \left(\frac{2\pi\Delta\varphi D}{W_c - 2\pi\Delta\varphi D} \right) \quad (38)$$

In the general equation (16) for the film thickness we associate D with the diameter of the sphere and determine K and m from the experiments. To this end we have calculated B/D and $\mu/\rho D v$ from the experimental

available range by noting that the forced convection is given by equation (37), in which

$$B = 35. D \left(\frac{\mu}{\rho D v} \right)^{2/3} \quad \text{cm.} \quad (39)$$

where D = Sphere diameter in cm.

μ/ρ = Viscosity divided by density of the fluid,
for the geometrical mean of the sphere

FIG. 9

data in Table IV and plotted the results on log: log paper in Fig. 8. From Fig. 8 we observe that the majority of points fall on a single curve having a slope $m = 2/3$. The three lowest temperature points show systematic departures which are probably due to experimental errors. The average value of the constant K is 35, assuming $m = 2/3$.

We may summarize our data on spheres for the

and ambient temperatures, measured in c. g. s. units.

v = Velocity of fluid in cm. per sec.

VI. Forced Heat Convection in F

For this case we have the valuable contribution of Nusselt⁷. His data were given in the form the units being kilogram calories per hour

Fig. 10

meter of surface per degree centigrade temperature difference against mean gas velocity in meters per second. We have reproduced his curves as well as the scale would permit in Fig. 9, the units being changed to watts per square cm. per deg. cent. against meters per second velocity. In Table V we have calculated B/D and $\mu/\rho D v$ for air at different densities. For small values of B/D the film thickness has been calculated from the relation.

$$W_c = (A/B) \Delta \varphi \quad \text{watts convection} \quad (40)$$

where A = Area of heat flow path in sq. cm.

B = Film thickness in cm.

$\Delta \varphi$ = Thermal conduction watts per cm.

For the larger values of B/D the film thickness has been calculated from the relation

$$W_c = \frac{2 \pi L \Delta \varphi}{\log_e D/b} \quad \text{watts convection} \quad (41)$$

where L = Length of pipe, assumed long compared with the diameter, measured in cm.

$\Delta \varphi$ = Thermal conduction in watts per cm.

D = Diameter of pipe in cm.

$b = D - 2B$ = Inside diameter of film in cm.

In Fig. 10 the values of B/D have been plotted against $\mu/\rho D v$ for the geometrical mean temperature on log : log paper. The points lie on a single curve as required by the theory. The mean slope is $m = 0.77$ and the constant $K = 37$. Without producing an appreciable error we may force the slope to $m = 3/4$ and use $K = 30$. Obviously we should not attempt to apply the film theory of forced convection below the critical velocity, that is, for values of $\mu/\rho D v$ greater than 0.0004 where stream line motion exists.

To summarize our results on the heat transfer in pipes, we use equation (40) when the film thickness is small compared with the pipe diameter and equation (41) when the film is more than 5 per cent of the pipe diameter. The film thickness is given by

$$B = K D \left(\frac{\mu}{\rho D v} \right)^m \quad \text{cm.} \quad (42)$$

D = Pipe diameter in cm.

μ/ρ = Viscosity divided by density of fluid at the geometric mean temperature of the pipe and contained fluid measured in c. g. s. units

v = Mean velocity of flow in cm per sec.

The best values of the exponent and corresponding value of the constant are

$m = 0.77$ and $K = 37$.

Without producing an appreciable error we may use the simpler values

$m = 3/4$ and $K = 30$.

VII. Experiments on Forced Heat Convection in Gases and Liquids

The present work was undertaken at the suggestion of Dr. Whitney to determine the relative forced heat convection in various gases. It is included here as a supplement to the data already discussed.

Fig. 11 will give a general idea of the apparatus used. Fig. 12 is a cross-section of the constricted section showing the torpedo-shaped heating unit with the principal dimensions.

The procedure for making a run at atmospheric pressure consisted in scavenging out the apparatus by running the centrifugal blower and passing gas into and out of the system until a state of sufficient purity was reached. The apparatus was quite tight but in order to insure pure gas during the tests a small constant inflow and outflow was maintained.

Upon leaving the centrifugal fan in a four-inch diameter pipe, the gas entered a reducing cone which was connected to the two-inch constriction. The velocity was here measured in the center of the pipe with a

FIG. 11—FORCED HEAT CONVECTION IN GASES AND LIQUIDS

pitot tube, and is therefore approximately the maximum velocity, not the mean velocity. The pressure and velocity orifices of the pitot tube were connected to a large diameter U-tube (3/4 in. inside diameter) which was filled at first with water and later with a mineral oil of density 0.88 grams per cc. at 25 deg. cent. The oil and large diameter U-tube were used to reduce the meniscus errors. The velocity was calculated from the usual equation for pitot tubes, the constant C being assumed unity.

$$v = C \sqrt{2 g h \rho_1 / \rho_2} \quad \text{cm. per second} \quad (43)$$

where $g = 981$ cm. per sec.²

h = difference of levels in U-tube in cm.

ρ_1 = density of liquid in U-tube grams per cc.

ρ_2 = density of gas being measured, grams per cc.

The velocity of the gas was again increased by entering the constricted annular space around the torpedo-shaped heater. The velocity in this annular space was calculated from the observed central or maximum

velocity in the two-inch pipe by multiplying by the ratio of areas (1.37) and is the value plotted in the curves. After leaving the two-inch pipe the gas entered an expansion cone which brought it again to a four-inch pipe. The gas next passed through a cooler consisting of a helical copper tube with water circulation which was located in the upper part of the four-inch diameter pipe. The gas then returned to the intake of the centrifugal fan. A check on the velocity of flow in the different gases was obtained from the fan revolutions. The velocity was found to be proportional to the fan revolutions for all gases within the experimental error. The temperature of the gas approaching the heater was measured at the beginning of the reducing cone and the temperature of the gas leaving the heater was measured at the end of the expansion cone.

approximately constant. The resistance of the heater was determined by voltmeter and ammeter readings with reasonable accuracy. The variation of heater temperature for a given run might be $80 \text{ deg.} \pm 5 \text{ deg. cent.}$

For the tests in water a similar heater was placed in one side of a 20-inch by 2-inch diameter glass U-tube. The water was passed into the U-tube by an expanding cone from a 3/4-inch water pipe. After leaving the heater the water passed out of the other arm of the U-tube into the waste pipe. The velocity in this case was calculated from the quantity of flow as measured with stop watch and pail. The velocities are therefore mean velocities and are not strictly comparable with the velocities obtained by the pitot tube for the gas tests. The velocities plotted in the curves for water

FIG. 12

The gas entered the heater in the vicinity of 25 deg. cent. and left the heater from 1 deg. to 3 deg. cent. higher. The temperature of the heater was determined from the known temperature coefficient of copper according to the following relations

$$R_0 = \frac{R_t}{1 + 0.0042 t} \quad \text{ohms} \quad (44)$$

$$t = \frac{R_t - R_0}{0.0042 R_0} \quad \text{deg. cent.} \quad (45)$$

During a run on a particular gas the temperature of the heater was maintained approximately constant by adjustment of a series rheostat in order to maintain the viscosity, density, and heat conductivity of the gas

are these mean velocities. Correction to a common velocity basis was not considered necessary as the tests on water were quite rough and merely desired to check the order of magnitude.

During the tests on water with day light at a proper angle on the glass U-tube, a line of demarcation could be observed between the water very close to the heater and that at some distance. At high velocities this film appeared very thin, less than a millimeter, while at the low velocities it became thicker and wavy or spouting in appearance. A study of the surface condition of a heated body in a liquid in this manner would undoubtedly be of considerable interest in adding to our knowledge of heat transfer and the intimately related problem of fluid friction.

The radiation and conduction losses have been neglected. With this type of apparatus the conduction paths are lead losses, straight conduction through the gas and conduction from the wire on the cylindrical

apparatus. The ordinates give the watts dissipated per sq. cm. of surface per deg. cent. temperature difference. In figuring the temperature difference the mean of inflowing and outflowing gas temperature

FIG. 13

FIG. 14

part of the glass torpedo to the sheet tin supports. These losses are all small compared with the forced heat convection.

Fig. 13 summarizes the results for different gases at atmospheric pressure as obtained with the above

apparatus. The average temperature of the heater obtained from the resistance. The average condition for each gas is tabulated on the curve Fig. 13. The heater temperature for the individual points varying by as much as ± 10 deg. cent. in some cases.

The abscissas give the velocity measured by the pitot tube situated in the middle of the 2-in. pipe about 4 inches in front of the torpedo multiplied by the ratio of the two areas, *i. e.* multiplied by 1.37.

We have not as yet obtained a run with pure hydrogen. The difficulty here is that a small percentage of one of the heavier gases produces a marked effect on the

FIG. 15

density and consequently on velocity and heat transfer determinations.

Examination of the curves Fig. 15 shows that the heat convection at high velocities is approximately proportional to the gas velocity.

In Fig. 14 the effect of varying the air density at constant velocity is shown. We may observe from this that for high velocities the heat convection is approximately proportional to the density of the gas.

In Fig. 15 the observations obtained with water in the same type and dimensions of apparatus are given. The ordinates are the watts per square centimeter of heater surface per degree centigrade temperature difference. The abscissas give the mean velocity over the heater surface in the constricted annular space.

In Fig. 16 the heat convection is given for constant mean velocity as a function of the heater temperature.

In these experiments the film thickness is small compared with the dimensions of test body and therefore we may treat the problem as the flow of heat between parallel plane surfaces. We have therefore calculated the film thickness from equation (18). The values of B/D given in Table VI are obtained by dividing the film thickness by the diameter D of the heater unit which was 2.8 cm. The values of $\mu/\rho D v$ are for the geometric mean of the absolute temperature of the surface and of the ambient fluid.

For air we have used equation (33) to determine the kinematic viscosity as a function of the absolute temperature T at atmospheric pressure. In considering the effect of different gas pressures it should be recalled that both the kinetic theory and experiment have shown that the viscosity and heat conductivity are independent of the pressure.

FIG. 16

Langmuir's values of ϕ as given in Fig. 1 have been used for air. For carbon dioxide at atmospheric pressure and 322 deg. K. we have taken the following values.

$$\rho = 0.001675 \text{ grams per cc.}$$

$$\mu = 0.0001625 \text{ cm.}^{-1} \text{ grams sec.}^{-1}.$$

The heat conductivity has been calculated from the following relation given by Jeans¹⁶

$$k = 1/4 (9\gamma - 5) \mu c_v \text{ cal. sec.}^{-1} \text{ cm.}^{-1} \text{ deg. cent.}^{-1} \quad (46)$$

For $C O_2$ we have assumed

$$\gamma = C_p/C_v = 1.3 \quad \text{Ratio of specific heats} \quad (47)$$

$$c_v = 0.165 \text{ cal. grams}^{-1} \text{ at const. vol.}$$

For our temperature range in $C O_2$ we thus obtain

$$\Delta \phi = 0.00943 \text{ watts per cm.}$$

For ammonia by a similar process we have obtained for 324 deg. K. the following

$$\rho = 0.00065 \text{ grams per c.c.}$$

$$\mu = 0.000126 \text{ cm.}^{-1} \text{ grams sec.}^{-1}$$

For the heat conductivity of $N H_3$ at 325 deg. K.

$$k = 0.00036 \text{ watts per cm. per deg. cent.}$$

For the average temperature of the surface and ambient $C O_2$, of 323 deg. K. we have

$$k = 0.000045 \text{ cal sec.}^{-1} \text{ cm.}^{-1} \text{ deg. cent.}^{-1}$$

Multiplying by 4.19 we have

$$k = 0.0001885 \text{ watts cm.}^{-1} \text{ deg. cent.}^{-1}$$

For small temperature differences we may write

$$\Delta \phi = k_{avg. temp.} \Delta t \quad \text{watts per cm.} \quad (48)$$

Assuming $\gamma = 1.31$; $c_v = 0.39 \text{ cal gram}^{-1} \text{ at const. val.}$

For ethyl chloride we have taken the following approximate values to represent the condition at 319 deg. K.

$$\rho = 0.00244 \text{ grams per c.c.}$$

$$\mu = 0.000106 \text{ cm.}^{-1} \text{ grams sec.}^{-1}$$

$$k = 0.000139 \text{ watts per cm. per deg. cent.}$$

16. J. H. Jeans Dynamical Theory of Gases, Camb. Univ. Press, p. 318, 1916. (Second Edition).

Assuming $r = 1.13$; $c_v = 0.243$ cal gram.⁻¹ at const. volume.

For water the values of viscosity and density given in Fig. 17, were taken from Kaye and Laby (Physical and Chemical Constants).

The heat conductivity of H₂O is from Jakob's¹⁴ recent work, which may be summarized in the range from $t = 0$ deg. cent. to $t = 100$ deg. cent. by

$$k = 0.00555 (1 + 0.00298 t) \text{ watts per cm. per deg. cent.} \quad (49)$$

In Fig. 18, B/D vs. $\mu/\rho D v$ has been plotted on log : log paper. All of the points fall approximately on a single curve of slope $m = 0.88$. Assuming this value of slope the average value of the constant is $K = 25$. We have also dotted in an average curve of slope $m = 1.0$ which gives for the constant, $K = 100$. This simpler relation may be used for convenience over the present range of data without exceeding a 15 per cent error.

We may now summarize our data on the forced convection from the rough wire wound cylindrical surface as follows: In these experiments the film thickness is small compared with the dimensions of the heater and therefore the convection will be given by equation (40).

In view of the cylindrical nature of the heater we may write

$$A = \pi D L \quad \text{cm.}^2 \quad (49)$$

Also for the small temperature range we may substitute equation (48) and write the convection as

$$W_c = \frac{\pi D L}{B} k_{avg \text{ temp.}} \Delta t \quad \text{watts} \quad (50)$$

The film thickness is given by

$$B = K D \left(\frac{\mu}{\rho D v} \right)^m \quad \text{cm.} \quad (51)$$

Where D = diameter of heater in cm.

$\mu/\rho = \nu$ = kinematic viscosity of fluid at the geometric mean of heater and ambient fluid, absolute temperatures, in c. g. s. units.

v = Velocity of flow in cm. per sec.

The best average values from the data give

$$m = 0.88; K = 25$$

By forcing the slope we may use with fair accuracy

$$m = 1.0; K = 100.$$

A comparison of these data with Nusselt's data on the heat transfer in smooth pipes shows that for the same value of $\mu/\rho D v$ Nusselt's value of B/D is approximately five times the value which we obtained for the rough copper wire heater. This means that our rate of heat transfer is approximately five times as great as Nusselt's. A portion of this difference is probably due to the increased area of the rough surface; the remainder being due to the difference in the flow conditions.

VIII. Forced Convection from Large Surfaces

For high velocities and large bodies the film thickness will usually be small compared with the dimensions of the body and therefore the "shape conductance" will have the simple form given by equation (17) and the forced convection will be

$$W_c = (A/B) \Delta \varphi \quad \text{watts convection} \quad (52)$$

Where A = Area of cross-section of heat flow path in square cm.

$\Delta \varphi$ = Thermal conductance of fluid in watts per cm.

B = Film thickness or length of heat flow path in cm.

We have shown by the method of dimensions that the film thickness B is given by

$$B = K D \left(\frac{\mu}{\rho D v} \right)^m \quad \text{cm.} \quad (53)$$

Where D = Linear dimension characterizing the form of the body

$\mu/\rho = \nu$ = Kinematic viscosity of fluid for the geometric mean of the absolute temperature of the surface and ambient fluid, measured in c. g. s. units.

v = Mean velocity of fluid in cm. per sec.

K = Numerical constant, depending on the form of object, to be determined by experiment

m = Numerical exponent, depending on the form of object, to be determined by experiment.

The values of m and K may be determined by experiments on similar bodies of various sizes or by variations of the ambient fluid. In practical work, where such experiments are not available for the body under consideration, a good approximation can usually be obtained by substituting an equivalent cylinder, sphere, etc., for the desired form.

If we substitute equation (53) in (52) we obtain

$$W_c = \frac{A}{K D} \left(\frac{\rho D v}{\mu} \right)^m \Delta \varphi \quad \text{watts} \quad (54)$$

as our general expression for the forced convection from surfaces in which the film thickness is small compared with the size of the body. For small temperature differences, of the order of 100 deg. cent., we may write

$$\Delta \varphi = k_{avg.} \Delta t \quad \text{watts per cm.} \quad (54)$$

where $k_{avg.}$ = Heat conductivity of fluid for the average of the surface and ambient fluid temperatures measured in watts per cm. per deg. cent.

Δt = Temperature difference between surface and ambient fluid in deg. cent.

CYLINDERS

For cylinders in a stream of fluid at right angles to the axis we have for the case of thin films, namely; B/D less than 0.05

$$m = 1/2 \text{ and } K = 2.2 \quad (55)$$

If we substitute these values in equation (54) writing for the area A of length L .

$$A = \pi D L \quad \text{sq. cm.} \quad (56)$$

We obtain

$$W_c = \frac{\pi L}{2.2} \left(\frac{\rho D v}{\mu} \right)^{1/2} \Delta \varphi \quad \text{watts} \quad (57)$$

For gases we have the following relations

$$\rho = \rho_0 (273/T) \quad \text{grams cm.}^{-3} \quad (58)$$

$$\mu = \mu_0 (T/273)^n \quad \text{cm.}^{-1} \text{ gram sec.}^{-1} \quad (59)$$

$$k = 1.05 (9 \gamma - 5) \mu c_v \quad \text{watts cm.}^{-1} \text{ deg. cent.}^{-1} \quad (60)$$

where ρ_0 = Density of gas at 76 cm. Hg. and 0 deg. cent. in grams cm.⁻³

μ_0 = Viscosity of gas at 0 deg. cent. in cm.⁻¹ gram sec.⁻¹ (the viscosity is independent of pressure).

T = Absolute temperature of gas in deg. K.

n = Exponent depending on gas. The following values are taken from Jeans¹⁶ page 302, Air, $n = 0.754$; H_2 , $n = 0.69$; CO_2 , $n = 0.98$

$\gamma = c_p/c_v$ Ratio of specific heats

c_v = specific heat at constant volume calories gram⁻¹ deg. cent.⁻¹

The heat conductivity of a gas is independent of the pressure.

For Air we have

$$\rho_0 = 0.00129 \text{ grams cm.}^{-3} \text{ at 76 cm. Hg.}$$

$$\mu_0 = 0.0001705 \text{ cm.}^{-1} \text{ gram sec.}^{-1}$$

$$n = 0.754$$

From which we have for air at atmospheric pressure

$$\rho/\mu = 7.56 (273/T)^{1.754} \quad \text{cm.}^{-2} \text{ sec.} \quad (61)$$

$$\sqrt{\rho/\mu} = 2.75 (273/T)^{0.877} \quad (62)$$

We have shown¹ that the heat conductivity of air at moderate temperature may be written

$$k = 3.4 \times 10^{-6} T^{0.754} \text{ watts cm.}^{-1} \text{ deg. cent.}^{-1} \quad (63)$$

For moderate temperature differences of the order of 100 deg. cent. we may substitute equation (54) in equation (57). For air we may substitute equations (62) and (63) and obtain the following equation for the forced convection from cylinders in air where the film thickness is small compared to the cylinder diameter.

$$W_c = 0.0018 L \sqrt{p D v} \frac{\Delta t}{T_{avg}^{0.123}} \text{ watts convection} \quad (46)$$

where L = Length of cylinder in cm.

p = Absolute air pressure in atmospheres

D = Cylinder diameter in cm.

v = Air velocity in cm. per sec.

Δt = Temperature difference between surface of cylinder and ambient air in deg. cent.

$T_{avg.}$ = Average absolute temperature of surface and ambient air deg. K.

In deriving equation (64) we have used the arithmetic mean temperature in determining the kinematic viscosity since for moderate temperature differences the geometric and arithmetic means are approximately the same. As a check on the relation let us apply it to calculating the convection given by Hughes for the 1.93 cm. diameter cylinder given in Table III. We have

L = 1 cm. (Length of cylinder under consideration)

p = 1 atmosphere (absolute air pressure)

D = 1.93 cm. (cylinder diameter)

v = 500 cm. per sec. (air velocity)

Δt = 100 deg. - 15 deg. = 85 deg. cent. (Temperature difference)

$T_{avg.}$ = 331 deg. K. (Average of Cyl. and Amb. Air Temp.)

W_c = 2.46 watts convection observed

From equation (64) we have

W_c = 2.34 watts convection calculated

The calculated result is 6 per cent low, which is within the experimental error.

SPHERES

For the case of spheres in which the film thickness is small compared with the diameter, we associate D in equation (53) with the sphere diameter and take

$$m = 2/3 \text{ and } K = 35 \quad (65)$$

If we substitute these values in equation (54) writing

$$A = \pi D^2 \quad \text{sq. cm.} \quad (66)$$

we obtain

$$W_c = \frac{\pi D}{35} \left(\frac{\rho D v}{\mu} \right)^{2/3} \Delta \varphi \quad (67)$$

For air at moderate temperature differences we may write equation (67) as follows

$$W_c = 0.00082 D^{5/3} (p v)^{2/3} \frac{\Delta t}{T_{avg.}^{0.416}} \quad \text{watts} \quad (68)$$

PIPES

For high velocity in pipes or where the film thickness is small compared with the diameter we associate D in equation (53) with the diameter of the pipe and take as a good approximation

$$m = 3/4 \text{ and } K = 30$$

Substituting these values in equation (54) we obtain

$$W_c = \frac{\pi L}{30} \left(\frac{\rho D v}{\mu} \right)^{3/4} \Delta \varphi \quad \text{watts} \quad (69)$$

For air at moderate temperature differences we may write equation (69) as

$$W_c = 0.002 L (\rho D v)^{3/4} \frac{\Delta t}{T_{avg.}^{0.561}} \quad \text{watts} \quad (70)$$

PLANE SURFACES

For plane surfaces the film thickness should be independent of any linear dimension. This condition requires us to put $m = 1$ in equation (53), from which

$$B = K \frac{\mu}{\rho v} \quad \text{cm.} \quad (71)$$

Substituting this relation in equation (52) we obtain for infinite plane surfaces

$$W_c = \frac{A \rho v}{K \mu} \Delta \varphi \quad \text{watts convection} \quad (72)$$

There are no data available on the forced convection from large plane surfaces but we may obtain an estimate of the value of K from Nusselt's data on heat transfer in pipes, and our data obtained with a cylindrical

$$K = \frac{1 \times 10 \times 5.5 \times 1330 \times 0.0225}{2.86} = 575. \quad (73)$$

From Table VI we write the following point for air at atmospheric pressure

$A = 1$ sq. cm. (Area of surface)

$p = 1$ atmosphere

$v = 8500$ cm. per sec.

$\Delta t = 80$ deg. cent. $- 25$ deg. cent. $= 55$ deg. cent.

$W_c = 0.125 \times 55$ deg. cent. $= 6.88$ watts per sq. cm.

$\Delta \varphi = 0.0144$ watts per cm.

$\rho/\mu = 5.6$ at Geom. mean temp.

Substituting these values in equation (72) and solving for K we obtain

$$K = 100 \quad (74)$$

FIG. 17

heater in the middle of a tube. Another way of viewing the matter is to observe that the conditions pertaining in an infinite pipe should be similar to an infinite plane surface. From Table V we have for air at 10 atmosphere pressures

$A = 1$ sq. cm. (Area of surface)

$p = 10$ atmospheres (Air pressure)

$v = 1330$ cm. per sec. (Mean Air Velocity)

$\Delta t = 100$ deg. cent. $- 15$ deg. cent. $= 85$ deg. cent.

$W_c = 0.0336 \times 85 = 2.86$ watts per sq. cm.

$\Delta \varphi = \varphi_2 - \varphi_1 = 0.0585 - 0.036 = 0.0225$ watts per cm.

$\rho/\mu = 7.56 (273/327)^{1.754} = 5.5$ at Geom. mean temp. and 76 cm. Hg. Substituting these values in equation (72) and solving for K we have

The value of K estimated from Nusselt's data is seen to be approximately six times as large as the value obtained from our data. In our tests the high-velocity gas was constricted in its flow over the wire wound heater by the surrounding tube. In Nusselt's tests the gas flowed through a smooth brass pipe. Thus a portion of the difference in the values of K is to be expected from the difference in test conditions and the remainder due to the greater roughness of our wire wound heater. In a subsequent paper, connecting the film thickness with the mechanical resistance to flow, it will be shown that the heat transfer from a rough surface, equivalent to coarse sand, is approximately twice that obtained from a smooth surface.

Data on the heat transfer at high velocities from

smooth and rough surfaces are needed to select the best value of K for engineering calculations. For the present we will take an average of the two values obtained above or

$$K = 340 \quad (75)$$

For moderate temperature differences we may substitute equation (54) in (72) and obtain for large plane surfaces at high velocities

$$W_c = 0.003 \frac{A \rho v}{\mu} k_{avg.} \Delta t \quad \text{watts} \quad (76)$$

Where

- A = Area of surface in sq. cm.
- ρ = Density of fluid in grams per cc. for the average of surface and ambient temperatures
- μ = Viscosity of the fluid in c. g. s. units for the average of surface and ambient temperatures
- v = Mean velocity of fluid over surface in cm. per sec.
- $k_{avg.}$ = Heat conductivity of fluid, for the average of surface and ambient temperatures, in watts per cm. per deg. cent.
- Δt = Temperature difference deg. cent.

The arithmetic mean has been used instead of the geometric mean temperature in determining the kinematic viscosity of the fluid since, for the moderate temperature differences here under consideration, the two means are practically equal.

For *air* we may substitute equations (61) and (63) in (76) and obtain

$$W_c = 0.0014 A p v \frac{\Delta t}{T_{avg.}} \quad \text{watts convection} \quad (77)$$

- Where A = Area of surface in sq. cm.
- p = Absolute air pressure in atmosphere
- v = Air velocity in cm. per sec.
- Δt = Temperature difference deg. cent.
- $T_{avg.}$ = Average of absolute temperature of surface and ambient air in deg. K.

From this we see that for the same temperature difference the forced convection decreases as the ambient temperature is raised.

A rough check on equation (77) may be had by applying it to calculate the heat dissipated from the rotor of a large turbo-alternator for the following assumed conditions:

- Rotor diameter..... $D = 114$ cm.
- Rotor length..... $L = 376$ cm.
- Rotor area..... $A = \pi D L = 135,000$ sq. cm.
- Air pressure..... $p = 1$ atmosphere
- Velocity of air in air gap..... $v = 4570$ cm. per sec.
- Mean air temperature..... $= 30$ deg. cent.
- Mean rotor surface temperatures.. $= 65$ deg. cent.
- Surface film drop..... $\Delta t = 35$ deg. cent.

Average of surface and ambient

temperature..... $= 321$ deg. K.

$$W_c = 0.0014 \times 135,000 \times 1 \times 4570 \times 35/321 = 94 \text{ kw.}$$

The above assumed conditions represent the approximate values obtaining in practise with 100-kw. rotor excitation.

IX Forced Heat Convection in Mixtures

To determine the free or forced heat convection in mixtures we require a knowledge of k , ρ and μ for the mixture under consideration.

The viscosity of gaseous mixtures have been investigated experimentally and theoretically at some length by Graham¹⁷, Maxwell¹⁸, Puluji¹⁹, Sutherland²⁰, Thiesen²¹, Schmitt²². Chapman²³ has recently studied the problem from the theoretical side in three classical papers, where the experimental and theoretical material are fully discussed.

The heat conductivity of mixtures of gases has not received much experimental study. Data on the heat conductivity of Helium and Argon is given by Wachsmuth²⁴ and we have data on mixtures of oxygen and hydrogen by Wassilewja²⁵.

Chapman²³ discusses the problem from the theoretical point of view from mon-atomic gases. His equations are probably also approximately correct for calculating the heat conductivity of poly-atomic mixtures though this question has not been checked.

In Fig. 19 we have taken the data on heat conductivity for mixtures of Helium and Argon by Wachsmuth²⁴ as recorded by Chapman²³ first reference. The viscosity data is by Schmitt²² as given by Chapman²³, first reference.

In Fig. 20 mixtures of oxygen and hydrogen are similarly treated. The data on viscosity are by Schmitt²² and the heat conductivity by Wassilewja²⁵. In both cases the densities have been taken from Kaye and Laby, Physical and Chemical Constants.

We have seen from equation (76) that the forced convection at high velocities from large plane surface for moderate temperature differences may be written as

$$W_c = \frac{A v}{K} \left(\frac{k \rho}{\mu} \right)_{avg.} \Delta t \quad \text{watts} \quad (78)$$

From this we see that the heat transfer per square

FIG. 18

FIG. 19

5 per cent O_2 mixture. We thus assume the following values to represent *commercial* H_2

$$\rho = 0.000148 (273/T) \text{ grams per cc.} \quad (86)$$

$$\mu = 0.000102 (T/273)^{0.69} \text{ cm.}^{-1} \text{ gram sec.}^{-1} \quad (87)$$

$$k = 31.9 \times 10^{-6} T^{0.69} \text{ watts per cm. per deg. cent.} \quad (88)$$

$$\mu/\rho = 0.69 (T/273)^{1.69} \text{ cm.}^2 \text{ sec.}^{-1} \quad (89)$$

$$\frac{k\rho}{\mu} = 0.602/T \text{ watt sec. deg. cent.}^{-1} \text{ cm.}^{-3} \quad (90)$$

For air we have obtained the following values

$$\rho = 0.00129 (273/T) \text{ grams per cc.} \quad (91)$$

$$\mu = 0.0001705 (T/273)^{0.754} \text{ cm.}^{-1} \text{ gram sec.}^{-1} \quad (92)$$

$$k = 3.4 \times 10^{-6} T^{0.754} \text{ watts per cm. per deg. cent.} \quad (93)$$

$$\mu/\rho = 0.132 (T/273)^{1.754} \text{ cm.}^2 \text{ sec.}^{-1} \quad (94)$$

$$\frac{k\rho}{\mu} = 0.475/T \text{ watt sec. deg. cent.}^{-1} \text{ cm.}^{-3} \quad (95)$$

Let us now calculate the forced convection from a single radiator tube in the three mediums. We will assume the same values used in the example of section VIII which are as follows:

$$L = 1 \text{ cm. (Length of tube under consideration)}$$

$$p = 1 \text{ atmosphere (Absolute gas pressure)}$$

$$D = 1.93 \text{ cm. (Outside diameter of tube)}$$

$$v = 500 \text{ cm. per sec. (Stream velocity)}$$

$$\Delta t = 100 \text{ deg. cent.} - 15 \text{ deg. cent.} = 85 \text{ deg. cent. (Temperature conditions)}$$

$$T_{avg.} = 331 \text{ deg. K. (Avg. of tube and amb. temperatures)}$$

For air

$$\frac{\mu}{\rho D v} = 0.132 (331/273)^{1.754} \times \frac{1}{1.93 \times 500} = 0.000191 \quad (96)$$

This value is less than 0.013 and therefore we use $m = 1/2$ and $K = 2.15$ in equation (36) and obtain

$$B/D = 2.15 (0.000191)^{1/2} = 0.0297 \quad (97)$$

From this we see that we are dealing with a thin film and may therefore employ equation (64) in calculating the forced convection.

$$W_c = 0.0018 \sqrt{1.93 \times 500} \times 85/331^{0.123} = 2.34 \text{ watts} \quad (98)$$

For Pure H_2

$$\frac{\mu}{\rho D v} = 0.00136 \quad (99)$$

We therefore employ $m = 1/2$ and $K = 2.15$ and obtain

$$B/D = 0.0794 \quad (100)$$

Here the film thickness is getting rather thick, and it is best to calculate the forced convection from equation

(35). We may substitute the approximation of equation (54) and obtain

$$W_c = \frac{2 \pi L k_{avg.} \Delta t}{\log_e \frac{2B + D}{D}} \text{ watts} \quad (101)$$

From equation (100)

$$B = 0.153 \text{ cm.} \quad (102)$$

$$W_c = \frac{2 \pi \times 33.8 \times 10^{-6} \times 54.5 \times 85}{0.144} = 6.85 \text{ watts} \quad (103)$$

For commercial H_2

$$\frac{\mu}{\rho D v} = 0.00099 \quad (104)$$

From equation (36) or from figure 6 we have

$$B/D = 0.0675 \quad (105)$$

From equation (35) and approximation of equation (54)

$$W_c = 7.3 \text{ watts} \quad (106)$$

From these calculations we see that for the same size of radiator tube and same gas velocity the forced convection in *Pure* H_2 will be 2.9 times as great as in air. In *commercial* H_2 the ratio is 3.1, showing a still greater heat transfer. Somewhat the same ratio should be found in the case of built up radiators, since the spacing between the tubes will be large compared with the film thickness and the mutual influence of the tubes should be small.

From equation (78) we see that the rates of heat transfer, from large plane surfaces with moderate temperature differences, in the three gases will be proportional to the coefficients given by equations (85), (90) and (95). Thus, pure H_2 is approximately the same as air and commercial H_2 is about 1.3 times as effective as air.

The heat conductivity and viscosity of a gas is independent of the pressure and since the density is directly proportional to the pressure, the forced convection from large surfaces will be proportional to the gas pressure. For cylinders the effect is less pronounced. Equation (57) shows that for moderate temperature differences and thin films, the rate of heat transfer will be proportional to the square root of the absolute pressure of the gas. The necessity for using large areas in steam condensers to obtain a good vacuum is thus apparent. We may also observe that other things being equal a heavy vapor cycle has an advantage over steam.

From equation (57) we may observe that the forced convection per sq. cm. of tube surface is inversely proportional to the square root of the tube diameter. Thus, generally speaking, small radiator or condenser tubes are more efficient than large ones.

In Table VII the properties of a few gases and liquids are given for purposes of comparison. The values given for the liquids are chiefly from Landolt Börnstein Tabellen. The heat conductivities of the gases have

been calculated from equation (46) with the exception of "Impure H_2 ." For mixtures of a light with a heavy gas equation (46) does not hold and the values given are those previously estimated from Wassilewja's²⁵ experimental data on mixtures of H_2 and O_2 .

The specific heats of the mon-atomic gases Neon, Krypton and Xenon are not available but fortunately the kinetic theory of gases provides us with a method of calculating their values. For mon-atomic gases we assume that any possible internal atomic energy does not contribute to the specific heat and we therefore have from Jeans¹⁶ (page 198, equation 512)

Substituting (108) in (107) we have

$$c_v = 3/2 \frac{R N_0}{J \rho_0} \text{ Cal. gram}^{-1} \text{ deg. cent.}^{-1} \quad (109),$$

and substituting the numerical values we have for the specific heat of a mon-atomic gas

$$c_v = .000133/\rho_0 \text{ Cal. gram}^{-1} \text{ deg. cent.}^{-1} \text{ at const. volume} \quad (110)$$

IX. Summary and Conclusions

1. The present investigation shows that Langmuir's film theory of convection can be successfully applied to

$$c_v = 3/2 \frac{R}{J m} \text{ Cal gram}^{-1} \text{ deg. cent.}^{-1} \text{ at const. vol.} \quad (107)$$

Where R = Gas constant = 1.35×10^{-16}

J = Mech. equiv. of heat = 4.19×10^7 ergs

m = Atomic mass grams

We also have

$m = N_0/\rho_0$ grams (108)

where N_0 = Number of atoms in 1 cc. of gas at 0 deg. cent. and 76 cm. Hg = 2.75×10^{19}

ρ_0 = Density of gas at 0 deg. cent. and 76 cm. Hg. in grams per cc.

the calculation of forced convection.

2. The method of dimensions gives the following general expression for the film thickness B .

$$B = K D \left(\frac{\mu}{\rho D v} \right)^m \text{ cm.} \quad (111)$$

where K = Numerical constant to be determined by experiment

m = Numerical exponent to be determined experimentally

$\mu/\rho = \nu$ = Kinematic viscosity of the ambient fluid for the geometric mean of the ambient and surface temperatures in c. g. s. units.

D = Linear dimension describing the body under consideration measured in cm.

v = Ambient fluid velocity, cm. per sec.

3. The forced convection from long cylinders in which the fluid flows normal to the axis has been tested for a wide range of conditions. These tests include cylinders from 0.0028 cm. to 5.06 cm. diameter at temperatures from room to 1000 deg. cent. and air pressures ranging from 1/2 atmosphere to 4 atmospheres. One point is also available for water. For this wide range the forced convection is given by the following relation:

$$W_c = \frac{2 \pi L \Delta \varphi}{\log_e b/D} \quad \text{watts convection} \quad (112)$$

Where L = Length of cylinder in cm.

$\Delta \varphi$ = Thermal conduction of fluid in watts per cm.

D = Diameter of cylinder in cm.

$b = 2B + D$ = Outside diameter of film in cm.

The film thickness B is given by equation (111) in which we associate D with the diameter of the cylinder and use the following values for the experimental constants:

When $\frac{\mu}{\rho D v}$ is less than 0.013 and B/D is less than 0.24, we have $m = 1/2$ and $K = 2.15$

When $\frac{\mu}{\rho D v}$ is greater than 0.013 and B/D is greater than 0.24 we have $m = 2/3$ and $K = 4.27$

4. The forced convection from spheres is given by

$$W_c = \frac{2 \pi \Delta \varphi}{1/D - 1/b} \quad \text{watts convection} \quad (113)$$

Where $\Delta \varphi$ = Thermal conduction in watts per cm.

D = Diameter of sphere in cm.

$b = 2B + D$ = Outer diameter of film in cm.

The film thickness B is given by equation (111) in which we associate D with the diameter of the sphere. From the meager data we obtain $m = 2/3$ and $K = 35$.

5. The forced convection in pipes is given by the following relation:

$$W_c = \frac{2 \pi L \Delta \varphi}{\log_e D/b} \quad \text{watts convection} \quad (114)$$

Where L = Length of pipe under consideration, cm.

$\Delta \varphi$ = Thermal conduction in watts per cm.

D = Internal diameter of pipe cm.

$b = D - 2B$ = Internal diameter of film in cm.

The value of B is given by equation (111) in which $m = 0.77$ and $K = 37$ or without appreciable error we may force the slope to $m = 3/4$ and use $K = 30$.

6. The tests using the copper wire heater included air, CO_2 , NH_3 , $\text{C}_2\text{H}_5\text{Cl}$, Impure H_2 and water. The tests were made at high velocities and the conditions were such as to give thin films. Moderate temperature differences we used. We may therefore summarize the data as follows:

$$W_c = \frac{\pi D L k_{\text{avg. temp.}}}{B} \Delta t \quad \text{watts} \quad (115)$$

The film thickness B will be given by equation (111) using $m = 0.88$ and $K = 25$ or by forcing the slope to $m = 1$, we may use $K = 100$ with reasonable accuracy.

7. For large surfaces the film thickness will usually be small compared with the dimensions of the body and we may, therefore, write the forced convection

$$W_c = A/B \Delta \varphi \quad \text{watts} \quad (116)$$

Where A = Area of surface in square cm.

$\Delta \varphi$ = Thermal conduction in watts per cm.

B = Film thickness in cm.

If we substitute the general expression for the film thickness as given by equation (111) in equation (116) we obtain as our general expression for the convection from large bodies having thin films.

$$W_c = \frac{A}{K D} \left(\frac{\rho D v}{\mu} \right)^m \Delta \varphi \quad \text{watts} \quad (117)$$

Here the slope m and constant K have to be determined for a given geometrical form by experiments on similar bodies of various sizes or from a single body under different ambient fluid conditions.

8. For moderate temperature differences we may write with sufficient approximation.

$$\Delta \varphi = k_{\text{avg. temp.}} \Delta t \quad \text{watts per cm.} \quad (118)$$

where $k_{\text{avg. temp.}}$ = Heat conductivity of fluid at the average of the surface and ambient fluid temperatures in watts per cm. per deg. cent.

Δt = Temperature difference between surface and ambient fluid in deg. cent.

9. For cylinders in which the film thickness is small compared with the diameter, namely B/D less than 0.05, we have obtained $m = 1/2$ and $K = 2.2$. Therefore, we obtain for moderate temperature differences

$$W_c = \frac{\pi L}{2.2} \left(\frac{\rho D v}{\mu} \right)^{1/2} k_{\text{avg.}} \Delta t \quad \text{watts} \quad (119)$$

10. For gases we have the following relations

$$\rho = \rho_0 (273/T) \quad \text{grams per cc.} \quad (120)$$

$$\mu = \mu_0 (T/273)^n \quad \text{cm.}^{-1} \text{ gram sec.}^{-1} \quad (121)$$

$$k = 1.05 (9 \gamma - 5) \mu c_v \quad \text{watts per cm. per deg. cent.} \quad (122)$$

where ρ_0 = Density of gas at 76 cm. Hg. and 0 deg. cent. in grams per cc.

μ_0 = Viscosity of gas at 0 deg. cent in c. g. s. units

(The viscosity is independent of pressure)

- T = Absolute temperature of gas in deg. K.
 n = Exponent depending on gas. The following values are taken from Jeans¹⁶, page 302; Air, $n = 0.754$; H_2 , $n = 0.69$; CO_2 , $n = 0.98$
 $\gamma = c_p/c_v$ = Ratio of specific heats
 c_v = Specific heat at constant volume in cal per gram per deg. cent.
 k = Heat conductivity of gas and is independent of the pressure.

For Air we have

- $\rho_0 = 0.00129$ grams per cc.
 $\mu_0 = 0.0001705$ c. g. s. units
 $n = 0.754$

From which we have for air at atmospheric pressure

$$\rho/\mu = 7.56 (273/T)^{1.754} \text{ cm.}^{-2} \text{ sec.} \quad (123)$$

In the paper on Free Convection¹ it was shown that the heat conductivity of air at moderate temperatures may be written

$$k = 3.4 \times 10^{-6} T^{0.754} \text{ watts per cm. per deg. cent.} \quad (124)$$

11. Application of these relations to equation (119) gives the following expression for the forced convection from cylinders in air under the conditions of thin films and moderate temperature differences.

$$W_c = 0.0018 L \sqrt{p D v} \frac{\Delta t}{T_{avg.}^{0.123}} \text{ watts} \quad (125)$$

convection

where L = Length of cylinder under consideration in cm.

- p = Absolute air pressure in atmospheres
 D = Diameter of cylinder in cm.
 v = Air velocity in cm. per sec.
 Δt = Temperature difference between surface and ambient fluid deg. cent.
 $T_{avg.}$ = Average of absolute temperature of surface and ambient fluid deg. K.

12. For spheres in which the film thickness is small compared with the diameter we obtain

$$W_c = \frac{\pi D}{35} \left(\frac{\rho D v}{\mu} \right)^{2/3} \Delta \varphi \text{ watts} \quad (126)$$

For air at moderate temperatures we may write it

$$W_c = 0.00082 D^{5/3} (p v)^{2/3} \frac{\Delta t}{T_{avg.}^{1.416}} \text{ watts} \quad (127)$$

where D = Diameter of sphere in cm.

The other symbols have the significance given in equation (125).

13. For pipes in which the film thickness is small compared with the diameter we obtain

$$W_c = \frac{\pi L}{30} \left(\frac{\rho D v}{\mu} \right)^{3/4} \Delta \varphi \text{ watts} \quad (128)$$

For air at moderate temperature differences

$$W_c = 0.002 L (p D v)^{3/4} \frac{\Delta t}{T_{avg.}^{1.561}} \text{ watts} \quad (129)$$

Here D is the inside diameter of the pipe and the other symbols are as defined in equation (125).

14. For plane surfaces we have taken the following relation to represent average conditions:

$$W_c = 0.003 \frac{A \rho v}{\mu} \Delta \varphi \text{ watts} \quad (130)$$

For air at moderate temperature differences, we may write it

$$W_c = 0.0014 A p v \frac{\Delta t}{T_{avg.}} \text{ watts} \quad (131)$$

15. We observe from these relations that in gases the forced convection for the same temperature difference decreases as we increase the ambient temperature. In liquids the opposite effect takes place in general.

16. The forced convection in fluid mixtures requires a knowledge of k , ρ and μ for the mixture. It has been shown that for a certain mixture of a light with a heavy gas the forced convection from plane surfaces may be considerably greater than for either gas alone. This effect is shown in our tests on the forced convection using impure hydrogen. Here the observed forced convection was approximately 1.3 times as great as it would be in pure hydrogen or in air.

17. For pure hydrogen we have the following relations:

$$\rho = 0.00008987 (273/T) \text{ grams per cc.} \quad (132)$$

$$\mu = 0.000085 (T/273)^{0.69} \text{ c. g. s. units} \quad (133)$$

For moderate temperatures we may use

$$k = 33.8 \times 10^{-6} T^{0.69} \text{ watts per cm. per deg. cent.} \quad (134)$$

18. For commercial hydrogen we have assumed the following values:

$$\rho = 0.000148 (273/T) \text{ grams per cc.} \quad (135)$$

$$\mu = 0.000102 (T/273)^{0.69} \text{ c. g. s. units} \quad (136)$$

For moderate temperatures

$$k = 31.9 \times 10^{-6} T^{0.69} \text{ watts per cm. per deg. cent.} \quad (137)$$

19. The forced convection from a smooth cylinder under the following conditions

$L = 1$ cm. (Length of tube under consideration)

$p = 1$ atmosphere (Absolute gas pressure)

$D = 1.93$ cm. (Outside diameter of tube)

$v = 500$ cm. per sec. (Steam velocity)

$\Delta t = (100 \text{ deg. cent.} - 15 \text{ deg. cent.} = 85 \text{ deg. cent.})$ (Temperature condition)

$T_{avg.} = 331 \text{ deg. K.}$ (Avg. of tube and ambient absolute temperatures) gives for

$$W_c = 2.34 \text{ watts}$$

For pure hydrogen

$$W_c = 6.85 \text{ watts}$$

For commercial hydrogen

$$W_c = 7.3 \text{ watts} \quad (140)$$

Thus under the assumed conditions the forced convection from the radiator tube in pure H_2 is 2.9 times as great as in air. In commercial H_2 the ratio is 3.1, showing a still greater heat transfer. In actual built up radiators the same general effect should be observed, since the spacing between the tubes will be large compared with the film thickness and the mutual influence of the tubes should not be great.

20. The heat conductivity and viscosity of gases are independent of the pressure, and, since the density is directly proportional to the pressure, the forced convection from large plane surfaces at high velocities will be directly proportional to the gas pressure. For cylinders the effect of pressure is less pronounced, since the forced convection is only proportional to the square root of the pressure.

21. The forced convection per sq. cm. of tube surface, for thin films, is inversely proportional to the square root of the cylinder diameter. Thus, generally speaking, small radiator tubes are more efficient than large ones.

22. From Table VII we see that the forced convection from a large plane surface in water is approximately 178 times as great as for air. It is also evident that transil oil is not as effective as water. This presents the problem of using dielectrics having better heat transfer properties than oil for certain engineering applications.

23. We have seen that the physical assumption of Langmuir's film theory combined with dimensional reasoning gives equations from which the forced convection from bodies of various shapes may be accurately calculated in any gas or liquid. In the paper on Free Convection¹, similar assumptions were found to give simple solutions for free convection problems. It, therefore, seems certain that when a successful mathematical solution of the actual convection problems is obtained, it will show the existence of a relatively stationary film with a turbulent boundary as postulated by Langmuir's film theory.

Acknowledgment is made to Dr. W. R. Whitney for suggesting the investigation and for the inspiration which his interest in the subject largely supplied. The writer is also indebted to Mr. E. W. Kellogg for the many valuable suggestions which he contributed during the investigation, and to Mr. E. P. Lawsing, for his valuable assistance in making the tests.

Discussion

V. M. Montsinger: I think I am safe in making the statement that there is no other problem which offers any more difficulties than does that of heating and cooling. This is especially so in investigating free convection. In fact there are usually so many factors to be taken into consideration that

it is practically impossible to arrive at any simple rule or formula that will hold for all the conditions met with in practice. I think one of the most important points to be considered in deriving a formula for free convection is that of the size of the area, that is, whether the heated surface is concentrated in a small area or whether it covers a large area several feet in height. Mr. Rice has considered this within a certain range of sizes. Another important point is the range in temperature used.

As most of the data used by Mr. Rice were obtained either from relatively small areas or at fairly high temperatures, that is, above 100 deg. cent. rise and as a contributing part to this compendium, I would like therefore to give in brief some of the results of my experience covering a period of several years in cooling mostly by free convection, of large areas at relatively low temperature rises, less than 100 deg. cent. rise. This lower region of temperature rise is a very important one from a practical standpoint for the reason that the limiting temperature of all class A insulating materials used so extensively in electrical apparatus comes within this range.

First, in reference to the question of the film of inactive air next to the heated surface I think perhaps it may be of interest

FIG. 1—CURVES SHOWING EFFECT OF SIZE OF COIL DUCTS ON COOLING OF VERTICAL COILS BY FREE CONVECTION IN GASES AT 200 LB. (ABS.) PRESSURE

if I give in a very general way the results of a recently conducted experimental observation which confirms very conclusively the existence of a film of apparently stationary gas on the heated surface.

The experiment consisted in cooling by free convection a series of vertical transformer coils separated by various ducts of different sizes in, (1), a light gas of hydrogen, (2), in a heavy gas of nitrogen and (3), in a mixture of the two gases.

For the larger sizes of coil ducts used around 1/2 in. to 3/4 in., the relative heat transfer or convected losses for a given temperature rise for the two gases checked fairly closely the values calculated by Mr. Rice's formula in which the loss varies directly with the product of heat conductivity and the square root of the gas density and inversely with the square root of the viscosity.

But for the smallest coil duct used around 3/16 in., it was found that there was practically no difference in the cooling by either of the gases when under 200 pounds absolute pressure. What appeared at first to be somewhat puzzling occurred when mixtures of these gases were used varying from 100 per cent nitrogen to 100 per cent hydrogen by volume. For instance, with a 50-50 mixture, the loss dissipated for a given rise was

approximately 50 per cent greater than for either of the pure gases, and this difference in cooling with the pure gases and their mixtures gradually decreased as the mixture approached either one of the pure gases.

This hump in the efficiency curve gradually disappeared (as the coils with larger ducts were used) by moving over in the direction of the $\frac{3}{4}$ in. ducts and, of course, as the ducts became larger the cooling became better and better for the hydrogen gas, as compared with nitrogen. This is illustrated in Fig. 1.

The important point however is this: what was the cause of it? According to Mr. Rice's formula, nitrogen has a thin film of inactive gas on the surface and hydrogen gas has a relatively thick film—about 2.6 times greater than that of nitrogen at 50 deg. cent. and at 200 pounds pressure. Naturally then for small constricted paths the thick hydrogen film was clogging the circulation whereas the thin film of nitrogen allowed a much more free circulation and it so happened for this particular size of duct that the cooling was about equal, whereas for unrestricted circulation the cooling of hydrogen ranges from 2 to 3 times as great as that of the nitrogen.

Beginning with hydrogen as the cooling medium and as nitrogen was gradually added, thus forming a mixture, the gain due to decreasing the film thickness was up to a certain point more than the loss due to the addition of the poor cooling gas (and consequently loss of equal amount of hydrogen) but finally at approximately 50-50 mixture the conditions of gain and loss reversed themselves and the cooling again decreased. This phenomena proves conclusively the existence of a gas film upon which Mr. Rice's formulas are based.

Second, in reference to the question of the variation of free convection loss with temperature rise as given by Mr. Rice's equation (126), I wish to make the following comments: if we choose some definite ambient temperature, say 30 deg. cent., the equation expresses the loss as a function of the average of the absolute temperatures of the heated surface and ambient raised to the 0.754 power multiplied by the temperature difference in degrees cent. If we calculate the loss by this equation and plot loss as ordinates and temperature rise as abscissa on double-log paper we find that the loss varies up to 100 deg. almost exactly as the temperature raised to the 1.06 power. But as Mr. Rice states in the paper from 100 to 500 deg. the average exponential value is around 1.25. For example the following tabulation gives the values of the exponent between each 100 deg. rise up to 500 deg. cent. as calculated from his formula.

For temperature rise Between limits of:	Loss varies approx. as temperature rise raised to power of:
0-100 deg. cent.	1.06
100-200 deg. cent.	1.14
200-300 deg. cent.	1.24
300-400 deg. cent.	1.265
400-500 deg. cent.	1.37
Average from 100 to 500 deg. cent. = 1.254.	

However, I have found as I pointed out in my article in June 1916 proceedings that the exponent of 1.25 holds from 0 to 100 deg. and I am quite certain that loss by convection for large areas does not vary even approximately as the first power of the temperature rise as given by equation (126).

I have been using for over ten years this value of the exponent, namely 1.25, in connection with the cooling of large selfcooled transformers having tanks with irregular surface where the greater part of the heat is dissipated by convection and I find that it always checks very closely with the test results. The difference between the loss calculated on the basis of using an exponent of 1.06 and one of 1.25 is quite an appreciable amount. For instance, if the constant is so chosen that the lines cross at 10 deg. rise the difference in loss at 100 deg. rise is in the ratio of about 1 to 1.5.

To obtain laboratory accuracy on the loss of heat by free convection from rather tall vertical surfaces I recently made a series of tests on a cast iron plate about 31.5 in long by 13.1 in. wide by $1\frac{1}{16}$ in. in thickness. In the plate were imbedded sheath wire units of equal resistance about 2 in. apart so as to obtain a uniform temperature throughout the whole area including both sides of the plate. This eliminated the necessity of making corrections for stray losses in case one side of the plate had been blanketed, as is sometimes done in investigations of this kind.

The plate was suspended in a vertical position in the air in an open room having a constant temperature. Fifteen thermocouples were soldered in holes in the surface on one side and five on the other side of the plate, the five being used merely as a check to see if both sides were at the same temperature. Direct current was used to supply the loss. All readings of volts and amperes and thermocouples were taken with a potentiometer. For convection, the air was used as the ambient. For radiation the temperature of the walls of the room about 10 feet distance was used for the ambient although the air and wall temperatures were usually the same.

Three series of runs were made with both sides of the hot plate under the same conditions, namely:

(1) painted a lamp black; (2) nickel plated and polished, and (3) with the surfaces partly oxidized and set permanently at about 325 deg. cent. before making any test.

For the first condition the paint began to scale off when the temperature reached approximately 100 deg. cent. or about

FIG. 2—HEAT LOSS BY FREE CONVECTION FROM PLANE 31.5" HEIGHT AND 13.1" WIDTH, PAINTED LAMP BLACK

72 deg. rise and the test had to be discontinued. Up to this point the loss by convection was taken as the difference between the total loss and the loss calculated by the standard radiation law and assuming that the emissivity factor was 0.9 that of a perfect black body. The radiation constant used was 3.68×10^{-11} .

The convection loss points fell on a straight line on double-log paper the equation of the line being

$$W_c = 1.40 \times 10^{-3} \theta^{1.265} \quad (1)$$

in which W_c is the watts per square inch of surface and θ is the temperature rise in deg. cent. The loss is plotted against temperature rise raised to the $5/4$ power in Fig. 2.

For the other two conditions of the plate surface the emissivity factor for radiation was assumed to be that obtained by subtracting from the total loss for a given rise around 50 or 60 deg. cent. the convection loss according to equation (1). The resulting value of emissivity was used throughout the range of test temperatures in determining the convection loss points.

According to the above method of procedure the emissivity factor for the nickel plated and polished surface was 0.07.

Up to about 150 deg. cent. rise the convection loss points fell in a straight line on double-log paper, the slope of the line being about 1.26. From 150 to 300 rise the points gradually drew away from the straight line and at 300 deg. rise the loss was about 25 per cent higher than the straight line. Fig. 3 shows the loss plotted against temperature rise raised to $5/4$ power.

At first it was thought that this departure from a straight line on double-log paper was due to a change in the law but

(as will be seen later where tests were made with the surfaces partly oxidized did not show this departure), it was apparently due to a gradual oxidation of the surface which at first was not discernable to the eye but which gradually increased the emissivity factor. At about 300 deg. rise the surface became so tarnished that the tests were discontinued.

For the last set of tests the surfaces were painted black and then subjected to a temperature of 325 deg. cent., for about a day, so as to let it get "set" before making any test. Some of the paint came off and what remained turned a brownish color.

Tests were taken first with the temperature decreasing and

FIG. 3—HEAT LOSS BY FREE CONVECTION FROM VERTICAL PLANE 31.5 IN. HEIGHT AND 13.1 IN. WIDTH. NICKEL PLATED AND POLISHED

second with an increasing temperature. The emissivity factor, determined as described before, was 0.52. The convection loss where plotted vs. temperature rise on double-log paper fell practically on a straight line up to 280 deg. cent. rise—as far as the temperature was taken—with a slope of the line of 1.25. This is shown in Fig. 4.

As stated before, the results above approximately 100 deg. rise agree fairly well with Mr. Rice's formula and I do not think that because they disagree below 100 deg. rise they contradict the film theory. As I stated in the beginning of the discussion the conditions of cooling a large plate are so radically different

FIG. 4—HEAT LOSS BY FREE CONVECTION FROM VERTICAL PLANE 31.5 IN. HEIGHT AND 13.1 IN. WIDTH. SURFACES PARTLY OXIDIZED BEFORE TESTS

from that of cooling a small area where the heat is concentrated and especially at low temperature differences that possibly the same equations would not be expected to hold for both conditions.

The point which I wish to emphasize is that for a large vertical surface and for temperature rises used in most electrical apparatus the loss can be expressed close enough for practical purposes by a simple exponential equation in which the loss varies as the 5/4 power of the temperature rise. This agrees with the results found by Messrs. Ezer, Griffiths and A. H. Davis conducted under the auspices of the Department of Scientific and Industrial Research, and shown in their Special Report

No. 9 issued last year on "The Transmission of Heat by Radiation and Convection." This was for temperature rises up to 100 deg. cent. and for vertical planes up to approximately 35 in. in height. For heights of 69 and 104 in. the values of the exponent were 1.3 and 1.34 respectively. The constant in their formula was the same (1.28×10^3) for all heights above 12 in. (30 cm.). For smaller heights than 12 in. they found that the constant increased. The constant I found from the tests on the hot plate was 1.4×10^3 or about 9 per cent higher than Griffiths and Davis' value, for corresponding heights.

Chester W. Rice: (by letter Oct. 18, 1923.) In the above discussion Mr. Montsinger called my attention to the fact that the free convection from vertical plane surfaces varies as the 5/4 power of the temperature difference whereas my equations make the convection vary approximately as the first power of the temperature rise for small temperature differences. In view of this lack of agreement between the theory and experiment for low temperature differences, it seemed desirable to reexamine the available data on the basis of a more general expression for the film thickness so as to obtain, if possible, a single expression which would be universally applicable for both large and small temperature differences. In a subsequent paper it will be shown that the desired universal expression can be readily found and that it leads to the following conclusions.

(1) The more general expression for the effective film thickness, here developed, is seen to be superior to the simpler expression of the previous paper since the resulting equations account accurately for the convection from large and small bodies at both high and low temperature differences.

(2) The general expression for the effective film thickness obtained by the method of dimensions for free convection is

$$B = K D (k/\mu c_p)^2 [\nu/(\alpha g \Delta t)^{1/2} D^{3/2}]^n \quad \text{cm.} \quad (1)$$

where K = Experimental constant depending on the system of similar bodies under consideration

D = Characteristic linear dimension of body in cm.

k = Heat conductivity at average temperature watt cm.⁻¹ deg. cent.⁻¹

μ = Viscosity of fluid at average temperature cm.⁻¹ gram sec.⁻¹

c_p = Specific heat at constant pressure for average temperature Joule gram⁻¹ deg. cent.⁻¹

p = Experimental exponent

ν = μ/ρ = Kinematic viscosity of fluid for average temperature cm.² sec.⁻¹

α = Coef. of density change per deg. cent. for average temperature in deg. cent.⁻¹, for ideal gases $\alpha = 1/273$

g = Acceleration of gravity = 980 cm. sec.²

Δt = Difference between surface and ambient temperature deg. cent.

n = Experimental exponent for the system of similar bodies under consideration.

(3) When dealing with *ideal gases*, the first factor in equation (1) can be neglected since it does not vary greatly from one gas to another. Under these conditions we write the effective film thickness

$$B = K_1 D [\nu/(\alpha g \Delta t)^{1/2} D^{3/2}]^n \quad \text{cm.} \quad (2)$$

(4) The free convection from *long horizontal cylinders* in *gases* and *liquids* is given by

$$W_c = 2 \pi L \Delta \phi / \log_e [(2B + D)/D] \quad \text{watt} \quad (3)$$

where L = Length of cylinder in cm.

$\Delta \phi$ = Thermal conduction in watts per cm.

D = Diameter of cylinder in cm.

B = Film thickness in cm. from Eq. (1).

A sufficiently close approximation is usually obtained by taking $n = 1/2$; $K = 2.12$ and $p = 1/4$ in equation (1).

(5) The free convection from *long vertical cylinders* in *gases* is given by equation (3) and the film thickness by equation (2). The meager available data give $n = 2/3$ and $K_1 = 8.65$.

where R = mechanical resistance dynes cm. $^{-2}$

(8) We may write equation (15) in the following form

$$W_c = (A c_p \Delta t R/v) (k/\mu c_p)^{1-p} \quad \text{watt} \quad (16)$$

which is seen to conform to Reynolds Law as given by Stanton.

(9) If we substitute Lees equation for the resistance to flow in *smooth pipes* in equation (16), and assume $p = 1/2$ we obtain for *gases and liquids*.

$$W_c = (k/\mu c_p)^{1/2} A \rho c_p v \Delta t [0.0009 + 0.0763/(v D \rho/\mu)^{.35}] \quad \text{watt} \quad (17)$$

This equation takes into account the variation of the resistance with the degree of turbulence and therefore should be applicable over the entire range above the critical velocity.

For *ideal gases* we may take with sufficient approximation

$$W_c = 1.16 A \rho c_p v \Delta t [0.0009 + 0.0763/(v D \rho/\mu)^{.35}] \quad \text{watt} \quad (18)$$

For *air* equation (18) becomes approximately

$$W_c = (0.417 A p v \Delta t / T_{avg.}) [0.0009 + 0.00012 T_{avg.}^{.615} / (v D p)^{.35}] \quad \text{watt} \quad (19)$$

where p = absolute air pressure in atmospheres

$T_{avg.}$ = Average of surface and ambient absolute temperature

(10) For *rough pipes* (fine sand paper) we will assume $x = 1$, $p = 1/2$ and $K_0 = 136$ in equation (13).

For *ideal gases* we then obtain

$$\overline{W}_c = 0.00635 A \rho v k \Delta t / \mu \quad \text{watt} \quad (20)$$

For *air* we have

$$W_c = 0.0031 A p v \Delta t / T_{avg.} \quad \text{watt} \quad (21)$$

(11) For cylinders in *ideal gases* the values obtained in the previous paper still hold. We therefore take $x = 1/2$ and $K = 2.2$ in equation (14) and obtain for thin films

$$W_c = (A k \Delta t / 2.2 D) (\rho D v / \mu)^{1/2} \quad \text{watt} \quad (22)$$

where D = Diameter of cylinder in cm.

For *air* we obtain

$$W_c = 0.0018 L \sqrt{p D v \Delta t / T_{avg.}}^{.123} \quad \text{watt} \quad (23)$$

where L = Length of cylinder in cm.

(12) The heat transfer in gaseous mixtures are covered by the general equations which apply to liquids and gases.

In conclusion the writer wishes to express his thanks to Mr. Montsinger for his valuable criticism of the paper which brought out the limitations of the previous theory and stimulated the writer to work out the present more general relations.

The Electrical Plant of Transocean Radio Telegraphy

BY E. F. W. ALEXANDERSON, A. E. REOCH and C. H. TAYLOR

Fellow, A. I. E. E.

Associate, A. I. E. E.

All of the Radio Corporation of America

Review of the Subject.—A description of the expansion of the Transocean Communication System of the Radio Corporation of America from a few isolated plants to a unified group of electrical plants all controlled for communication purposes from a central

traffic in New York City, with a summary of the technical conditions covering the design of the Radio Central Station and of the technical conditions to be met in operating efficiently a modern radio communication system.

AT the beginning of 1920 the United States Government removed the war restriction on commercial radio service, and the Navy Department restored to the Radio Corporation of America those stations which were built and equipped in 1914 by the Marconi Wireless Telegraph Company of America for transocean service.

In addition to the agreements previously entered into with countries in Europe for transocean radio service, the Corporation faced the situation arising out of the Great War, in which practically every European country demanded direct radio communication with the United States.

The need for the provision of modern facilities for carrying on radio communication with those countries with which agreements had already been made, was imperative, and hardly less imperative was the need for the expansion of our facilities to meet the new situation.

The radio equipment in all of the installations restored to the Corporation was of obsolete type and based on the use of damped waves, except in the case of the New Brunswick station. At that station the Navy Department had instructed the General Electric Company to install high-frequency alternator equipment and to modify the antenna circuit to meet the requirements of their system. Accordingly, an alternator equipment was installed which was able to supply to the antenna circuit 200 kilowatts at the high frequency to which the antenna circuit is tuned. The antenna at this station had been erected as an inverted L, approximately a mile long and 550 feet wide. This was changed to the multiple-tuned type by adding five tuned down leads, equally spaced along the length of the antenna, and connecting them through a balanced distribution system to the ground and counterpoise wires. This installation has been described by technical papers read in 1920 and 1921.

Operation of the system of the Radio Corporation started with two transmitting stations — at New Brunswick, New Jersey, and at Marion, Massachusetts. Each of these transmitting stations had its corresponding receiving station at Belmar, New Jersey, and at Chatham, Massachusetts, respectively. New Brunswick was used for communication with England, and Marion for communication with Norway. The telegraphic operation of the English circuit was centered

in Belmar, and the operation of the Norwegian circuit was centered in Chatham. Messages to England or Norway were telegraphed to Belmar and Chatham respectively, where they were copied and transmitted over the radio circuit via New Brunswick and Marion. Similarly, messages from England and Norway were received in Belmar or Chatham, were copied by hand, and re-telegraphed to New York. This process involved several relays of telegraph operators with the consequent high expense and possible delays and errors.

With the present system of operation, the Radio Corporation has six transmitters on the Atlantic coast, two in Tuckerton, one in New Brunswick, one in Marion, and two in the Radio Central station on Long Island. All these transmitters are controlled directly from the traffic office in New York City.

Only one receiving station is needed for all incoming messages. This receiving station is located at Riverhead, Long Island. It has a single antenna of a new and special type, which will be described later. This antenna intercepts the waves from all European transmitting stations. The receiving apparatus, also of a new type, separates this conglomeration of ether waves which come in over the receiving antenna, into separate messages which are automatically relayed over telephone wires so that all messages are received and copied in the same traffic office in New York.

The transmitting station on Long Island — known as "Radio Central" — and the receiving station at Riverhead, Long Island, represent the modern system of the Radio Corporation. The stations at New Brunswick, Marion, and Tuckerton, are adaptations of the modern transmitting apparatus developed by the General Electric Company and antennas built before the war. The characteristic features of the transmitting system are: The high-frequency alternator, the multiple-tuned antenna, the speed or wave-length regulator, and the magnetic amplifier.

In the Riverhead receiving station the method of centralization has been carried to its logical conclusion by concentration of all radio apparatus in the one station, and concentration of all reception in New York. The advantage of such concentration is obvious. New receiving circuits for communication with any new station in Europe can be added at a negligible cost by installing a new set of receiving apparatus on some of the shelves provided for that purpose in the Riverhead receiving station.

The Radio Central transmitting station has been

Presented at the Annual Convention of the A. I. E. E., Swampscott, Mass., June 25-29, 1923.

planned in such a way that the cost of additional transmitting units will be a minimum. The choice of the site of the Radio Central transmitting station was carefully considered, looking forward to a growth of international radio communication which would require as much as twelve transmitters in this new station. Two of these twelve transmitters are already completed.

The principal considerations in selecting the site for the Radio Central station were:

1. The site must be within a reasonable distance from New York — the center of traffic.

was to be the controlling factor. The engineers thus undertook to remedy by new developments in the technique what nature had failed to provide — a good ground. Much progress had already been made to reduce ground resistance by multiple tuning and ground equalizers, but this experience had been gained in stations like New Brunswick, Marion, and Tuckerton, where the natural ground resistance was low. However, we had sufficient faith in the further possibilities of development of improved grounding methods to take the responsibility for starting the construction of the new station while investigation was going on to find a

FIG. 1

2. A large tract of land of a desirable nature must be available, at a moderate cost.

3. A good power supply must be within easy reach.

4. There must be direct and reliable wire line communication with New York City.

The site selected on Long Island fulfilled these requirements in an ideal way, but another desideratum which, in the past, had been the deciding factor in selecting sites for transmitting stations, was not fulfilled in the Long Island location — a natural low ground resistance. The Long Island ground consists of quartz sand of extraordinarily high resistance. The decision, therefore, regarding the selection of this site was a grave responsibility for the engineers of the Radio Corporation. It meant a radical departure from the generally accepted theories. It implied that tactical operation rather than technical considerations

solution for the grounding problem. The development work of the new ground system required as much time as the completion of the rest of the station, but by the time the station was ready to go into service the ground system was also ready and proved to be successful beyond the most sanguine expectations.

The Radio Central transmitting station of the Radio Corporation of America is the first of our stations that has been planned and designed from the beginning to meet modern requirements, the other stations having been made to conform to modern practise by modification of equipment installed in earlier times. The Radio Central type of station is being duplicated in Poland and Sweden. This station has been frequently described and while its 400 ft. steel towers with 150 ft. cross arms are quite well known, little has been published regarding the technical performance of the plant.

Many reasons entered into the decision to use this type of tower, three of which may be mentioned here. One consideration was, the average height of the antenna wires. With a group of similar antenna wires, equally loaded, suspended on a springstay between two towers, the height above ground of the point of suspension of a wire decreases as the distance between this point and the nearest tower is increased. With a similar group of wires suspended from the bridge arm of a tower, there is no similar variation.

Another engineering consideration was the variation in antenna constants caused by high winds. The suspension of the group of antenna wires from a springstay slung between the tops of two masts or towers, has been used at our New Brunswick, Marion, and similar stations. It has been found that whenever there is a high wind blowing across the antenna wires, the spring stay assumes a new position varying with the strength and direction of the wind. With gusty winds of high velocity, this change of position is continuously occurring. There is, in addition, the variation in the position of the antenna wires due to the cross wind on the wire span between the spring stays. The result of these changes in position of the wires is that the constants of the antenna circuit change, and detune the antenna from the alternator which is operated at an accurately regulated wave length. The resulting fluctuations in radiation have been so great at times as to seriously impair the commercial effectiveness of this station. Now, with a fixed point of suspension, such as the tower bridge arm, the only variations in position of the wires, are those due to the wind on the wire span between the towers. Those due to the variation in the position of the spring stay are not present.

The antenna circuits at all of our stations are equipped with variometers to correct for these changes and our experience is that the variations are less severe with Radio Central type of antenna than with that of New Brunswick.

As Long Island is well within that zone of the United States in which sleet and glare formation must be expected on all structures exposed to the weather during the winter months, provision has been made to melt such ice as may form around the antenna wires. The heating current for sleet melting, is supplied from the power house, at 60-cycles, through special transformers and reactances. The antenna wires are connected together at the far end of the circuit. By opening switches at the power house end of this circuit, the wires can be disconnected from the radio frequency feeder circuit and the 60 cycle power circuit can be connected. If the several downleads were connected directly to the antenna wires throughout their length the path of the heating current would be short-circuited. Two satisfactory methods have been used to avoid such short circuit. One method consists in dividing the wires into four groups and connecting only the wires

belonging to one group at each of the four intermediate points. At both ends, all wires are connected. The other method consists of making the connection of each wire through a specially designed condenser.

The inductors used at each download of the multiple tuned antennas are installed without any protection from the weather. This type of installation has proved satisfactory except at some locations close to the sea where the spray from the sea water deposits salt on the insulators.

FIG. 3

The standard outdoor coil is shown in Fig. 3. Fig. 4 shows coils housed in frame structures lined with copper.

At stations where more than one antenna circuit is installed, attention must be given to the disposition of the several antennas and of their individual feed circuits in order to minimize their mutual interaction. In enlarging or remodelling an existing station, it is not always expedient to attempt to bring all antenna circuits to the close proximity of the power house. This is particularly true of a station where the original antenna circuit is of umbrella design and where a second antenna circuit is to be installed, which can be operated simultaneously with the first and on a long wave length differing from that of the first by only a few per cent. Such a situation confronted us at our Tuckerton station. The space immediately surrounding the power house was occupied by the umbrella antenna, which was in continuous commercial use. The new antenna could be erected on some vacant land

just beyond the boundary of the space occupied by the umbrella antenna provided this antenna circuit could be fed with power at radio frequency from the power plant. The study of a transmission line that would be suitable for supplying to this antenna from the power plant, 200 kw., at frequencies of around 18,000 per sec. with little loss on the line, disclosed that this was quite practical. The antenna has been erected, this high-frequency line has been installed and the circuit has been operated very satisfactorily now for over a year. The power delivered to the antenna circuit is 92 per cent of the power supplied to the line.

The success of this type of antenna feed circuit will have a profound effect upon the design of stations operating two or more antenna circuits simultaneously.

GROUNDING SYSTEM

The first decision to be made in the development of the ground system was whether it should be of the buried wire type, or the type known as "counterpoise" or "earth screen." The New Brunswick station has a ground system combining counterpoise and buried

FIG. 4

wires. Experience had shown that while the counterpoise type might be ideal, from a theoretical point of view, it would be undesirable from the point of view of practical maintenance.

A counterpoise consists of a network of wires mounted on poles. These wires carry fairly high potential and the failure of any one wire will cause interruption of service until the fault is located and repaired. The overhead system of wires is also undesirable because it is an obstruction, making the maintenance of the overhead antenna wiring difficult and expensive. Theoretical considerations indicated that a buried wire system would be as effective as an insulated counterpoise provided that its dimensions and design were carefully planned with reference to the character of the soil.

To determine the basic factors for the design of a buried ground system, measurements were made of

wave propagation on wires of different lengths buried in the Long Island soil. As a result it was found that the velocity of wave propagation on a wire in this soil is about one-tenth of the velocity of wires suspended in the air. It was found, furthermore, that the resistance of the wire is a function of the wavelength. With increasing length of the wire, the conductivity increases as a linear function up to a length of one-quarter wavelength, where it reaches a maximum, after which it becomes a periodic function of the wavelength and the length of the wire. The results of these measurements showed that the maximum length of wire which could be used effectively must be something less than one-quarter wavelength of the wave propagation in the buried wire.

Measurements of wave propagation in the buried wires indicated that while lengths as great as 1200 feet could be used economically in the Long Island soil, it was furthermore determined, through calculations of the electric field distribution around the antenna, that 76 per cent of the electric lines of force radiating from the antenna would be collected by these ground wires if they were made 1000 feet long. One thousand feet on each side of the center line of the antenna was therefore considered sufficient; the result is that the Long Island antenna, in effect, stands on a plate of copper 2000 feet wide and 3 miles long, and therefore the functioning of this antenna is made independent of the resistance of the soil.

The combined antenna and ground system offers a total equivalent resistance to the antenna currents of only 40 hundredths of an ohm, made up as follows:

Radiation resistance.....	0.05 ohms at 16,500 meters
Ground resistance.....	0.10 ohms
Tuning coil resistance.....	0.15 ohms
Conductor resistance.....	0.05 ohms
Insulator and other losses...	0.05 ohms

Total..... 0.40 ohms

The unit is operated with 200 kw. in the antenna, and the antenna current is 700 amperes, resulting in a radiation of 60,000 meter amperes.

A special plow was constructed by which the wires could be laid cheaply. The plow carried a coil of wire. It had a blade which introduced the wire in the ground at a depth of twenty inches. The plow was drawn by two Ford tractors.

The ground network consists of wires each 2000 feet long buried in the ground a depth of 15 to 20 inches in lines at right angles to the line of the antenna with the center point of the ground wire under the center line of the antenna. The ground wires are spaced 10 feet apart and as the antenna is 7500 feet long there are therefore 750 such wires making the total length of buried wire approximately 1,500,000 feet. The ground wires are connected to a heavy underground bus which runs in the ground under the center line of the antenna. There is also an aerial bus feeder which is connected

to the buried bus through inductive reactances in such a manner as to make all paths to ground of equal reactance, resulting in equal distribution of the antenna current to all sections of the ground system.

CONSTANCY OF WAVELENGTHS

A factor of great importance is that of maintaining the frequency or wavelength radiated absolutely constant for reasons that will be referred to later. In radio stations using high-frequency generators of the alternator type the speed of the alternator determines the frequency of the waves radiated. In many other forms of transmitters the frequency is affected by the

FIG. 5
New Brunswick, N. J.

antenna constants if not actually controlled by the antenna, with the result that as the antenna wires are blown about by wind; and ground and insulators are affected by dry, wet or frosty weather; changes in frequency will constantly occur. In the case of the alternator the problem resolves itself into maintaining the driving motor at constant speed regardless of voltage or frequency fluctuations in the power supply or the telegraph load fluctuations to which it is subjected by the alternator. This is accomplished by a system of relays operated in synchronism with the telegraph key by means of which the voltage applied to the motor terminals and the resistance in series with the wound rotor is varied so that the motor torque

FIG. 6
Radio Central, Long Island.

is always just equal to the load to which it is applied. Tendency to change speed on account of the telegraph load is thereby eliminated. Speed fluctuations due to changes in the power supply are not so easily disposed of however. A portion of the generator output is utilized to energize a tuned circuit of low resistance adjusted to have a natural period slightly different from the frequency at which the generator is maintained so that if the alternator frequency varies only a few hundredths of one per cent in one direction, there will be a large increase in the current in this resonant circuit, or if the variation is in the other direction, there will be a correspondingly large decrease. A portion of the current in this resonant circuit is rectified and we are thus provided with a direct current which varies

up or down practically instantaneously with the slightest change in the alternator frequency. This direct current is made to control the voltage supplied to the motor terminals reducing the voltage to counterbalance a tendency towards increase in speed and vice versa. In order that there may be a visual indication of what is going on, a recording ammeter is inserted in the rectified current circuit; a fine straight line on the ammeter chart indicates a constant frequency, a thick line indicates small and continuous variations of frequency and so forth. Under usual conditions of operation, irregularities of the ammeter chart line can be included within two parallel lines 1/8 in. apart representing maximum frequency variations not exceeding one in 5000 or 4 cycles per second, or 3 meters when operating at 20,000 cycles and 15,000 meters.

Fig. 5 is a section of speed control ammeter chart from the New Brunswick station; the irregularities in this chart are due to various adjustments being made while in operation.

Fig. 6 is a section from a Speed Control Ammeter chart for one of the transmitters at the Radio Central Station.

FIG. 7

Fig. 7 is the corresponding section of the wattmeter chart of the same transmitter.

RECEIVING SYSTEM

The centralized receiving system is located at Riverhead, Long Island. The antenna is of a new type which gives uni-directional reception. This system is so oriented as to receive signals from the over-ocean transmitter and annul signals from all other directions, including the powerful home transmitter nearby.

The antenna consists of two copper wires strung on ordinary poles like a telephone line, and extending over a distance of nine miles, (15,000 meters). This antenna feeds a number of separate receiving circuits of different wave lengths without the slightest mutual interference or weakening of the signals.

Important as it is, from the point of view of centralization, to be able to receive an indefinite number of signals from the same antenna, the greatest importance in the use of this new receiving system is its remarkable properties of suppressing atmospheric disturbances or the so-called "static" which hitherto has been the bane of radio communication. The attainment of these results is not an accident; it is the result of development work covering a number of years. The "wave antenna" as now used in Riverhead, is the practical answer to the receiving problem of today. The principle of directive

Six sets of receiving equipment are normally coupled to this one antenna system, and the signals on six transoceanic circuits are separated by tuning, and copied simultaneously, each independent of the electrical operation of the other sets.

For this purpose, the antenna output transformer is built with several secondaries and the artificial lines are made up to accommodate a number of receiver sets. Many precautions are necessary in the design and arrangement of the receiving equipment to eliminate

FIG. 8—DIRECTIVE CURVE OF WAVE ANTENNA

cross talk and "beat note" interference between the different sets. With this end in view, the equipment for reception of long waves has been completely remodelled.

In the first place, all of the different elements in each receiving set must be thoroughly shielded. The tuning inductances are all balanced pairs of coils placed in an inner shielding of copper to eliminate the losses in the iron casing of the outer shield. In spite of the shielding, cross talk and beat note interference occurred until suitable chokes and filters were placed in both the positive filament and positive plate leads of all coupling tubes, amplifiers, detectors, and oscillators.

The receiving apparatus is arranged in line, with the antenna input panel at one end and the audio frequency output panel at the other end. The intervening units are placed in correct sequence so that the signal currents pass in progressive order along the line through all the various units from input to output panel without looping back over this same path.

The elements of a set are mounted on a sub-panel which is placed in an iron box, the front door of which

may be opened. All adjustments of tuning and filament control which are likely to be made frequently on a set tuned to a fixed wave length can readily be made without opening the front door of the iron boxes because such control handles are mounted on the outer doors in such a manner as to engage with the controls on the sub-panel when the iron door is closed.

These receivers are set up on racks holding three sets per rack. Each set is arranged as a complete unit on a shelf and the shelves are arranged in three tiers on the racks. The Riverhead station is equipped with three racks making space for the accommodation of nine receiving sets.

Fig. 9 gives the general view of the receiving equipment.

The signals received from the wave antenna are strong; so usually a total of four stages of amplification is sufficient to bring the intensity of normal European signals up to a strength that is rather uncomfortable to the ear.

Since all the local long wave stations, except Marion, are either behind or in the case of Rocky Point, at right angles, to the direction from which the European signals come, directive reception alone lowers the intensity of the local stations so much that tuning can easily eliminate their interference. Interference as strong for instance, as that from Marion, can be eliminated when the wavelength differs by not less than 3 per cent. For

FIG. 9

interference of considerably less intensity than that from Marion, as for instance, that from stations in Europe, or from a local station, reduced by directive reception, a 2 per cent difference in wavelength is sufficient.

For wavelength difference of 2 per cent and less the constancy of frequency of the transmitting station becomes of very great importance. Extremely good frequency regulation at the transmitting station will allow the use of filter circuits by means of which interference on wavelengths differing less than 2 per cent from that of the desired signal can be eliminated.

The receiving station at Riverhead, L. I., is about 70 miles east of New York and the next phase of the

problem was the automatic transfer of the radio signals to the central control office in New York City in order to eliminate the double handling of traffic, the slowing up of the circuit, and the other delays inseparable from the older system. The requirements of this circuit were studied and then the American Tel. & Tel. Co. was requested to provide a suitable tone circuit from Riverhead to our Broad Street office, New York City. For a period of several months experiments were conducted over this temporary line, during which it was demonstrated that it was feasible to send these tone signals over a 70-mile circuit without detriment to the readability of the signals. Continuous commercial operation over a single tone circuit was started about July 1st, 1921. Subsequently additional tone circuits were built for the commercial operation and control of Riverhead station in this manner.

CENTRAL OPERATING ROOM

The operating room at the city offices is the place where the written message is converted to the dot and dash of the Morse code. The continental code is used in radio as in all other international telegraphic communication. During the last few years a great change has taken place in the transmission of the message. Whereas formerly the manually operated telegraph key was used almost universally for speeds of transmission of 40 words per minute or less, this has been entirely displaced by the machine transmitter. The advantages of machine transmission over hand transmission are (1) that the operator is required to work a typewriter keyboard only and need not necessarily be a skilled telegraphist, (2) that one operator can transmit messages in this manner at rates up to 100 words per minute, whereas the best that can be done by hand is 35 or 40 words per minute, (3) that all characters are perfectly formed and do not vary with the different operators, and (4) the machine is tireless and has no lost time. The telegraphic manipulation is actually accomplished by first punching the message on a paper tape and subsequently passing the punched paper tape through the mechanical transmitter which is an automatically operated telegraph key.

The transmitter sends telegraph impulses over the control wires between the city office and the transmitting station and operates the relay system at that station.

In order that a check can be kept on the performance of the automatic transmitter, the control wires, and the relay system of the transmitting station, a radio receiving set is provided at the city office which makes audible or visible to the operator the actual signal being transmitted into the ether. This receiver is a very simple piece of apparatus, since the reception of the signal from the nearby high power transmitter is not at all difficult, although of course, as there are so many transmitters operating in one locality with only small wavelength separation, very efficient tuning equipment must be provided.

The reception of a message at the city office requires a reversal of the above process. The signal as received at the receiving station is in the form of audio frequency current, the frequency of which is variable as desired, these signal currents are transferred to the city office by telephone wires. At the city office it is necessary to further amplify the currents before they are introduced into the telephone or the recorder. It is possible to use aural reception at speeds up to 35 or 40 words per minute. Better speeds can be secured at times by a combination of aural and recorder reception. At speeds over 40 words per minute tape reception must be used exclusively. It is possible for some tape readers to copy as fast as 60 words per minute but generally for speeds over 40 words per minute; the work is divided up among an increased number of operators; 40 to 70 words per minute two operators; 70 to 100 words per minute three operators, and so forth. The development of the tape recorder used for transoceanic radio reception was ably described in a paper presented to the Inst. of Radio Engineers by J. Weinberger in 1921.

The electrical equipment of the operating room of a city office, handling a large number of circuits, requires careful planning. In the city office of the Radio Corporation of America at 64 Broad Street, New York City, there are at present in continuous operation,

6 transoceanic receivers

6 local Monitor receivers

6 automatic transmitters

and over 30 land wires. To these will soon be added a number of new services.

Power supplies of different types are provided for the various electrical and mechanical devices and measures have been taken to prevent inductive interference effects between instruments.

WAVELENGTH DISTRIBUTION

The economical wavelength for communication over a certain distance can be selected by the practical rule that the economic range of a station for reliable communication is about 500 to 1000 times the wavelength. If too short a wave is selected the signals will be weak in daytime and strong but variable at night. This variation is most noticeable during the period when darkness exists over the area between the communicating stations. In some parts of the world it is possible to use short waves to advantage because the absorption is comparatively lower than on long waves and variations are unimportant but generally speaking for distances over 3000 miles the reliability of wavelengths of over 11,000 meters is so much greater than that of shorter waves. Long waves have therefore been universally adopted for long distance communication.

It can now be readily seen that since the ability to receive distinct signals depends on the separation of different frequencies there is a definite limit to the number of "channels" of communication between stations that can be set up.

If the wavelengths between 11,000 and 22,000 meters are divided into 2 per cent bands there are 35 "channels." If into 1 per cent bands, there are 70 "channels." Except to such extent as directional reception will permit the number of one way channels open for such, long distance communication is limited to the number of these bands.

If we suppose our plans to be based on the use of 1 per cent bands, it is evidently necessary first that each transmitter shall cause no radiation outside of the 1 per cent band allotted to it and furthermore shall maintain its actual radiation frequency exactly on the center of such band; and second that each receiver shall be capable of separation of currents from those differing only 1 per cent in frequency. The above requirements imposed upon the transmitter have already been proved practicable. But the realization of the full possibilities of radio communication requires that all transmitters of antiquated type which take undue space in the ether be replaced.

There are, however, other difficulties that cannot be so easily overcome. For instance while it is quite possible for the receiving station to separate currents of frequencies differing 1 per cent if the voltages induced at the station at the different frequencies are equal, it is not an easy matter to separate the currents when the voltage induced in one case is 1000 times the voltage induced in the other. This is the situation where in the case of a transatlantic circuit the receiving station in America receives from Europe on 15,000 meters and the transmitting station in America sends to Europe at the same time on 15,150 meters. In such cases, as described above, it is necessary to increase the separation between frequencies to 3 per cent and in order that such large separation may not be too numerous a rule has been established by precedence and informal agreement, that all the transmitters in one locality shall transmit on wavelengths close together. We have such a case in the concentration of American transmitters between 16,000 and 17,500 meters. In this band of wavelengths there are operating at present the following stations:

15,900 Meters Tuckerton No. 1 Transmitter
 16,300 Meters Kahuku No. 1 Transmitter
 16,465 Meters Radio Central No. 1 Transmitter
 16,700 Meters Tuckerton No. 2 Transmitter
 16,975 Meters Kahuku No. 2 Transmitter
 16,975 Meters Annapolis Compensating Wave Arc
 17,145 Meters Annapolis Signalling Wave Arc
 17,500 Meters Radio Central No. 2 Transmitter

It is planned to operate transmitters in Sweden, Poland and Argentina in the near future on wavelengths 18,000 meters to 19,000.

The French Government station at Lyon operates at 15,500 meters and there are a number of additional European and American Transmitters operating between that wavelength and 11,000 meters, while other Government and Commercial stations in France are at

present operating at wavelengths from 19,000 to 22,000 meters.

The congestion of the ether is therefore not a mere matter of looking into the future, but a real present day problem. The necessity for traffic regulation is at least enough to prevent reckless driving so to speak, is just as apparent as the undesirability of hidebound regulations until such time as the limit of possible improvements in technique have been more definitely determined.

Such is the present situation in the long distance radio ether. The congestion is due to the necessity for the use of the longer waves for long distance work and the fact that all high-power stations are broadcast

FIG. 10

stations; much improvement is possible in existing practise but radically new methods of operation must also be considered, such for example as directional radiation on shorter waves. With the realization of such possibilities the situation will take on a new aspect.

PROJECT OF NEW COMMUNICATIONS

Sufficient statistics are now available by means of which the technical and financial possibilities of new circuits of communication can be accurately predetermined.

Fig. 10 shows the daily, monthly and yearly reception curves for a typical transatlantic circuit. The ordinates of these curves show the capacity of the circuit at the different times of the day and year respectively. By the capacity of the circuit we mean the practically possible speed of reception in five-letter code words per

minute. The capacity of the circuit is a function of the strength of the signal and the intensity of the disturbance. The intensity of the signal is measured in absolute units of microvolts per meter.

Experience has shown that under any given condition of atmospheric disturbance, there is a direct proportionality between the strength of the signal measured in microvolts per meter and the traffic capacity of the circuit measured in words per minute. The proportionality defined above is almost exact between the

FIG. 11—TYPICAL DAILY VARIATION OF SIGNAL AND DISTURBANCES ON VERTICAL ANTENNA DURING SUMMER MONTHS AT BELMAR, N. J.

limits of oral reception ranging from 5 to 40 words per minute and it can be considered as substantially correct up to the highest speeds that are used. This simple relation between strength of signal and words per minute has given us a practical method of measuring the intensity of atmospheric disturbances.

As an actual standard method of measurement an artificial signal is introduced into the receiving system and regulated so that the capacity of the receiver is 20 words per minute. The number of microvolts per

meter which must be introduced to permit reception at 20 words per minute is thus a direct measure of the intensity of disturbance.

Fig. 11 shows a typical daily curve of variation of signal strength and disturbance, measured on a simple vertical antenna.

If a transmitting station is to be designed for a new geographic location, measurements of disturbances are taken in that location. The results of these measurements, which may be taken over a large part of a year, show what strength of signal will be needed during the different months of the year to carry a desired traffic. Fig. 12 shows a typical chart of this kind. Comparison between this chart and the known typical yearly chart for a transatlantic circuit gives a direct indication of the capacity of the new circuit in terms of the circuit in operation. The chart for the projected circuit shows the capacity of a 50,000-meter ampere and of a 100,000-meter ampere transmitting station.

FIG. 12

Curve A — Typical East-West circuit.
Curve B — Typical North-South circuit. Calculated for 100,000 M.A.
Curve C — Typical North-South circuit. Calculated for 50,000 M.A.

Thus it can be stated that guess work has been eliminated from the development of radio communication, and that sound foundations, both technically and financially, can be laid for all future expansions of our system.

Transatlantic Radio Telephony

and

LLOYD ESPENSCHIED

Member, A. I. E. E.
Amer. Tel. and Tel. Co.

Review of the Subject.—The first transmission of the human voice across the Atlantic was accomplished by means of radio in 1915. Since that time substantial progress has been made in the art of radio telephony and in January of this year another important step was taken in the accomplishment of transoceanic voice communication. At a prearranged time telephonic messages were received in London from New York clearly and with uniform intensity over a period of about two hours.

These recent talking tests were part of a series of experiments on transatlantic telephony which are now under way, the results of which to date are reported in the paper.

A new method of transmission radiating only a single side-band is being employed for the first time. As compared with the ordinary method of transmission, this system possesses the following important advantages:

The effectiveness of transmission is greatly increased because all of the energy radiated is effective in conveying the message; whereas in the ordinary method, most of the energy is not thus effective.

The stability of transmission is improved.

The frequency band required for transmission is reduced, thus conserving wave length space in the ether and also simplifying the transmitting antenna problem.

An important element of the high-power transmitter is the water-cooled tubes, by means of which the power of the transmitted currents is amplified to the order of 100 kilowatts or more. The

direct-current power for these tubes is supplied from a 60-cycle, a-c. source through water-cooled rectifier tubes.

A highly selective and stable type of receiving circuit is employed. Methods and apparatus have been developed for measuring the strength of the electromagnetic field which is delivered to the receiving point and for measuring the interference produced by static.

The transmission tests so far have been conducted on a wave length of 5260 meters (57,000 cycles per second). The results of the measurements during the first quarter of the year on the transmission from the United States to England show large diurnal variations in the strength of the received signal and in the radio noise strength, as is to be expected, and correspondingly large diurnal variations in the ratio of the signal to noise strength and in the resulting reception of spoken words. Also, the measurements, although as yet incomplete, show a large seasonal variation.

The character of the diurnal and seasonal variations is clearly indicated in the figures. The curves present the most accurate and complete data of this kind yet obtained.

ON January 15, of this year, a group of about 60 people gathered in London at a prearranged time and listened to messages spoken by officials of the American Telephone and Telegraph Company from their offices at 195 Broadway, New York City. The transmission was conducted through a period of about two hours, and during this time the words were received in London with as much clearness and uniformity as they would be received over an ordinary wire telephone circuit. During a part of the time a loud speaker was used in connection with the receiving set, instead of head receivers. The reporters present easily made a transcription of all the remarks, both with the head sets and with the loud speaker.

These tests were made possible by cooperation between the engineers of the American Telephone and Telegraph Company and the Western Electric Company, and the engineers of the Radio Corporation of America and its associated companies. The sending apparatus was installed in the station of the Radio Corporation of America, at Rocky Point, L. I., in order to make use of that company's very efficient multiple-tuned antenna. The receiving apparatus was installed in the buildings of the Western Electric Company, Ltd., at New Southgate, England.

Presented at the Annual Convention of the A. I. E. E., Swampscott, Mass., June 26-29, 1923.

This was not the first time speech had been transmitted from America to Europe. Transatlantic telephony was first accomplished in 1915, when the American Telephone and Telegraph Company transmitted from the Navy station at Arlington, Va. to the Eiffel Tower, Paris. In these earlier tests, however, speech was received in Paris only at occasional moments when transmission conditions were exceptionally favorable. The success of the present tests indicates the large amount of development which has been carried out since this first date.

The recent talking tests were carried out as part of an investigation of transatlantic radio telephony. This investigation is directed at determining (1) the effectiveness of new methods and apparatus which have been developed for telephonically modulating and transmitting the large amounts of power necessary for transoceanic operation, (2) the efficacy of improved methods for the reception of this transmission and for so selecting it as to give an extremely sharp differentiation between the range of frequencies transmitted and all the frequencies outside of this range; and (3) determining the transmission characteristics for transatlantic distances and the variation of the characteristics with the time of day and the season of the year, including the measurement of the amount of static interference.

The tests are being continued, particularly as regards the study of transmission efficiency.

SINGLE SIDE-BAND ELIMINATED CARRIER METHOD OF TRANSMISSION

The method of transmission used in these experiments is what we know as the single side-band eliminated carrier method¹. With this method,¹ the narrowest possible band of wave lengths in the ether is used, and all of the energy radiated has maximum effectiveness in transmitting the message.

As has been pointed out in other papers², when a carrier is modulated by telephone waves, the power given out is distributed over a frequency range, and may be conveniently considered in three parts: (1) energy at the carrier frequency itself, (2) energy distributed in a frequency band extending from the carrier upward, and having a width equal to the frequencies appearing in the telephone waves, and (3) energy in a band extending from the carrier downward, and having a similar width. The power at the carrier frequency itself makes up somewhat more than two-thirds of the total power, even when modulation is as complete as possible. Furthermore, this energy can, in itself, convey no message, as is self evident. In the present method, therefore, the carrier-frequency component is eliminated, by methods explained in detail below with the result that a large saving in power is effected. Each of the remaining frequency ranges, generally known as the upper and the lower side-band respectively, transmits power representing the complete message. It is therefore unnecessary to transmit both of these side-bands, so that in the present method one of them is eliminated. In this way the transmission of the message uses only half the frequency band required in the usual method of operation. Similarly the frequency-band accepted by the receiving set is narrowed to conform to a single side-band as compared with the usual double side-band reception, and as a result the ratio of signal to interference is improved. Certain other advantages of this method will be brought out in the further discussion.

While these advantages of the single side-band eliminated carrier method hold good for radio telephone transmission generally, they become of the utmost importance in transoceanic work, because of the necessity of conserving power in a system where the transmitting powers are large, and also because the very limited frequency range available for long distance transmission makes it imperative that each part of the range shall be utilized with the greatest of care. Before discussing the method further, the circuits and apparatus which are actually used in the tests will be described.

THE TRANSMITTING SYSTEM

The transmitting system is shown in simplified circuit form in Fig. 1. It is illustrated as grouped into three parts: The low-power modulating and amplifying stages, shown below in light lines; the high-power amplifiers, shown in heavy lines above and to the right; and the rectifier which supplies the power amplifier with high-tension direct current, shown in the upper left-hand portion of the diagram.

Referring first to the low-power portion of the system, it will be seen that the voice currents (from either a telephone line or a local microphone) are fed into a balanced type of modulator circuit and are modulated with a carrier current of a frequency of about 33,000 cycles. The operation of the balanced type of modulator in suppressing the unmodulated carrier component is explained in the Colpitts and Blackwell carrier current paper referred to above. The result of this modulating action is to produce in the output circuit of modulator No. 1, modulated current representing the two side-bands, for example, the upper one extending from 33,300 to 36,000 cycles and the lower one from 32,700 down to 30,000 cycles. These components are impressed upon a band filter circuit which selects the lower side-band to the exclusion of the upper one and of any remaining part of the carrier, with the result that only one side-band is impressed upon the input of the second modulator. This second modulator is provided with an oscillator which supplies a carrier current of 88,500 cycles. The result of modulation between the single side-band and this carrier current is to produce a pair of side-bands which are widely separated in frequency, the upper one, representing the sum of the two frequencies, extending from 118,500 to 121,200 cycles and the lower one, representing the difference between the two frequencies, extending from 58,500 down to 55,800 cycles. In this second stage of modulation there is a relatively wide separation between the two-side bands which facilitates the selection at these higher frequencies of one side-band to the exclusion of the other. Another important advantage is that it allows a range of adjustment of the transmitted frequency without changing filters. This is accomplished by varying the frequency of the oscillator in the second step. In the present case, the frequency desired for transmission is that corresponding to the lower side-band of the second modulator. The lower side-band of from 58,500 to 55,800 is therefore selected by means of the filter indicated. This filter excludes not only the other side-band but also any small residual of 90,000-cycle unmodulated carrier current which may get through the second modulator circuit if it is imperfectly balanced.

Having prepared at low power the side-band of desired frequency it is necessary to amplify the required magnitude for application to transmitting antenna. This amplification is ca-

1. For a more complete exposition of this method see U. S. patent No. 1449382 issued to John R. Carson to whom belongs the credit for having first suggested it. Also see Carson patents Nos. 1,343,306 and 1,343,307.

three stages. The first stage increases the power to about 750 watts, and is shown in Fig. 1 together with the modulating circuits. This amplifier employs in its last stage three glass vacuum tubes rated at 250 watts each and operating at 1500 volts.

The output of the 750 watt amplifier is applied to the input of the larger-power amplifying system begin-

ned by means of an inter-phase reactor which serves to smooth out the resultant current and by distributing the load between tubes of adjacent phases increases the effective load capacity of the rectifier. The ripple is further reduced by the filtering retardation coil and condensers shown.

Reproductions of the apparatus comprising the

FIG. 1—SINGLE SIDE-BAND ELIMINATED CARRIER TRANSMITTER

ning with the 15 kw-amplifier of Fig. 1. This consists of two water-cooled tubes in parallel, operating at approximately 10,000 volts. The output of this amplifier is applied by means of a transformer to the input of the 150-kw. amplifier which consists of two units of ten water-cooled tubes each, all operating in parallel at about 10,000 volts.

The high-voltage, d-c. supply is furnished by a large vacuum tube rectifier unit rated at 200 kw. It employs water-cooled tubes similar to those used in

transmitter system as described above are given in Figs. 2, 3, 4 and 5.

Fig. 2 shows the apparatus comprising the low-power stage of the transmitting system. The right-hand rack contains the two weak-power modulating units and the two single-side-band selecting filters.

FIG. 2

FIG. 3

The left hand rack is the 750-watt amplifier unit. The three radiation-cooled tubes of 250 watt capacity each will be seen near the top. Below are the smaller amplifying stages. The power supply board is shown in the center of the photograph.

Fig. 3 is a side view of the 15-kw. amplifier unit. The face of the panel from which the control handles protrude is on the left. Mounted in the cage behind the front panel are two water-jackets for accommodating the water-cooled tubes, also a coiled hose for increasing the electrical resistance of the water supply circuit (the water-cooled anodes of the tubes being operated above ground potential).

The final amplifier of 150 kw. capacity is shown in Fig. 4. It comprises two units each of 75 kw. Each unit contains 10 water-cooled tubes which can be seen

the power amplifiers except that they are of the two-electrode type. The rectifier operates from a 60-cycle, three-phase supply circuit and utilizes both halves of each wave. The two sets of rectified waves are com-

mounted in their water jackets. To the right of these units is located the 200-kw. rectifier unit shown in Fig. 5. The unit contains actually 12 tubes, there being two tubes for each of the six half waves. The

FIG. 4

pancake coils on the top of the rack are protective choke coils to guard the transformer secondary winding against steep wave fronts in case of tube failure.

From the above description it will be understood that the transmitting system is one in which the useful

FIG. 5

side-band is first developed by modulation and filtration at low powers and then its power is built up to a large value in a succession of powerful amplifiers. It will be appreciated, therefore, that the large power amplifiers and in particular the water-cooled tubes which are their essential elements represent one of the major problems of the development.

HIGH-POWER TUBES

The development of the high-power tubes is described quite fully in another paper³. The present discussion is, therefore, limited to a few of the outstanding features.

In the design of high-power tubes for use in this system the main problem is to insure the ready disposal of the large amounts of heat generated at the anodes. For the conditions of use in the present type of system where the tube is employed as an amplifier, the power which must be disposed of as heat at the anode is of the same order of magnitude as the power which the tube will deliver to the antenna. In the case of the present equipment, therefore, the tube must be so designed as to operate continuously with a heat dissipation at the anode of more than 10 kw. It is obviously difficult to secure so large a dissipation in a tube enclosed with glass walls, and a tube was therefore designed in which the anode forms a part of the wall of the containing vessel and the heat generated in it is removed by circulating water. The tube used is shown in Fig. 6. The lower cylindrical portion is the anode which is drawn from a sheet of copper. The upper

FIG. 6

portion is of glass and serves both to support and insulate the grid and filament elements.

The three principal difficulties met in the construction of these tubes are the making of a vacuum-tight seal between the copper and the glass, the provision of adequate means for conducting through the glass wall the large currents necessary to heat the filament, and the obtaining of the necessary vacuum for high-power operation.

The first of these problems was solved by the development of a new metal to glass seal. In making this seal the glass and metal parts are brought into contact while hot, the temperature being high enough for the glass to wet the metal. The part of the metal in contact with the glass is made so thin that the stresses which are set up when the seal cools are not great enough to fracture the glass or to break it away from the metal at the surface of contact. Seals made in this way are sufficiently rugged to stand repeated heating and cooling from the temperature of liquid air to that of molten glass without deterioration.

A seal employing the same principle but differing in form is also used at the point where the lead carrying the filament current passes through the glass walls of the tube. The lead is made of copper 0.064 in. in diameter and passes through the center of a copper disk, 0.010 in. thick, the joint between the lead and the

3. Bell System Technical Journal, July 1922.

disk being made vacuum-tight by the use of a high-melting-point solder. The disk is sealed to the end of a glass tube which is in turn sealed into the glass wall of the vacuum tube.

In exhausting the tubes it has been found necessary to subject all the metal parts to a preliminary heat treatment in a vacuum furnace during which the great bulk of the occluded gasses is removed. By this method the time of exhaust can be considerably reduced but the vacuum conditions to be met are so stringent that the final processes of evacuation must be carefully controlled and often occupy as much as twelve hours.

The tubes are operated at a plate voltage of 10,000 volts and are capable of delivering 10 kw. at this voltage in a suitable oscillatory circuit. For this performance an average electron current of 1.35 amperes is required. The total electron current that the filament must be capable of supplying to insure steady operation is about 6 amperes.

When the tubes are used to amplify modulated currents with large peak values such as are characteristic of telephone signals it is essential that the maximum electron current through the tube shall be several times the normal operating current and therefore to insure the necessary high quality of transmission these tubes are operated for telephone purposes with an average output of about 5 kw.

THE RECEIVING SYSTEM

In the method of transmission ordinarily employed in radio telephony by which the carrier and both sidebands are sent out from the transmitting station and

current of the carrier frequency obtained from a local source. Thus, in the present experiments, if a current of the original carrier frequency, 55,500 cycles, is supplied to the detector it will remodulate or "beat" with the received side-band of, say 55,800 to 58,500 cycles and a difference-frequency band of 300 to 3000 cycles, *i. e.*, the voice frequency band will result.

The arrangement actually used, however, is not quite so simple as this. It is shown schematically in Fig. 7. Reception is carried out in two steps, the received side-band being stepped down to a lower frequency before it is detected. The stepping down action is accomplished by combining in the first detector the incoming band of 55,800 to 58,500 cycles with a locally generated current of about 90,000 cycles. In the output circuit of the detector the difference-frequency band of 34,200 to 31,500 cycles is selected by a band filter and passed through amplifiers and thence to the second detector. This detector is supplied with a carrier of 34,500 cycles which, upon "beating" with the selected band, gives in the output of the detector the original voice-frequency band.

The object of thus stepping down the received frequency is to secure the combination of a high degree of selectivity with flexibility in tuning. The high selectivity is obtained by the use of a band filter. It is further improved by applying the filter after the frequency is stepped down rather than before. To illustrate this improvement assume that there is present an interfering signal at 60,000 cycles, 1500 cycles off from the edge of the received telephone band. This is a frequency difference of about $2\frac{1}{2}$ per cent; but after each of these frequencies is subtracted from 90,000

FIG. 7

received at the distant end, detection is readily accomplished merely by permitting all of these components to pass through the detector tube. The detecting action whereby the voice-frequency currents are derived, is accomplished by a remodulation of the carrier with each sideband.

With the present eliminated carrier method of transmission the side-band is unaccompanied by any carrier with which to remodulate in the receiving detector. It is necessary, therefore, to supply the detector with

cycles, the difference of 1500 cycles becomes almost 5 per cent. This enables the filter to effect a sharper discrimination against the interfering signal. Furthermore, the filter is not required to be of variable frequency as would be the case were it employed directly at the received frequency since by adjusting the frequency of the beating down oscillator the filter is in effect readily applied anywhere in a wide range of received frequencies. The receiving method, therefore, enables the filter circuit, and indeed also the inter-

modulated by a single frequency tone. In such a completely modulated wave, only $1/3$ of the total power contains the message, the remaining $2/3$ conveying only the carrier frequency which can as well be supplied from an oscillator of small power at the receiving station. It is obvious, therefore, that by eliminating the carrier only $1/3$ as much power need be used as would be required were all the elements of the completely modulated wave transmitted. To realize the maximum advantage of this mode of operation, the system eliminates the carrier at low power and, thereby, the high-power apparatus is devoted exclusively to the amplification of the essential part of the signal.

If, after having suppressed the carrier, both side-bands were transmitted, their reception would require perfect synchronism between the carrier resupplied at the receiving end and that eliminated at the sending end, a condition which is practically impossible to meet without transmitting some form of synchronizing channel, which is, indeed, much the same as transmitting the carrier itself. If the receiving carrier is not synchronized, the two side bands will interfere with each other upon being detected. By eliminating one side-band, this interference is prevented and reception may be carried on, using a locally supplied frequency which is only approximately equal to that of the suppressed carrier. The two may differ by as much as 50 cycles before the quality of the received speech is greatly impaired. The importance to the carrier suppression method of eliminating one side-band will, therefore, be appreciated. The present system eliminates one side-band while still in the low-power stage. While it would be possible to do this selecting after they have both been raised to the full transmitting power, this would require the use of a filter of high-power carrying capacity, which would make the filter very costly and also render the system inflexible to change of wave length. The present system overcomes both of these difficulties by filtering out one side-band at low power levels and by the use of the double modulation method.

Another very important reason for the transmission of a frequency band as narrow as is possible lies in the difficulty of constructing an antenna to transmit more or less uniformly at these long waves a band of frequencies which is an appreciable fraction of the main carrier frequencies. For example, in the ordinary method of transmission an antenna which was intended to transmit a 30,000-cycle carrier and its two speech side-bands would need to be designed to transmit all the frequencies from 27,000 cycles to 33,000 cycles, a band which is equal to 20 per cent of the carrier frequency. This band is considerably wider than that given by the resonance curve of a highly efficient long wave antenna. To accommodate both side-bands would require flattening out the resonance curve either by damping, which means sacrifice in power efficiency, or by special

design of the antenna, possibly throwing it into a series of interacting networks and causing it to become a rather elaborate wave filter. The importance, from the antenna standpoint, of narrowing the frequency band required to be transmitted is, therefore, evident.

It is extremely important that the received signal be affected as little as possible by changes in the transmission efficiency of the medium. The voice frequency currents produced at the receiving end, after detection, are proportional to the product of the carrier wave and the side-band. If the carrier as well as the side-band is transmitted through the medium, then a given variation in the transmission efficiency of the medium will affect both components and will change the received speech in proportion to the square of the variation, as compared to the first power if only the side-band is transmitted and the carrier is supplied locally. Thus it will be seen that the omission of the carrier from the sending end and the resupplying of it from the constant source at the receiving end gives greater stability of transmission.

Without discussing the system in further detail the advantages of it may be summarized as follows:

1. It conserves the frequency (wave length) band required for radio telephony, which is particularly important at long wave lengths.
2. It conserves power, in that all of the power transmitted is useful signal-producing power. This is particularly important also in long distance transmission which requires the use of large powers.
3. The fact that only a single band of frequencies is transmitted simplifies the antenna problem at long wave lengths, where the resonance band becomes too narrow to transmit both side-bands.
4. As compared with a system which eliminates the carrier but transmits both side-bands the simple side-band system has the important advantage of not requiring an extreme accuracy of frequency in the carrier which is resupplied at the receiver. Were both side-bands transmitted very perfect synchronism would be required for good quality.
5. It improves the transmission stability of the radio circuit since variations in the ether attenuation affect only one (the side-band) of the two components effective in carrying out the detecting action in the receiver.
6. The receiving part of the overall system has two advantages:
 - a. It need accept only half of the frequency band which would be required in double side band transmission, thereby accepting only half of the "static" interfering energy.
 - b. By stepping down the frequency of the received currents and filtering and amplifying at the low-frequency stage a very sharp cutoff is obtained for frequencies outside of the desired band and a very stable and easily maintained amplifying system is obtained.

STUDY OF TRANSATLANTIC TRANSMISSION

We come now to a consideration of the second major part of the investigation, namely, that having to do with the transmission of the waves across the Atlantic. It will be evident, from what has been said earlier, that the transmission question is essentially one of how best to deliver, through the variable conditions of the ether to the receiving station, speech-carrying waves sufficiently free from interference to be readily interpretable in the receiving telephone. The transmission efficiency of the medium varies with time of day and year, and is different for different wave lengths. The interference conditions are also influenced by these same factors.

Now we can study this transmission medium in much the same way we would a physical telephone circuit, by putting into it, at the sending end, electromagnetic waves of a known amount of power and measuring the power delivered at the receiving end. The interference at the receiving station likewise may be measured and the ratio of the strength of the signal waves to the interfering waves may be taken as a measure of freedom from interference; this in turn being directly related to the readiness with which the messages are understood. Accordingly, there has been included as an integral part of the investigation of transatlantic radio telephony, the development of suitable methods and apparatus for measuring the strength of the signal waves and of the interfering waves, as they arrive at the receiving station. The apparatus⁴ employed in measuring the field strength of the received signals has been outlined above under Receiving System and need not be gone into further. However, a word of explanation about the method which is employed in making the measurement may be helpful. It will be recalled that the specially designed receiving set is provided with a local source of high frequency from which can be originated signals of predetermined strength. A measurement of the field strength of a signal received from the distant transmitter is made by listening first to the distant signal and then to the locally produced signal, shifting back and forth between these signals and adjusting the strength of the local signal until the two are substantially of the same strength. Then, knowing the power delivered by the local source, the power received from the distant station is likewise known. The relation between the power in the input of the radio receiving circuit to the field strength required to deliver that power is known through the geometry of the receiving antenna (in this case a loop) and, therefore, the measured power of the signal can be translated directly into the field strength of the received waves.

The measurement tone signal is transmitted from the Rocky Point sending station by substituting for the microphone telephone transmitter a source of weak alternating current of about 1/100 watt at a frequency

of approximately 1500 cycles. This tone modulates the radio telephone transmitter in the same way that voice currents would and is radiated from the antenna as a single-frequency wave of 5260 meters (57,000 cycles per second). It, therefore, constitutes a means of sending out a single-frequency continuous wave for measurement purposes. At the receiving end this continuous wave is demodulated to the same tone frequency which it originally had.

For measuring the strength of the received noise, *i. e.*, the radio frequency currents arising from static or other station interference, the method is quite similar. In this case, however, the noise received is so different from that which can be set up artificially in any simple manner that no attempt is made to compare it directly with a local noise standard. Instead the volume of the interfering noise is expressed in terms of its effect in interfering with the audibility of a local tone signal by measuring the local signal which can just be definitely discerned through it. This is a threshold type of measurement which is necessarily difficult to carry out with accuracy. In order to increase the sharpness of definition of the local signal and to make it correspond more closely to speech reception the signal tone is subjected to a continuous frequency fluctuation. The comparison signal has therefore a warbling tone which occupies a frequency band not unlike that of the voice. This method of measuring the interference is discussed in more detail also in the measurement paper referred to above.

Procedure in Making Transmission Measurements. The three quantities which are included in the transmission measurements, namely, the signal strength, the noise strength, and the percentage of words received correctly, are observed one after another in what might be termed a unit test period. Although the duration of this test period and the order of making the measurements has been changed somewhat during the course of the experiments, the following program is representative of the conditions under which the data presented below were taken.

A 25-minute test period divided as follows:

5 minutes of tone telegraph identification signals (for receiving adjustment purposes).

10 minutes of disconnected spoken words.

10 minutes of a succession of five-second tone dashes separated by five-second intervals, (for measurement of the received field strength, the intervals between the dashes being used for throwing on the local receiving source and adjusting its strength to equal that of the received signals by alternately listening to one and then the other).

Immediately following this test period the London observers measured the noise level.

This unit test period was repeated every hour over a period which varied from several hours to as long as two days' duration. Most of the test periods ran for about 28 hours, starting about eleven o'clock Sunday morning

4. It is described in detail in the paper entitled, "Radio Transmission Measurements" by Bown, Englund, and Friis, *Proc. Institute of Radio Engrs.*, April 1923.

and continuing until about three o'clock Monday morning, London time. During this time the telegraph load through the Rocky Point station of the Radio Corporation was sufficiently light to enable one of the two antennas to be devoted to these experiments. The

FIG. 9—TRANSATLANTIC RADIO TRANSMISSION MEASUREMENTS. DIURNAL SIGNAL AND NOISE VARIATION, JANUARY 1,—FEBRUARY 23, 1923.

measurements were started January 1, 1923 and are still in progress.

At the present time (April) the results for the first three months of the tests are available. These results are not yet sufficiently complete nor do they cover a

TRANSATLANTIC RADIO TRANSMISSION MEASUREMENTS
DIURNAL SIGNAL & NOISE VARIATION
Feb 25—Apr 9, 1923.

FIG. 10

sufficient number of variables in terms of time, wave length, etc., to enable any very definite conclusions to be drawn from them. They do illustrate, however, the usefulness of the methods employed, and even in their incomplete state show some factors of considerable interest.

The results of the measurements of received signal strength and received noise are given in Figs. 9 and 10. The data have been divided and plotted in these two sets of curves because the transmission conditions across the North Atlantic appeared to suffer a rather rapid change about February 23rd. Fig. 9 therefore covers the winter period from January 1 (when the test started) to February 23; and Fig. 10 covers the next period from February 25 to April 9.

The curves are plotted between time of day as abscissas and field strength in microvolts per meter as ordinates. The time during which darkness prevailed at Rocky Point and at London is indicated by the block-fills on the time scales. The overlap of these block-fills indicates the time during which darkness extended over the entire transatlantic path. For Fig. 9 the darkness-belt is as of February 1 and for Fig. 10 as of March 21. The curves show the mean of the results and also the boundaries of the maximum and minimum values observed.

Received Signal Strength. The outstanding factors to be noted concerning the signal strength curves are:

1. The diurnal variations are plainly in evidence. During the first test period covered by Fig. 9, for example, the field strength varied in the ratio of the order of 15 to 1 between day and night conditions, running about 100 microvolts per meter during the night and averaging about 6 microvolts per meter during the day. The diurnal variation is also to be seen in Fig. 10 although the variations between night and day transmission are less marked.

The measured daylight values lend support to the Austin-Cohen absorption coefficient. The average of the observed daylight values for the period of these tests is between 7 and 8 microvolts per meter, while the calculated value is 9.5. Concerning the high field strengths obtaining at night, it should be noted that the maximum observed value of 237 microvolts per meter does not exceed the value of some 340 microvolts which it is estimated should obtain at London were no absorption present in the intervening medium, *i. e.*, were the waves attenuated in accordance with the simple inverse-with-distance law. While no definite conclusions can yet be drawn from these results as to the cause of the diurnal variations, this indication that the upper limit of the variation is the no-absorption condition suggests that the diurnal fluctuations are controlled by the absorption conditions of the medium rather than by reflection or refraction effects.

2. An indication of the seasonal variation which apparently occurs in developing from winter to early spring is found in a comparison of the signal strength curves of Fig. 9 and 10. On the whole the signal strength received in the second test period is considerably less than that received for the first period. This drop in the average of the 24 hours is caused by a large decrease in the night-time transmission efficiency. The daylight transmission does not change much, but

what little change there is lies in the direction of an increase as the season advances.

3. A decrease in the transmission efficiency is observed between the time of sundown in London and sundown in New York, that is, during the period when the sunset condition intervenes in the transmission path. This dip is particularly noticeable in the signal strength curve of Fig. 10. It is not noticeable in Fig. 9, except for the fact that the rise in signal strength corresponding to night conditions in London is delayed until the major part of the transmission path is in darkness.

Strength of Received Noise. The variation in the strength of received noise is shown by the noise curves of Figs. 9 and 10.

1. The diurnal variation of that portion of the noise which is due to atmospheric or "static" disturbances is somewhat obscured by the presence of artificial noise, *i. e.*, noise caused by interference from other stations. The rise in the noise curve at 12 noon is known to be due to artificial interference. In general, however, the large noise values shown to prevail throughout the night in London between about 6 p. m. and 4 a. m. are known to be due to atmospherics. This diurnal variation shows up quite prominently in both figures.

The maximum noise is reached at 2 a. m. London time. Up to this time the night belt extends over London and a sector of the earth considerably to the east and including Europe, Africa and Asia. The noise begins to drop off shortly thereafter and reaches its minimum at sunrise in London. This could be accounted for on the assumption that the major source of the noise lies considerably to the east of London and that transmission of the stray electric waves to London is gradually diminished in efficiency as daylight overtakes the path of transmission.

2. The seasonal variation, as shown by a comparison of the noise curve of Fig. 9 with that of Fig. 10, is not so great as is the case with the transmission efficiency of the signal. However, the noise level is noticeably higher during the second period of the tests,^b as shown by the average curve of Fig. 10, particularly during the night when the maximum noise obtains.

This indicates that the noise is largely of continental origin lying to the east or south east of London which is in agreement with rough observations made by means of a loop and suggests that the employment of directional antennas would be of considerable advantage. It is expected to include such antennas in the further measurement work.

In connection with these noise curves it should be noted that what they represent is in reality the strength of a local warbling tone-signal, expressed in terms of equivalent field strength in microvolts, which is just definitely audible through the noise. The actual value of the noise currents, were they measured by an inte-

grating device such as a thermocouple, for example, would be a number of times larger than indicated.

Ratio of Signal to Noise Strength; Words Received. The noise curve of Fig. 9 and that of Fig. 10 can, therefore, be read as "The strength of the signal tone which can just be heard through the noise." It can, therefore, be directly compared with the signal curve itself and the difference between the two curves is a measure of the level of the actual signal strength above that which would just permit of the signals being heard. Actually, the difference between the two curves, as shown in the figures, is proportional to the *ratio* of the signal to the noise strength, because the curves are plotted to a logarithmic scale.

This signal to noise ratio is plotted in Fig. 11 for the test period which corresponds to Fig. 9, and Fig. 12 for the test period which corresponds to Fig. 10. These ratio curves are derived by going back to the original data and taking the ratio for each unit measurement period and spotting it upon the chart as shown by the black points. An average is taken of the points for each hour of the 24-hour period as shown by the circle points. The dash line curves of Figs. 11 and 12, therefore, trace the average diurnal variation of signal to noise ratio.

These curves show:

1. That the signal-to-noise ratio reaches its minimum during the time when the sunset period intervenes between London and New York.

2. During the night in London the ratio increases more or less continuously and reaches a maximum around the time of sunrise in London.

3. During the course of the daylight period in London the ratio starts out high and drops rather rapidly during the forenoon and assumes a more or less constant intermediate value during the afternoon until sundown. It is during this afternoon period in London that the business hours of the day in London and New York coincide, so that this is the most important period from a telephone communication standpoint.

The drop in the very low ratios obtaining in London in the early evening is due to the fact that an increase in noise occurring at this time is accompanied by a decrease in transmission efficiency from America. This may readily be seen by referring to Fig. 10. The noise increases as the night belt, proceeding westward, envelopes England and improves the transmission of atmospherics, which arise possibly in continental Europe, Asia and Africa. As the shadow wall, proceeding westward, intervenes between England and America, the transmission efficiency of the desired signals from America drops and it is not until the night belt extends as far west as America that the transmission efficiency improves sufficiently to overcome the disadvantage in London of the large noise values which night there had brought on. Conversely, the high signal to noise ratio, obtaining at about sunrise in London, appears to be due to the fact that as the termi-

5. The results obtained more recently than time has permitted to include in the curves show a continual rise in the level of the noise during April.

nation of the night belt, moving westward, intervenes between England and the source of atmospherics to the east, the noise level drops rapidly and has reached low values by the time sunrise arrives in London. At this

FIG. 11—TRANSATLANTIC RADIO TRANSMISSION MEASUREMENTS. DIURNAL VARIATIONS OF SIGNAL TO NOISE RATIO, JANUARY 1—FEBRUARY 23, 1923.

time, however, darkness still extends to the west and the transmission efficiency from America is at its maximum. It is, therefore, due to this interplay between these two factors, signal strength and noise strength,

FIG. 12—TRANSATLANTIC RADIO TRANSMISSION MEASUREMENTS. DIURNAL VARIATIONS OF SIGNAL TO NOISE RATIO, FEBRUARY 23—APRIL 9, 1923.

controlled very largely by the transition periods between day and night, that the signal to static ratio varies diurnally in the manner pictured in Figs. 11 and 12.

Concerning seasonal variation, shown by a comparison of Figs. 11 and 12, the following can be said: The diminution in signal-to-noise ratio in the second test period as compared with the first is caused by the fact that the signal strength has decreased and at the same time the noise has somewhat increased. There is just

one other point and that concerns the dip in the ratio occurring at night in London between 12 midnight and 3 a. m. This dip is due to an increase in the noise which occurs around 2 a. m. (A further reduction during this time, and one which extends the time of minimum ratio from sundown on through the night until 2 a. m. is shown by the April measurements which time has not permitted including in the curves).

During each test period lists of disconnected words were spoken over the systems. As an approximate and easily applied method of indicating the talking effi-

ciency of the circuit, note was made of the percentage of the words which were correctly received.

The curves of Figs. 13 and 14 show the manner in which the percentage of the words which were correctly received varies through the 24 hours. Each point corresponds to the percentage of words correctly received during one unit test period. In many of these tests the interference was noted to be caused by radio telegraph stations, and the data in which the inter-

ference is of this character, in so far as identified, are indicated by the triangular dots. It will be seen that most of the poor receptions were due to this cause. Especially is this true of tests at 12 noon at which

Frequency Measurement in Electrical Communication

BY J. W. HORTON, N. H. RICKER and W. A. MARRISON

Research Laboratories of the
American Telephone and Telegraph Company and the
Western Electric Company, Incorporated.

Review of the Subject.—The need for increased accuracy in the measurement of any frequency between one and several million cycles per second is first considered.

A brief discussion of general types of frequency standards leads to the reasons for choosing a continuously operating generator of alternating current. The generator developed is, in effect, a regenerative system comprising a 100-cycle tuning fork, of low decrement, maintained in vibration by a vacuum tube amplifier.

The absolute value of the frequency of the alternating current delivered by this generator is determined by counting the number of cycles executed in an accurately known time. A small synchronous motor is used for making this count. Recording apparatus for comparing the rate of the fork with various time indicators is described.

Data are given showing the effect upon the frequency of such external conditions as temperature, potential of power supply, circuit constants of the amplifier and vacuum tubes. This information is obtained either by comparisons with a constant frequency or by determinations of the absolute value of the frequency. The ratio of the rate of the fork to the rate of a carefully maintained clock has been found to be constant to within six parts in 1,000,000 over considerable periods of time.

For measuring the frequency of any alternating current used in electrical communication in terms of the known frequency there has been developed a decade arrangement of harmonic producers and a special modulator-rectifier circuit for combining known harmonics of the base and comparing other frequencies with them. These circuits are described in detail.

THE art of electrical communication has at its disposal such a wide variety of methods for the transmission of intelligence that it now employs alternating currents having frequencies which cover the entire range between a few cycles per second and several million. Refinements in these methods have reached a point where it is imperative that determinations of the frequency of any of these alternating currents may be made with an accuracy considerably higher than has been possible hitherto.

For example, in the field of radio broadcasting, it has already become necessary to establish a carefully planned assignment of wave-lengths for the many stations now operating throughout the country. Great care must be exercised in maintaining these stations at their allotted frequency in order that the general scheme may be effective in preventing undue interference.

Accuracy with respect to frequency is also of much interest to the electro-physicist. In certain of his indirect measurements it is considered one of the known variables and many determinations, such as those of the absolute value of inductance or of capacity, would be greatly facilitated if more significant figures could be written into the frequency term on the right-hand side of the equation.

A survey of existing practise discloses much that is worthy of consideration. The work of Prof. D. C. Miller is, of course, known throughout the country. For many years he has been recognized as one of the leading authorities on the standardization of tuning forks. Much has also been accomplished by the Bureau of Standards, both in the calibration of tuning forks and in the construction of electrically resonant circuits from inductances and capacities of known value. A discussion of these or of other noteworthy efforts to obtain increased accuracy in the measurement of

frequency cannot, however, be entered upon here. It is sufficient to say that, with the particular requirements of electrical communication in mind, it was felt desirable to undertake the development of a suitable standard of frequency and of means for measuring a wide range of frequencies in terms of this standard.

Recently introduced methods for multiplex telephony and telegraphy by means of carrier currents over wires have placed exceedingly rigorous limits on the frequency adjustment of certain types of apparatus. It is sometimes necessary to hold such circuits as oscillators or filters to within 0.1 per cent of a given value under commercial operating conditions. It is, therefore, apparent that the calibrating devices used in the manufacture and maintenance of such circuits must be reliable to 0.01 per cent and that the primary standard should be good to 0.001 per cent. The goal which we have set for ourselves, then, is the development of a primary standard of frequency, the absolute value of which is known to one part in 100,000, and of means for comparing the frequency of any alternating current having a frequency between one and several million cycles per second with this standard.

SOURCE OF CURRENT OF CONSTANT FREQUENCY

In selecting the form of the primary standard, a number of general types were considered. After examining methods for determining the absolute value of the standard and for comparing it with other frequencies it was thought that a continuously operating generator of alternating current would be preferable to any indicator having a known relation between response and frequency. It was further felt that the frequency of the alternating current should be fixed by some inherent property of the generator rather than that it should be controlled or regulated by any reaction consequent upon a departure from a given value. Inasmuch as the determination of the absolute value of the frequency of the alternating current involves counting the number of cycles which it executes in some

finite time it is necessary that the rate of the generator be sufficiently constant to permit us to use the average value over this interval as the instantaneous value at any time.

The most promising method of meeting the above conditions appears to be one in which some highly resonant system is maintained in continuous vibration by the application of energy from an external source. In general such arrangements operate through some form of trigger action, controlled by the vibration of the resonant system, which periodically releases energy from the driving source. This will be found to be equally true for a clock, for an organ pipe or for any other continuously maintained vibrating system. Any such device constitutes a regenerative system.

The period of vibration of the resonant element, to be acceptable in our standard, must be little affected by changes in external conditions, including those associated with the source of energy maintaining the vibration. This in turn requires that the trigger action be extremely sensitive and at the same time capable of accurately controlling the driving energy.

Since resonant elements of small decrement are more effective than those of higher decrement in controlling the frequency of such regenerative systems, it is generally true that mechanically vibrating bodies are superior to electrically resonant circuits.

The reasoning so far has led us to a device having the general characteristics of a good clock. In fact, if we think of a clock as a standard of frequency it will be found that we have little more to ask in the matter of accuracy. There remains, however, the problem of comparing the frequency of the mechanically vibrating element—the pendulum—with the frequency of any alternating current. It is a simple matter to obtain from a clock, by means of some form of contact, an alternating current having a frequency in the neighborhood of one cycle per second. Such an alternating current is not entirely satisfactory for our purpose because of the high frequencies to which our comparisons must be carried. Any departures from a fixed frequency on the part of the fundamental are multiplied in absolute value as the frequency is stepped up to its higher harmonics. Because of this effect we should be seriously troubled by any minute variation in period of successive cycles, due to irregularities in the contact or in the mechanism, as we multiply such a fundamental frequency sufficiently to use it in the calibration of radio apparatus.

Difficulties of this nature may be reduced in two ways: First by applying the driving force as uniformly as possible and second by making the frequency as high as the demands of the work will permit, thus reducing the multiplication necessary to reach the higher frequencies.

The requirements thus far laid down for the energy supply portion of our regenerative system are admirably met by thermionic amplifiers. By using high

amplification the controlling elements may be made extremely sensitive and consequently may be coupled so loosely to the vibrating element as to be practically without effect upon it. Further, the driving force is not disturbed by any irregularities such as are present in the usual clock mechanisms. This removes one of the major causes of variation in the length of successive periods.

For the particular problem in mind it is not essential to measure accurately frequencies differing by less than 100 cycles per second. This led to the choice of a 100-cycle tuning fork as the resonant member of our system. The decrement of such a device is, perhaps, not as small as that of a good pendulum but its frequency is more suitable for our present needs. In a more complete solution of the general problem it would be desirable to investigate the possibilities of a pendu-

FIG. 1

lum maintained in vibration by a thermionic amplifier. Such an arrangement could be adjusted to generate a frequency of one cycle per second which is, in some respects, the logical frequency for a master standard.

With this brief general discussion of the factors involved in the development of a frequency standard for alternating-current measurements, we may proceed to a detailed description of the apparatus which has been set up.

The fork used in the major portion of this work was made by the Standard Scientific Company. It was especially designed to have a low decrement. In order that there should be small energy loss in the mounting and no variation in energy absorption due to change in location, the fork is mounted on a heavy cast iron base, as shown in Fig. 1. It is keyed into its socket and is clamped firmly by a nut on the underside of the base. The photograph also shows the electromagnets used for coupling the fork to the vacuum tube amplifier. Energy picked up by one electro-

A schematic of the amplifier circuit is shown in Fig. 4. *A* and *B* are respectively the control and driving magnets of the fork. The retard coil, L_1 , the condenser, C_2 , and the resistance, R_1 , constitute the usual direct coupling between the two tubes. C_1 is a small fixed condenser which is found to be necessary for most efficient operation. This condenser has about one tenth the capacity which would resonate the control coil at 100 cycles per second. Its effect upon the frequency of the system will be considered later. In this circuit the use of transformers was avoided because of the possibility of introducing a phase change in the amplifier. The amplifier delivers sufficient energy to drive the fork at any desirable amplitude. In the system actually set up, only part of the total output energy is used. This is accomplished by putting a high series resistance, R , in the circuit between the second stage of the amplifier and the driving magnet. This has a stabilizing effect on the regenerative system by making the load impedance of the amplifier more nearly constant.

The system thus far described provides solely for maintaining the fork in vibration. Since we are interested in obtaining an alternating current for use in various measurements, provision must be made for

is shown on a panel together with associated apparatus. This panel is the one containing five tubes. Although the schematic shows but two tubes in the regenerative amplifier, there are actually provided two pairs of tubes, the grids and plates of one pair being in parallel with the corresponding grids and plates of the other. The filaments of the two pairs of tubes may be lighted independently. The fork may, therefore, be driven by either pair of tubes, one pair being placed in operation before the other is turned off, thus maintaining the

FIG. 5

supplying energy to external circuits in such a manner that there can be no reaction upon the regenerative system which might cause a variation in its frequency. This is accomplished by means of the third tube shown in the figure. Any change in the load impedance of this tube produces an entirely negligible change in its shunting effect on the regenerative system. The transformer, T_1 , supplies a second load circuit, the purposes of which will be discussed later.

In the photograph of Fig. 5 the fork drive amplifier

FIG. 6—PATH OF RAYS THROUGH OPTICAL SYSTEM

fork with no discontinuity in the output of the 100-cycle current from the transformer, T_1 . This is done so that tubes or batteries may be replaced at any time without interrupting the operation of the system.

In order to study such external conditions as may affect the rate of the form certain additional apparatus has been provided. The fork and driving magnets are placed in a cast iron tank provided with a glass cover, ground to fit. This tank is immersed in a temperature controlled bath. Means are also provided for exhausting the tank so that the effect of pressure variations may be studied.

In order that observations of the amplitude of the fork may be easily and quickly made, an optical system has been set up by means of which a band of light, the width of which varies linearly with the amplitude of the fork, is projected on a scale. This scheme is based on the fact that the corner of a fork prong is not a sharp angle but is a quadrant of a cylinder of very small radius. If this cylinder is illuminated by a bright source of light one element will appear to an observer as a very bright narrow line parallel with the prong of the fork. As the fork vibrates this illuminated element will apparently broaden into a band the breadth of which indicates the amplitude of vibration. An enlarged image of this band may be projected upon a scale by a suitable objective. The lens used is a Bausch and Lomb triple aplanat which has a large aperture

recorder was arranged so as to mark simultaneously, on a single tape, second impulses, from the laboratory standard clock, and commutator impulses as controlled by the fork. Care was taken to have the tape moving at a sufficiently uniform speed to permit measurements to be made with an accuracy better than 0.01 of a second. In this connection it is interesting to examine the accuracy with which the commutator, driven by the synchronous motor, indicates 100-cycle intervals. This was tested as follows:

A small amount of the 100-cycle current from the output of the regenerative circuit was passed through a distortion-producing amplifier giving a sharply peaked wave. The current from this amplifier was interrupted by the commutator and recorded by a Dudell oscillograph. The peak of the wave is used to indicate a definite portion of the cycle. The instant at which the commutator closes the circuit is indicated by a shift of the zero axis on the record, due to the introduc-

ning and at the end of any suitable period of time we may find the number of fork intervals in any given whole number of clock intervals. Since our fork intervals correspond to 100 cycles, the total number of cycles executed in any known time may be easily computed and the rate of the fork thus determined. The accuracy of the method is fixed partly by the precision with which measurements of length can be made on the tape and partly by the regularity in operation of intermediate relays and of the recorder. It has been found that measurements may be depended upon to within 0.01 second, which gives an accuracy better than one part in 6000 over a period of one minute or than one part in 360,000 over a period of one hour. Many sets of tape records have been made to check the rate of the fork and the stability of the recording apparatus. In Table I are given the results of observations made on the number of cycles occurring in successive five minute intervals, as indicated by the

FIG. 11

tion of a small battery into the circuit. A series of records show that the commutator makes successive contacts at the same part of the cycle to well within one-tenth of a cycle. These tests were made without the mercury-filled fly-wheel and, therefore, include errors due to the hunting of the motor. A number of these oscillograms is shown in Fig. 10.

In Fig. 11 a series of tape records taken at one minute intervals is shown. The upper dashes represent second intervals as marked by the clock; the lower dashes indicate 100-cycle intervals as marked by the commutator. It will be noticed that a dash marked by the fork lags behind the corresponding dash from the clock about 0.2 of a fork interval more than did the fork dash taken a minute previous. This means that while the clock records sixty complete clock intervals, the fork records about 59.8 fork intervals. In this manner, by making a measurement at the begin-

laboratory standard clock, for a period of two hours. It will be observed that the average difference between any single observation and the average rate for the entire time is about 6 parts in 1,000,000. This indicates either that the fork and the laboratory clock are both constant, or that they both vary together, within this limit. This last supposition is hardly conceivable.

In order to observe sudden changes in the frequency of the fork, such as might be occasioned by mechanical jarring or by some slight change in external conditions, it has been found advantageous to employ the well known method of beats. By comparing a high harmonic of the fork frequency with the frequency of the current from a suitable vacuum tube oscillator a very small change in the frequency of the fork becomes readily detectable. It has been found possible by passing current from the fork system through a special harmonic producer, (to be described later) to obtain

TABLE 1

Time: As indicated by the Laboratory Clock. Observations made every 300 seconds.

Lag: The fraction of a fork interval by which a fork dash lags behind the corresponding clock dash.

Difference: The amount by which the lag decreases during 300 seconds. This is measured on every 299th fork impulse. Indicating this decrease by *D* the number of cycles made in 300 seconds is then 100 (299 + *D*).

Frequency: $\frac{100 (299 + D)}{300} = 99.6667 + 1/3 D$.

Deviation: The difference between the frequency observed for a given interval and the mean frequency throughout the run.

a sufficient amount of the 500th harmonic to give an easily perceptible beat with a current of 50,000 cycles supplied by a vacuum tube oscillator. Over small intervals of time the frequency of the oscillator will remain fixed, therefore any slight changes in the frequency of the fork, magnified 500-fold in absolute value by the harmonic producer, will result in a considerable change in the rate of these beats. In this way it is possible to determine quickly and accurately the effect of certain variables on the frequency of the fork. It is possible, for example, to observe the result of such transients as occur when the amplitude of the fork is suddenly increased or decreased. The precision of this method is evidently high. In fact, since the frequencies between which beats are observed are of the order of 50,000 cycles, and since it is easy to detect differences in beat frequency of one cycle in 10 seconds, a change in frequency of one part in 500,000 is readily observed. It should be understood, of course, that although this method is very useful for determining the order of magnitude of various effects it should not be relied upon for absolute quantitative data.

In order that an accurate check might be kept on the rate of the laboratory standard clock, provision has been made for recording United States Naval Observatory time signals, as sent out by Arlington, on the tape of the Wheatstone recorder simultaneously

with second impulses from the clock. It is thus possible to check the average rate of the laboratory clock to approximately 0.01 second per day. The electrical equipment for recording the Arlington signals consists of a radio receiver and of a vacuum tube amplifier containing a resonant circuit tuned to the audio frequency. This audio signal is rectified and the resulting direct current used for operating one pen of the recorder. The jack panel shown at the bottom of the rack in the photograph of Fig. 5 furnishes means for connecting any source of electrical impulses to the recorder so that comparisons may be made between the rates of any two such sources.

CHARACTERISTICS OF STANDARD SOURCE

Observations of the rate of the fork have been made over a considerable period of time to determine its frequency and the extent to which it is affected by variations in external conditions. The data of Table I is an example of the constancy of the ratio of the rates of the fork and of the laboratory clock. At present we are unable to say which has the greater absolute constancy.

It is probable that the temperature of the fork is one of the most important of the factors affecting its frequency. A large amount of data has been taken showing the rate of the fork at various room temperatures and also at the temperature of melting ice. The average change in frequency between 0 deg. and 22 deg. cent. is 0.0109 per cent per 1 deg. cent.

In order that the frequency of the fork may be relied upon to one part in 100,000 it is apparent that its temperature must be known to be better than 0.1 deg. cent. While this is not particularly difficult, under average laboratory conditions, it is highly desirable that some other material be found from which to build the fork. A steel having such coefficients of expansion and of elasticity that the resultant coefficient of frequency is small would be desirable. It is, of course, necessary that the properties of the material be such that the fork has as low a decrement as possible. The use of steel has advantages since it lends itself so readily to electromagnetic driving. Other materials, notably fused quartz, have such commendable properties that it would undoubtedly be profitable to consider means for coupling the vacuum tube amplifier to a fork built of such material.

The relation between the amplitude at which the fork is driven and its frequency is also of much interest. The problem, however, concerns the properties of the amplifier more than it does those of the fork. It is very difficult to readjust the system so that the fork may be maintained at various amplitudes without at the same time introducing changes which have a far greater influence upon the frequency than does the change in amplitude, *per se*. It is certain that anything which alters the phase relation between the currents in the windings of the control and driving

magnets is of vital importance in regard to both the frequency and the amplitude. The present regenerative system has been so designed that it is in a stable oscillating condition with the fork vibrating at a double amplitude of approximately 0.25 mm. In general a small amplitude is to be desired because it is accompanied with small frictional and hysteresis losses. With large amplitudes these losses would introduce appreciable damping into the resonant system.

In studying the influence of the amplifier circuit upon the frequency of the fork tests have been made in which the tubes, the plate and filament batteries and the condenser across the control magnet were varied.

As has been previously mentioned, the amplifier contains two pairs of tubes, either of which may be used to drive the fork. Due to slight differences in the connections to these tubes the frequency of the fork when driven by one pair differs by one part in 200,000 from its frequency when driven by the other. When both pairs are operating simultaneously the frequency differs by about one part in 100,000 from the frequency obtained with the amplifier normally used.

In order to show what happens when changes, such as aging, occur in the tubes themselves a series of tests was made in which five pairs of tubes were used, successively, in one pair of sockets. During these tests there was no observable variation in the frequency. This means that any change must have been less than one part in 500,000.

The batteries supplying the plate potential and the filament current are, as many of us have observed, the least constant of the elements of any vacuum tube circuit. Tests have been made, therefore, to determine what change in frequency may be expected as a result

FIG. 12

of moderate variations in these batteries. On the curve of Fig. 12 the departure of the frequency of the standard sources from the value which it has at normal plate potential is plotted against the plate potential. From this curve it is seen that the battery may drop nearly 5 volts from its usual operating potential without introducing a change of more than one part in 100,000. Since this battery can be maintained to much better than 5 volts over long periods of time errors due to the plate battery will not be large enough to give trouble.

In fact, in bringing the frequency of the fork to exactly 100 cycles per second, it is planned to make the final adjustment by means of the plate potential.

Observations made on the frequency of the fork as a function of the filament current showed no detectable change until the current was reduced to 80 per cent of its normal value. With storage batteries of adequate capacity, therefore, the variation of potential during discharge will be quite without disturbing effect upon the operation of the standard.

Reference has already been made to the condenser

FIG. 13

which is placed across the coils of the control magnets. The effect upon the frequency of such changes as might occur in this condenser was investigated by varying its capacity over the range between 0.01 μ f. and 0.1 μ f. The decrease in frequency with increase in capacity is plotted on the curve of Fig. 13. It has been found that a capacity of 0.05 μ f. gives satisfactory results with respect to both efficiency and stability. The slope of the curve at this point is such as to indicate a change of frequency of three parts in 1,000,000 for each 1 per cent change in capacity. The temperature coefficient of this condenser is known to be about 0.003 per cent per 1 deg. cent. It is thus evident that the resultant effect upon the frequency is in the neighborhood of one part in 100,000,000 for each 1 deg. cent. change in the temperature of the condenser.

As a result of the tests described above it appears that, by suitably maintaining the fork and its associated equipment, the frequency of the alternating current produced may be relied upon, both as to constancy and as to absolute value, to one part in 100,000.

MEASUREMENT OF FREQUENCY IN TERMS OF THE STANDARD

The third major portion of our problem concerns means for comparing the frequency of any alternating current which may be used in electrical communication with the frequency of the alternating current delivered by our standard. This is accomplished by a system of harmonic generation. In order to compare the higher

ditions there appear in the output circuit alternating currents having frequencies corresponding to the sum and to the difference of the input frequencies. Thus, if we impress a voltage having a frequency of 1000 cycles upon the transformer T_1 and a voltage having a frequency of 10,000 cycles upon the transformer T_2 , there will appear in the output of the transformer T_3 , in addition to the amplified 1000-cycle current, alternating currents having frequencies of 9000 and 11,000 cycles. Any component of the output current may be selected by means of the tuned circuit and amplified in the single vacuum tube shown. The two tubes at the right of the schematic constitute a balanced rectifier. These tubes have on the grid a constant potential of such value that when there is no voltage across the

cal and the meter will stand at its zero position. As the phase continues to change, the resultant voltages will unbalance the bridge in the opposite direction and the deflection of the meter will be reversed. It is thus seen that the deflection of the meter indicates the phase difference between the two voltages and may be used in determining the frequency difference between them, so long as this difference is not too great to be followed by the needle.

Because of the balanced arrangement of the input circuit of this rectifier the frequencies of currents from two vacuum tube oscillators or similar devices may be compared without any tendency on the part of one to influence the operation of the other. In fact it has been found possible to adjust two oscillators, operating at

FIG. 15

input transformer there will be no plate current in either tube. Should voltage be impressed upon the transformer T_4 the potentials impressed upon the grids of the two tubes will be such that they will alternately draw current from the plate battery. This will set up across the outer ends of resistances R_1 and R_2 an alternating potential having a frequency equal to that impressed upon the transformer. Since this voltage is symmetrical with respect to the meter there will be no motion of the needle, unless the frequency is extremely low. Voltages impressed upon the transformer T_4 cause both tubes to draw current from the plate battery during that portion of the wave which makes the total grid potential less negative than that of the grid battery. Under these conditions there will be no difference of potential across the outer ends of the resistances R_1 and R_2 . If, however, two voltages of nearly the same frequency are impressed upon the two input transformers, they will not effect the two tubes equally. At the instant when they are in such phase relation that their sum will be effective on one tube their difference will be effective on the other. Under this condition the bridge circuit, composed of the two resistances and the two tubes, will be unbalanced and the needle of the meter will be deflected. As the phase relation changes so that the two voltages are 90 deg. apart, the effects upon the two tubes become symmetri-

cal and the meter will stand at its zero position. As the phase continues to change, the resultant voltages will unbalance the bridge in the opposite direction and the deflection of the meter will be reversed.

The layout of the complete calibrating system is given in Fig. 16. A switching arrangement is provided

FIG. 16

so that any of the inputs to the modulator-rectifier circuit may be connected to the output of any of the amplifiers associated with the several harmonic producers, or to any of a number of vacuum tube oscillators.

Telephone Equipment for Long Cable Circuits

BY CHARLES S. DEMAREST

Member, A. I. E. E.
American Telephone and Telegraph Co.

Review of the Subject.—Some of the important developments contemplated in the apparatus and equipment for long toll cable circuits are described. The large number of equipment units per station in the cable plant and the greater number of stations in a given length of cable than in an open-wire system, have made the economic importance of the equipment design such that a comprehensive program of development, affecting many types of equipment, has been undertaken. The outstanding features of some of the more

important of these, including the telephone repeater equipment, test board equipment, and signaling equipment, are described. The necessity for compactness in the dimensions of equipment units, uniformity in assembly arrangements, and simplicity in design, together with the need of careful correlation of the electrical and mechanical requirements, are emphasized. The methods proposed for meeting these requirements generally, are described.

* * * * *

INTRODUCTION

THE use of lead-covered cables in place of bare copper wires for long distance telephone lines has been an important development and much interesting information on this subject has already been presented to the Institute. The engineering and construction features involved in a cable system of this sort were described by Mr. Pilliod in his article on the Philadelphia-Pittsburgh Section of the New York-Chicago cable, while the transmission characteristics of such a system were brought out in the recent paper by Mr. Clark. It is the purpose of the present paper to deal with some of the important developments in apparatus and equipment which are contemplated for the cable plant.

A cable system requires repeater stations at more frequent intervals throughout its length than an open-wire line, because of the much smaller gage conductors which it employs. Consequently, in such a system, a greater proportion of the plant investment is represented by the equipment within the offices than is the case with open-wire construction. Furthermore, the number of equipment units per station in a cable system is ordinarily much larger than in an open-wire office, due to the fact that the chief advantages in the use of long cable circuits, in place of open-wire construction, have occurred on routes carrying heavy traffic where many circuits are needed. Thus, the requirements of the cable plant have been such as to emphasize the economic importance of the equipment design.

To meet these requirements it has been necessary to undertake a comprehensive plan of development affecting many types of equipment. This has involved careful consideration of both the electrical arrangements and the mechanical design, which are being closely coordinated with the purpose that both should contribute to the highest degree of efficiency in the functioning of the system.

It is not possible in this paper to give many details concerning these developments, but it is desired to present some of the principal features as applied to typical cases. Among the more important of these are the

telephone repeater equipment, the testboard equipment and the signaling equipment. These are closely associated with each other in their operation, as well as in their physical location, and it has been necessary, in the design of all units to have due regard to the system as a whole.

TELEPHONE REPEATER EQUIPMENT

The function of the telephone repeater as an amplifier in long distance lines is well known. The telephone repeater in its present form has been the chief factor in making long distance cable telephony practicable, and

FIG. 1—BOX TYPE REPEATER INSTALLATION AT SALT LAKE CITY, UTAH

it is probable that the developments in connection with telephone repeaters have been among the most rapid and comprehensive of any in the toll equipment. It will, therefore, be very interesting to note, in the illustrations which follow, the principal steps which have been taken in working out the form of the equipment to the degree of efficiency now required for the cable plant.

In Fig. 1 is shown one of the original forms of repeaters, a number of which were installed as early as 1914. This particular illustration was taken from an installation at Salt Lake City, Utah. In this case the repeater apparatus was assembled in boxes designed to mount on the wall, each box containing a one-way amplifier.

element circuit. Fig. 6 shows the general arrangement proposed for a group of sets of this type in a large installation, as in a cable office. This set is expected to have many advantages adapting it particularly to cable installations. When mounted as shown in Fig. 6 it will occupy but 1.5 square feet of floor space per unit. Fig. 7 shows how this set may be arranged in small installations where it may be desired to be mounted on a low rack.

FIG. 5—TYPICAL ASSEMBLY OF PANEL MOUNTED REPEATER SET

By the uniform use of these general mounting arrangements for all of the new repeater equipment, including the accessory apparatus as well as the repeater sets themselves, it will be possible, where desired, to serve a large number of repeaters with a small amount of testing equipment. For example, in the case of the voltmeters and ammeters required, it will be possible to employ but one meter panel for an entire cable installation. Thus, an economy in equipment as well as a saving in space will be effected.

FIG. 6—GROUP OF PANEL MOUNTED REPEATERS AS ARRANGED IN A LARGE INSTALLATION

Fig. 8 shows how some of the principal features of this proposed type of set, which distinguish it from the earlier types of repeaters, are related to the circuit arrangement, as well as to the mechanical design. Previously, the apparatus which it is now proposed to mount in distinct groups on separate panels, as indicated in this diagram, was assembled together in one repeater unit. Several types of sets were accordingly necessary to meet the various field conditions. This is to be

avoided in the new design by separating from the basic repeater unit such apparatus as may be required to be different under different conditions of use. For example, the basic repeater unit in the new repeater is to be the same for both "through line" and "cord circuit" use, and for large installations as well as for small ones. The signaling apparatus which may have different features in different types of offices, and which may not be needed with "through line" repeaters in some cases, will be furnished as a separate panel from the basic repeater unit. The apparatus which will permit the repeater to be used for cord circuit operation is also to be furnished as a separate unit and may be used in place of the through signaling unit, without changing the basic repeater. The filter which will determine the cut-off frequency of the repeater will also be furnished as a separate piece of apparatus mounted on the repeater set, so that the repeater may be suited to any desired type of line by providing the proper filter.

FIG. 7—PANEL MOUNTED REPEATERS AS ARRANGED IN SMALL INSTALLATION

Another interesting phase of repeater development has been that in connection with the power supply for the vacuum tubes. This includes (1) a source of filament current (2) a source of plate potential and (3) a source of grid potential. In meeting the requirements of cable installations the principal improvements desired have included the use of batteries common to as many repeaters as possible in place of individual batteries, closer regulation of potentials and the elimination of dry cells, where practicable.

In some of the earliest installations a separate six-volt storage battery was used to supply the filament current for the vacuum tubes of each repeater set. Later, the filament current supply was taken from an 11-cell central office storage battery through a rheostat. As the potential of the 11-cell central office battery, normally 24 volts, varied from 20 to 28 volts during the operation of a charge and discharge routine, it was necessary to adjust the rheostat at frequent intervals to maintain constant current in the vacuum tube

filaments. With the greatly increased number of repeaters per station which has occurred in cable systems, the maintenance involved in readjusting the filament currents would have become prohibitive on this basis. Accordingly, for the larger installations, duplicate 11-cell batteries normally floated from generators and provided with emergency cells to maintain voltage during an emergency discharge are proposed. By this improved arrangement it is expected to be possible to maintain the filament voltage within one volt up or down from its normal value, even during an emergency discharge, until the batteries are almost completely discharged. This improved regulation will entirely eliminate adjustments of the individual repeaters during operation to secure proper values of filament current.

For the plate voltage supply dry cells have sometimes been used in small installations. These are now being displaced, to a large extent, by small storage cells, two groups being used so that one group may be charged while the other is in service. In the large cable installations, the current drain on the 130-volt plate batteries has sometimes reached values as great as four or five

tubes in a large telephone repeater installation is considerable. Each filament requires a current in the neighborhood of one ampere and, while the filaments are connected in series in such a way as to utilize as efficiently as practicable the full potential of the central office battery, the load on this battery sometimes amounts to several hundred amperes.

Fig. 9 gives some idea as to the size of the storage batteries for a typical office of this kind. The large cells in wooden tanks are those making up the filament batteries, each of which is an 11-cell battery of 24-volt nominal rating. These two batteries in parallel are large enough to carry the office load for at least 12 hours in the event of a complete failure of charging equipment.

Fig. 10 shows the charging generators and power switchboard for a typical cable repeater office. The gas engine drives emergency generators to float filament and plate batteries in the event that the regular electric power supply service fails. Alarms are provided to indicate any abnormal condition such as a voltage higher or lower than normal, a blown fuse, etc. These are grouped in an annunciator cabinet on the wall.

amperes, so that it is now planned to float these batteries also, instead of operating on the charge and discharge basis. It is expected by this means to obtain regulation of the plate voltage within plus or minus five volts from the normal value of 130, at all times.

Consideration is being given to another possible improvement in the power arrangements for large repeater installations. This involves the proposal to use a storage battery common to all of the repeaters for supplying the grid potential. If it is found that this arrangement is practical, it will permit the elimination of the individual dry cell batteries which have been employed, with a consequent saving in maintenance which might be appreciable. It seems likely that a very small storage battery would serve for this purpose since the current drain is negligible.

The amount of power required to operate the vacuum

FIG. 9—TYPICAL STORAGE BATTERY ROOM FOR CABLE REPEATER STATION

FIG. 10—TYPICAL POWER ROOM FOR CABLE REPEATER STATION

TEST BOARD EQUIPMENT

The "test board" forms an important part of the cable plant equipment, since it is the one point in the office where all of the lines and the equipment as a whole may

the line conductors and the apparatus units are wired to "jacks" which are arranged to permit the transfer of the normal connections by the insertion of plugs wired to flexible cords. A temporary connection made in this manner, through a conducting cord wired to two plugs, is called a "patch." The apparatus for determining the location of line troubles is also located at the test board and is wired to cords and plugs so that it may be connected to any line in the office readily, upon the occurrence of line trouble, without necessitating changes in soldered connections.

The test boards used for the open-wire plant have been designed to take care of 40 to 80 line conductors in one position, that is, in a board three feet long. The amount of testing and patching work required on open-wire lines has been such as to make this a convenient number of circuits to handle within this space. In cable installations, however, the amount of testing and

FIG. 11—TOLL TESTING EQUIPMENT

Terminating phantom group circuit arranged for open-line installations. Simplified diagram.

be reached readily for purposes of testing and re-routing, in cases of line trouble or changes in layout. The form and arrangement of the test board equipment consequently have an important bearing on the effectiveness with which the facilities are handled by the maintenance forces. This is particularly true in the cable plant where the number of circuits involved is large.

In general, all toll line conductors are brought into a central office, from the outside, through a cable, and first appear at a rack called a "distributing frame" where they are soldered to exposed terminal lugs so that they may be reached for the purpose of connecting them to apparatus within the office. This arrangement is well suited to the permanent connections but is not intended to permit frequent changes or the ready removal of the apparatus for line testing.

The necessity for rearranging the connections between the apparatus and the lines in cases of line trouble make it desirable at times to be able to make such changes quickly, and the means which have been provided for this purpose are located at the "test board". Here both

patching per line conductor is less, while the number of circuits in such an office is much greater. Consequently, in cable offices it is possible to concentrate a larger number of wires within a given test board space. This is desirable from the standpoint of economy in space as well as from that of convenience in operation.

One of the first steps considered in the development of efficient testboard equipment for cable installations has been the reduction of the number of jacks per circuit. In open-wire installations it has been the practise to equip each line circuit and each equipment unit, such as a composite set or phantom coil, with a full complement of jacks suited to provide the maximum degree of flexibility in "patching", thus permitting the ready interchanging of individual equipment units, lines and drop circuits. In cable installations, where the circuits are more likely to be uniformly equipped with the same types of associated apparatus and where the line troubles are less frequent, it is expected to be possible to eliminate certain of the jacks, such as those associated with the composite sets and phantom sets, thus simplifying the equipment for terminating the toll

lines. Fig. 11 shows the typical open-wire arrangement for a terminating phantom group circuit in which the maximum number of jacks is furnished. This requires a total of 48 jacks. Fig. 12 shows the arrangement of a terminating phantom group circuit as planned for a cable installation. In this case a total of but 30 jacks is required.

Another important development expected in the

FIG. 12—TOLL TESTING EQUIPMENT

Terminating phantom group circuit arranged for cable installations. Simplified diagram.

test board arrangements to suit them to cable use is the grouping together of the jacks serving similar functions. Considerable improvement in operation is thought to be possible with the jacks having different functions located at different test board positions. In this way all of the line conductor jacks, for example, may be assembled together in consecutive order, and since several hundred of these may be involved in a single installation,

FIG. 13—TOLL TESTING EQUIPMENT

Typical assembly arrangement for jacks at toll test board.

this should greatly facilitate the identification of the desired circuits by the attendant in the process of patching and testing. This grouping of the jacks should also effect a saving in testing equipment, since it will eliminate the need of the line testing apparatus, such as the Wheatstone bridge, at positions where the line conductors will not appear.

Fig. 13 illustrates both the open-wire and the pro-

posed cable methods of grouping the jacks. In the arrangement for open-wire circuits the jacks associated with both the lines and equipment are terminated adjacent to each other in the same test board panel. In cable installations the jacks having similar functions are to be grouped together, the groups having different functions being mounted in different panels which may be located in different test board positions. These various groups, in the latter case, are planned as follows:

1. Primary line testing position for testing and "patching" toll lines only. This position to be used for locating faults in the cable circuits and equipped with a Wheatstone bridge and voltmeter, to permit the necessary electrical measurements for this purpose. This position is also to be used for making temporary changes in the assignments between the lines and the equipment as a whole, but is not to be arranged to permit changes in individual equipment units, such as composite sets, phantom sets, etc., The jacks to be

FIG. 14—TYPICAL ASSEMBLY OF FLOOR-MOUNTED TEST BOARD. ONE POSITION

located at this board are to include those designated as "line jacks" and "equipment jacks", in Fig. 12.

2. Secondary terminating line positions for testing and "patching" the lines between the "drop" side of the equipment and the toll switchboard circuit. This position is to be used for determining the general nature of a trouble and its general location, *i.e.*, whether it is in the direction of the line or in the direction of the "drop", and for clearing troubles not requiring line tests. This position is not to be equipped with Wheatstone bridge testing apparatus as at the primary board. The jacks to be located at this position are to include those designated as "secondary line jacks", "drop jacks" and "listening jacks", in Fig. 12.

3. Secondary telegraph line positions for testing and "patching" the telegraph line circuits. This position is to be used solely for interchanging telegraph lines and telegraph equipment, in cases of temporary changes in

assignment and is not to be equipped with line testing apparatus. This position will permit changes to be made in the telegraph assignments without interfering with the telephone circuits. The jacks to be located at this position are to include those designated in Fig. 12 as "telegraph line jacks" and "telegraph drop jacks".

A further and more extensive improvement in test board design is anticipated as a result of development

FIG. 15—TYPICAL GENERAL ASSEMBLY OF PANEL-MOUNTED TEST BOARD

FIG. 16—TYPICAL ASSEMBLY OF KEYSHELF EQUIPMENT UNIT FOR PANEL-MOUNTED TEST BOARD

work whereby it will be possible to employ panel mounted keyshelf equipment units, jacks and testing apparatus, which in the standard board are now housed in a large wooden section. This will have the advantage of uniformity with the other toll equipment, as well as requiring less space. It will also permit flexibility in the use and installation of the various combinations of keyshelf equipment, jack equipment and other testing

FIG. 17—TYPICAL ASSEMBLY OF JACK MOUNTINGS FOR PANEL-MOUNTED TEST BOARD

apparatus which may be required to suit each case. While this arrangement will have its chief advantages when applied to large cable installations, it will also be well suited to open-wire use and small installations, since its design will permit the highest degree of flexibility with respect to both the amount and type of equipment.

These points may be illustrated by comparing the

general features of the two types of boards. Fig. 14 shows the assembly of a one-position section of the present type of board employing a wooden framework. This board, with the necessary allowances for aisle space, requires a floor area amounting to about 24 square feet, while it houses a maximum of about 1000 jacks corresponding roughly to about 40 jacks per square foot. Fig. 15 shows a typical position employing the proposed panel mounting method. Such a board will occupy a floor space of about 10 square feet and will take care of about 600 jacks, corresponding roughly to a capacity of 60 jacks per square foot.

This latter type of board is to be made up of a number of panel units which are to be assembled on two vertical supports. The principal types of units to be provided for the purpose are the keyshelf units, the jack mountings and the equipment panels which may be combined together as desired to give the necessary facilities.

Fig. 16 shows a typical keyshelf unit designed for the panel type board. By constructing the keyshelf unit as a separate piece of apparatus, it is expected to be possible to standardize the necessary types of keyshelves to fit all ordinary field conditions and to

FIG. 18—TYPICAL ASSEMBLY OF APPARATUS PANEL FOR PANEL-MOUNTED TEST BOARD

specify the desired type of keyshelf to go with any particular arrangement or number of jacks. The number of keyshelf units of any given type may be as desired for each installation, thus the proportion between the jacks and the keyshelf equipment may be suited to each type of office.

Fig. 17 shows a typical arrangement of the jack equipment and the mountings which are to be employed for the jacks. This type of jack mounting will make it possible to mount the jacks on the same supports as the testing equipment. The mountings are to be attached to the supports by fasteners, each occupying a vertical space of $1\frac{3}{4}$ inches and drilled to fit the usual drillings in the supports. This will permit the close association of the jacks with the desired testing apparatus. It will also be possible, by this means, to use for the jacks only such of the available vertical space as may be desired, the remainder being used for other equipment, thereby effecting economy in the use of the space. This arrangement is thus expected to be advantageous both in large installations, where the various groups of jacks are desired to be arranged at separate primary and secondary positions, and in small installa-

Much of the sensitivity and selectivity which may be obtained with this signaling system are due to the design of the 135-cycle relay. As shown in Fig. 20, the relay is designed to make it capable of close and accurate adjustment. Both the magnetic air gap and the contact spacing may be adjusted, about 0.0015 inch or 0.038 millimeter being used ordinarily for the latter. The relay is mechanically tuned, the natural period of the reed with its adjustable weight corresponding closely to the frequency of the signaling current. A stop pin is provided which prevents undue vibration of the reed

FIG. 20—GENERAL STRUCTURE OF 135-CYCLE RELAY

due to transient impulses or excessive currents. Also, the relay circuit is electrically tuned by a shunt capacity and a series inductance and capacity. It is thus very selective and is relatively free from the ordinary sources of interference such as those caused by mechanical vibration, telegraph signals, switchhook impulses, voice currents, etc. The sensitivity of the relay is such that it will operate on as little power as 30 microwatts, corresponding to a current in the neighborhood of 0.25 milliamperes.

This relay is to be mounted so that it may be inserted

FIG. 21—TYPICAL ASSEMBLY OF 135-CYCLE COMPOSITE RINGER SET

in the circuit or removed from it in the manner of a plug and jack, without requiring changes in the permanent wiring and without affecting the circuit operation, except to interrupt the signal-receiving system while the relay is removed. Thus it will be very convenient to make the necessary adjustments of the relay separate from the circuit with which it may be associated in service. The relay will be well protected from mechanical interference, such as building vibration, by padding in the mounting which prevents rigid mechanical connection between the relay and its external support.

The assembly arrangements proposed for all of the new signaling apparatus are such as will fit in closely with the panel mounting methods designed for the remainder of the toll equipment in cable installations. Fig. 21 shows the assembly proposed for the new composite ringer set. This method of mounting the composite ringer set is a very desirable one since it permits a complete composite ringer set to be manufactured as a unit and installed as such.

Fig. 22 shows the manner in which a number of these composite ringer panels are planned to be mounted together with the associated testing equipment in a large installation. This close association of the composite ringers with the jacks and testing equipment is expected to be of considerable advantage in facilitating the maintenance of the apparatus.

The need in cable systems of a particularly well-regulated source of 135-cycle signaling current, with

FIG. 22—TYPICAL ASSEMBLY OF GROUP OF COMPOSITE RINGER SETS

sufficient capacity for a large number of lines, has made it desirable to undertake the development of both a special type of interrupter and a motor-generator for this purpose. Close frequency regulation is also very desirable in signaling over cable circuits, in view of the increased sensitivity in receiving which may be obtained by the use of very selective receiving apparatus.

Fig. 23 shows the circuit arrangement of the interrupter which is expected to be provided for this purpose. This includes a vibrating reed actuated by an electromagnet when direct current is applied. The contacts on the reed being in series with the battery circuit, intermittent operation is secured in the manner of an ordinary buzzer, the speed of operation for a given applied voltage being determined by the natural period of the reed. The actuating circuit of the vibrator also includes the primary side of a transformer, the second-

assembled on vertical supports consisting of I-beams or channels which extend from the floor to the ceiling, rolling ladders being employed to reach the apparatus above when necessary. As has been shown in the preceding views of individual equipment units, all of the adjustable apparatus is mounted on the front of each equipment panel and the material not requiring adjustment when in operation is mounted on the rear, since by this means the rear aisles can be made narrower than the front aisles. Thus, all available space is utilized to

FIG. 28—GENERAL VIEW SHOWING TYPICAL GROUP OF EQUIPMENT UNITS EMPLOYING PANEL MOUNTING METHODS

the extent that the floor area required per equipment unit in a cable installation will be as small as the maintenance, manufacturing and installation requirements for the apparatus will permit.

In view of the many different types of equipment units having a variety of special functions which are required to make up a complete cable installation, a high degree of uniformity in design is necessary to permit efficiency in their use. It is expected that this will be accomplished effectively by applying the panel assembly method in a uniform manner to practically

all types of equipment units. All panels are to be of a uniform length, designed to mount on vertical supports spaced $19\frac{1}{2}$ inches between centers. The height of the different panels will vary, according to the amount of apparatus in each unit, but this vertical dimension is in all cases to be a whole multiple of $13\frac{1}{4}$ inches. By applying these specifications widely, it will be possible to secure interchangeability between panels and to employ uniform methods in grouping the different units, thus facilitating their installation and use.

The simplicity of the design of the equipment units comprising the various panels is also of great importance. This has necessitated careful attention to the forms of the individual pieces of apparatus, in order that these might fulfill their specific functions efficiently while at the same time fitting in well with the general equipment arrangements. To this end, new types of apparatus, such as repeating coils, retardation coils, etc., are being developed especially for cable use. Much will also be accomplished toward the simplification of the panels by carefully avoiding duplication in the accessories to the different types of equipment and by dissociating from the individual units of all types any pieces of apparatus capable of being made common to a number of units, or subject to different methods of application in different types of offices.

Other important advantages are anticipated in the panel assembly method. One of these is that it will permit the assembling together on one panel of all of the pieces of apparatus of different types which may be desired to form a distinct equipment unit. In large installations, completely equipped racks including a number of equipment units with the associated testing apparatus may be assembled in the factory on the supporting uprights and wired to the terminals at the top of the rack, thus simplifying the installation work. The location of the testing apparatus on the same rack with the equipment panels has the further advantage that it will place the apparatus to be adjusted within easy reach of the testing facilities. Furthermore, the testing apparatus will serve for the maintenance of a greater number of equipment units when all of the space between the floor and ceiling is utilized, thus reducing the amount of testing equipment required.

The subcommittee also desires to again emphasize the necessity of further research and test to determine the possible effect or weight of other factors varying with the system involved, now the subject of research in other countries, such as for example, power factor and voltage reestablishment characteristics. It is hoped that early system tests will bring out any facts of importance in this connection, particularly if they be of a character which might influence the interrupting capacity ratings.

The subcommittee would also draw attention to the valuable work of similar import done in connection with fuses by some of the operating companies. The data obtained are a valuable contribution to the general phenomena of electrical energy interruption.

Subcommittee on Current-Limiting Reactors

N. L. POLLARD, *Chairman*

FAILURES

During the past year the Committee prepared and sent out a questionnaire requesting information on operating experience with current-limiting reactors. This questionnaire was sent to twenty-five of the larger operating companies using reactors.

The answers were not received in time to permit tabulating the information, but in general they indicate fewer failures than in previous years. Practically all the failures reported were for reactors that had been installed for several years. The latest designs are much better mechanically and electrically and will undoubtedly stand the strains that they will be subjected to in the rapidly growing systems of today.

HIGH-VOLTAGE REACTORS

The manufacturers are prepared to build reactors for any voltage in operation today for the protection of high-voltage tie lines. Reactors of this type are constructed like transformers without the iron core and are oil immersed in steel tanks. The highest voltage these have been built for to date is 66,000.

USE OF SHUNTING RESISTORS WITH REACTORS

One manufacturer reported further indications of the value of resistors shunting reactors having been obtained in recent tests made in disconnecting transformers from a large generating system. The tests showed that a resistor shunting a reactor reduces the over-voltages which arise due to the inductive kick.

THERMAL CAPACITY

Operating companies are beginning to realize the importance of installing reactors having a greater thermal capacity than formerly. This change in opinion has resulted from a number of causes:

1. During the past few years there has been a number of instances where short circuits have remained on systems for comparatively long periods of time and

as a result it seemed very desirable to install reactors having a greater thermal capacity.

2. The low price of copper and the high price of coal has made it economical to purchase reactors of lower losses than in the past.

UNUSUAL INSTALLATIONS

During the past year there has been a number of unusual installations of reactors, as follows:

One manufacturer reported receiving an order of 72-60-cycle, 96-kv-a., 478-volts, 200-ampere reactors for installing on a 27,600-volt system. This is the first system operating at as high voltage as 27,600 where such a large number of current-limiting reactors will be used. The same company received another order for 36 outdoor feeder reactors rated at 60 cycles, 120 kv-a., 381 volts, 214 amperes, to be installed outdoors on 22,000-volt circuits.

STANDARD SPECIFICATIONS

The subcommittee is continuing work on a standard specification which they hope to be able to complete before the end of the year.

PAPERS

A paper covering operating experience with different types of reactors was presented at the Spring Convention in Pittsburgh. Several other papers that will deal with the design features of reactors are practically ready for presentation whenever the Meetings and Papers Committee can arrange to use them.

Subcommittee on Lightning Arresters

F. L. HUNT, *Chairman*

During the past year the Lightning Arrester Subcommittee has been active in discussion and further study of the classification of lightning arresters, and has made some progress toward the preparation of a specification for lightning arresters. This work has been greatly facilitated by the cooperation of two of the large manufacturing companies, both of which have built up in their testing laboratories equipment which may be called lightning generators, and which are useful in making comparative tests on the performance of various classes of lightning arresters.

During the year the Committee visited the testing laboratory of the Westinghouse Electric & Manufacturing Company, at East Pittsburgh, where a demonstration of their lightning generator was given, and comparative tests made on several different classes of arresters. The Committee has also visited the testing laboratory at the General Electric Company's plant at Schenectady, where a very complete and instructive series of tests were made, bringing out the important features in the testing of lightning arresters and comparisons between some of the important characteristics of different types of arresters.

Definite progress can be reported on the development of a technical definition and specification of lightning arresters, although the work is not sufficiently com-

pleted to warrant the presentation at this time of any final results.

New types of arresters are being developed by some of the manufacturers as the result of experimental work which has been urged by this Committee, and as a result of the papers that have formerly been presented by this Committee. During the year the Committee arranged for a paper by Mr. A. L. Atherton on the development of the autovalve lightning arrester, which was read at the Midwinter Convention, and a paper by Mr. Malcolm MacLaren on lightning disturbances on distributed circuits, which was read at the Spring Convention at Pittsburgh.

Subcommittee on Grounding of Systems

E. C. STONE, *Chairman*

This is the second year of the existence of the Subcommittee on Grounding of Systems. The subcommittee having been created by action of the general committee on October 14th, 1921.

The principal activities of the subcommittee this year consisted in analyzing and editing the vast fund of information received in reply to the inquiry sent out last year and in arranging the program for the symposium on Grounding of Systems which was a very important part of the Spring Convention of the American Institute of Electrical Engineers held in Pittsburgh, April 24-27, 1923.

The data compiled from the inquiry above referred to included extensive information on thirty six of the principal operating companies in the United States with a total generating capacity of 6,371,850 kv-a. and a total transmission line mileage of 31,408 miles.

This report has now been printed and was presented at the 1923 Spring Convention as the first technical report of this subcommittee under the title "Present Day Practises in Grounding of Transmission Systems." This report was in two sections; the first section covering Systems Transmitting at Generated Voltage, being prepared by Mr. W. W. Woodruff of The Philadelphia Electric Company and the second section covering Systems Transmitting at Higher Than Generated Voltage by the Chairman of the Subcommittee.

As an added special assignment, data were also presented on the protection of underground cables operating at over 30,000 volts.

With the cooperation of the Chairman and members of the Protective Devices Committee, the Chairman of the Subcommittee was fortunate in obtaining, for the Spring Convention, a group of very interesting and valuable papers, summarizing the present state of the art as regards Grounding of Transmission Systems. These papers included the following:

General Considerations in Grounding the Neutral of Power Systems, by H. H. Dewey.

The Neutral Grounding Reactor by W. W. Lewis.

Operating Performance of a Petersen Earth Coil, by J. M. Oliver.

Third Class Conductors and Mechanism of Arcing Ground, by C. P. Steinmetz.

Voltages Induced by Arcing Grounds, by J. Slepian and J. F. Peters.

All of these papers were presented at the 1923 Spring Convention in conjunction with the Technical Report of this subcommittee and were actively discussed.

Acting under instructions given by the General Committee at the meeting held in Chicago, September 22nd, 1922, the Subcommittee this year sent out three inquiries on the following subjects:

Simultaneous Cable Failures

Protection of High-Voltage Cables

Trouble Report Forms

Copies of these inquiries are appended.

A considerable number of very interesting and complete reports have been received in reply to these inquiries, especially covering the subject of Simultaneous Cable Failures. There is still a number of important companies to be heard from however, and the subcommittee expects, during the summer, to obtain additional data from these companies.

It is hoped to submit an analysis and report of all data received in reply to these inquiries at the Fall meeting of the Protective Devices Committee.

RECOMMENDATION

The investigations of the subcommittee have developed the fact that:

There is still wide divergence of opinion as to the proper manner in which to ground a given transmission system;

That systems of different characteristics require different treatment; and

That special problems arise from time to time in connection with the operation of the grounded and ungrounded systems.

It is therefore our recommendation that the Subcommittee on Grounding of Systems be continued next year with instructions to follow the general situation as to practise in grounding of transmission systems and to make such special investigations along similar lines as the General Committee may see fit to assign to it.

APPENDIX—REQUESTS FOR INFORMATION

Simultaneous Cable Failures

The last general meeting of the Committee brought out the fact that a number of companies were suffering from several cables failing simultaneously at widely separated points.

This subject was assigned to the Grounding of Systems Committee. Accordingly the following information is requested:

1. System characteristic
 - (a) Voltage
 - (b) Frequency

(c) Type of system—3-phase 3-wire, 3-phase, 4-wire or what.

2. Is neutral grounded or ungrounded?

3. If neutral is grounded please give electrical characteristic of ground, such as dead ground, ohms, resistance, or reactance, etc.

4. How many miles of cable are in operation at this voltage?

5. Please give number of cases by years where two or more cables have failed simultaneously or closely in succession. For each case, please furnish year in which failure occurred, number of cables failing, type of failure as to ground or short, location of failures with reference to each other and to the system, cause and any other pertinent descriptive matter.

Please furnish a brief description for systems at each voltage at which you operate.

Protection of High-Voltage Cables

The protection of high-voltage cables having been assigned to the Subcommittee on Grounding of Systems, the following information pertaining to same is requested:

1. Please indicate number of miles of cable operated at each voltage which you use above 20,000.

2. For each voltage, please furnish the following information:

(a) How many conductors in one sheath.

(b) Are step-up and step-down transformers provided for each individual run of cable or are a number of cables operated from a common bus?

(c) Is the neutral grounded or ungrounded?

(d) If grounded, is resistance, reactor, or dead ground used? If former, how many ohms?

(e) Is switching performed on these cables by automatic circuit breakers at the cable voltage, or are the breakers installed on the low-voltage side of the step-up and step-down transformers?

(f) If lightning arresters are used, please give type, location and other pertinent data.

(g) What other protective devices if any are used?

Trouble Report Forms

Please furnish if possible copies of all report forms used by your company in reporting and recording system troubles.

Subcommittee on Relays

E. A. HESTER, *Chairman*

During this year the activities of the Relay Subcommittee have been centered in the preparation of the Relay Handbook, which is being compiled jointly by this subcommittee and the Relay Subcommittee of the N. E. L. A. Electrical Apparatus Committee.

It is estimated that at the present time the work on this handbook is something more than fifty per cent complete and it is hoped that it will be published some time before the end of the present calendar year. Leaflets have been prepared giving complete table of contents, purpose, physical description, and price of the handbook, together with a list of the contributors. The United States and Canada and some other foreign countries have been divided into districts and representatives appointed to handle the sales and distribution of the handbook in each district.

In order to finance the publication of this handbook by the National Electric Light Association, it is necessary that a certain minimum number of advance orders be obtained. An active sales campaign is now being carried on and more than a sufficient number of advance orders are in prospect to insure its publication.

This handbook will contain in convenient form the work of the various relay committees of the two societies for the past few years. All the relays and relay schemes which have been approved of merit by actual experience are fully described. All of the accompanying details of relay application are given in such a manner as to present the subject from every angle, thus obviating the necessity of referring to other publications and searching among widely scattered reports for desired data. It will represent the combined experience of the most progressive relay engineers in the country and will compare with the best electrical and mechanical handbooks of recent issue.

This relay handbook will be taken as a basis for all future committee work and the annual reports of the relay committees will be in the nature of additions to or revisions of the material contained therein. Reissues of the handbook will be printed as often as warranted by the demand.

Three important relay papers have been presented under the auspices of this subcommittee during the year. The first of these was a complete description of the protective scheme used on the high-tension transmission ring of the Duquesne Light Company around the city of Pittsburgh, together with a description of the actual service tests made in the field to determine its effectiveness. The second was a paper describing a means of obtaining the advantages of a grounded system on a delta-connected transmission and distribution system where a ground could not be conveniently obtained. The third was a description of a new relay which has recently been developed to a commercial stage. This relay takes advantage of the voltage drop between the point of short circuit and the point of application and is, therefore, automatic in its selection of faulty sections of line and does not require elaborate calculations for purposes of making settings.

It is felt that all three of these papers have added distinctly to the data made available through the work of the Protective Devices Committee.

four years of review of the many historical articles and books written on the subject, the Committee has completed a fifty page chronology of the electrical applications in the marine field from the beginning up to the present time. The report deals with electricity on merchant and naval vessels, domestic and foreign, treats of the many changes through which the art has passed and makes reference to the more important papers previously published. Your Committee considers the report a valuable asset and it is the hope that some means may be provided for publishing same. The committee's work in the future will consist of keeping the report up to date.

Radio, Subcommittee (E), this committee has had little to do this year and it is probable it will be discontinued in the near future as the Radio Committee of the Institute may take over all radio work.

Wires and Cables, Subcommittee (F), the work of this committee has been in collecting data on the wire and cable now in use with a view to making such modifications as appear warranted.

License and Education of Engineers, Subcommittee (G), as predicted in last year's report, the duties of this committee have been most arduous as it has encountered obstinate opposition where it expected assistance. The reason for this condition is that those in authority least of all of those concerned fail to realize the necessity for some action and this attitude is no doubt due to lack of knowledge of those in authority of the nature and extent of electrical apparatus being installed on ships today and for the past five years. Your Committee has had considerable correspondence with the Board of Supervising Inspectors, Steamboat Inspection Service and one personal interview with the Board. The results are not what was expected or what they should be. In order to give the matter a public hearing a paper entitled, "The Electrical Engineer on Shipboard," was read by your Chairman before the New York Section of the American Institute Electrical Engineers, November 1922; the meeting was well attended, discussions numerous and interesting and emphasized in detail perhaps more than the paper the abuse to which electrical plants on shipboard are subjected today.

Your Committee plans to have a somewhat similar paper presented at one of the sessions of the annual meeting of the Naval Architects and Marine Engineers in November this year. Mr. A. E. Waller Designing Engineer of the Ward Leonard Company, Chairman of this Committee, is deserving of great credit for the persistence and methodical manner in which this subject has been kept before the authorities and in the public press and the Committee feels quite confident that the desired results will be realized during the coming year.

Publicity, Subcommittee (H), recently appointed, has prepared several news items of interest in connection with marine electrical work and more will follow.

Interior Communication, Subcommittee (I), specifications for Telephones, Revolution Indicators and Electrical Thermometers have been prepared by the subcommittee, approved by the Marine Committee and are about to be forwarded to the Sectional Committee of the American Engineering Standards Committee.

Editing, Subcommittee (J), has completed all work accepted by the Marine Committee.

The Committee as a unit has worked harmoniously and the entire membership is to be congratulated for the attendance and enthusiasm. The coming year will require considerable effort on the part of the Subcommittee for License and Education of Engineers and also no doubt will be called upon to support the Sectional Committee of American Engineering Standards Committee to consummate its purposes. The question of varnished cambric and telephone cable and specifications for tank gages should receive the attention of next year's Committee.

G. A. PIERCE, *Chairman.*

REPORT OF THE INDUSTRIAL AND DOMESTIC POWER COMMITTEE

To the Board of Directors:

The work of this committee of the Institute is rather difficult to carry on because it covers such a wide field of electric power application. In many cases the electric drive is noteworthy from the aspect of the mechanical design of the drive and because of the very ingenious system of control which is used. Only in comparably few cases do these applications represent any marked departure in apparatus design or power consumption. The elements that interest the central station man, such as efficiency, power factor and apparatus design, are often lacking. Applications of this kind have their greatest economical interest, not in the power saved, but in the increased output of the operators. In other words, the interest in many cases is one of general economy, rather than that of purely engineering proclivity.

We are ever striving to appropriate for personal use more and more of this world's goods. At the same time we are striving to reduce our hours of productive labor in order, as we claim, that we may have more time for leisure and intellectual cultivation. At any one time the goods which can be obtained are directly proportional to the number of persons participating in the distribution. An increase in wages does not affect this distribution as a whole, but an unbalanced wage scale may cause an unequal distribution of goods giving certain classes of persons more than their share and operating as a hardship to other classes.

The great problem which leaders of industry are facing today is increased production per person in order that more goods may be produced with less hours of productive labor per person. This output has been

very greatly increased during the last twenty-five years by the substitution of the electric drive for the steam engine drive. The advantage of the electric drive is not so much one of economy in power consumption as of increased flexibility. Improvements in the electric motor have made many of these applications possible and also have materially reduced the personal hazard to the operator. By far the largest factor contributing to the success of the electric drive has been the improvement in control apparatus. The electric motor is restricted in its range of characteristics. The additional functions required for a particular drive must be supplied by the control equipment.

In viewing this situation broadly, we must not overlook the contribution made by the mechanical engineer in developing new and improved methods of drive and his able cooperation with the electrical engineer in adapting the electric drive to special machinery. In many cases the machine itself has been re-designed in order to take full advantage of the electric motor and the automatic features of its control.

In order to be of interest to the Institute membership as a whole, this committee should arrange for presentations illustrating the broad tendencies now existing, and also the lines along which development is taking place, describing the particular application selected for purposes of illustration.

This work can perhaps best be carried on by co-operating with Institute sections to arrange programs on industrial application subjects in addition to papers presented at Institute meetings. Many of the typical applications are of considerable local interest; for example, the textile industry in New England and the south, the lumber industry on the Pacific coast, the automobile industry in and about Detroit, etc. By this cooperation, it may be possible to hold several meetings on the subjects of this committee during the year and present material which will be not only of interest to the particular industry selected, but which will also illustrate in a broader way the trend of power applications.

Electric power can be broadly divided into two classes: (a) its generation and distribution, and (b) its utilization. All power generated must be sold at an average net profit, otherwise the industry would not exist. The companies are vitally interested in the utilization of their output and many papers have been written describing the load factor, power factor and other general matters of interest. In the main, however, the engineers of these companies have devoted their energy toward solving the immediate problems connected with the generation and distribution of this power. It is only recently that they have realized the advantages and economies of the electric drive for the auxiliary equipment in their power plants. The large per cent of connected load is made up of constant speed, squirrel-cage induction motors which are usually started and stopped by manual control. Both the motor and

its controller are so far standardized that they can be obtained as a stock article from all manufacturers of this apparatus. The application of these motors consists largely in determining the size of the motor necessary and devising the mechanical means for connecting the motor to the load. This work can usually be done by one of the power company's salesmen without the assistance of an expert. The more difficult applications represent a relatively small per cent of the connected load, but they are very important because in many cases they determine whether central station power can be economically used in a particular industry. In addition to these special problems, a study of production in an industry often shows that a machine that was previously driven at constant speed from the line shaft, and later on was connected to its own constant speed induction motor, can be improved and the output of its operator materially increased by adapting it to a motor and control which can quickly start and stop the machine, and, perhaps, operate it at different speeds.

POWER FACTOR

This is of great importance to the distributing companies. Careful investigations of the design of the induction motor indicates that very little improvement can be made in the power factor of this machine, but considerable may be done by more carefully applying the motor to operate closer to its normal load. The power factor can be improved mainly by means of additional devices such as static condensers, phase advancers or synchronous condensers. Many applications permit the use of synchronous motors which also can be used for power factor correction. Care should be taken in recommending the use of synchronous motors as it is only in relatively large sizes, in proportion to the rest of the load, that power factor correction can be economically obtained in this way. Where there are a large number of relatively small motors, 50 h. p. or less, it will often prove more economical, both as to first cost and to operation, to use induction motors and provide one synchronous condenser for the whole installation.

MAGNET CLUTCHES

The application of the synchronous motor has been materially widened by the use of the magnetic clutch which permits the motor to accelerate under no load and then gradually connect the load to the motor after synchronous speed is reached. Recently in flour mill electrification this factor has been taken advantage of. The group drive in this class of work necessitating fairly large horse power motors, also in cement mills where individual drive of large horse power is required. In rubber mill line drive the use of the clutch permits the use of synchronous motors and an additional advantage has been gained for quick stopping as the load can be disconnected from the motor very quickly and the brake which becomes a part of the clutch in such drives can be used for the quick stopping of the mills.

THE SYNCHRONOUS MOTOR

The design of the synchronous motor has been improved so that considerable starting torque can be obtained and the motor can be directly coupled to the load in many cases without the use of clutches. This is particularly true where the starting torque is less than full-load torque. It has also been found that a synchronous motor can be quickly stopped by over-exciting the field and short-circuiting the primary windings through a resistance. These improvements in the design of the motor have enabled engineers to extend its range of application. Where synchronous motors are applied, automatic control is more satisfactory and is being generally used.

SQUIRREL-CAGE INDUCTION MOTORS

The design of these motors has not been materially changed for a number of years, but improved forms of automatic starting devices are being placed on the market in increasing numbers and the tendency seems to be toward the "push button method" of starting for many applications.

Remote control is desirable for all types of motors and for most applications. It does not depend on the judgment of the operator and it is much safer respecting the personal hazard aspect because it removes the switching means from the immediate locality of the operator. In many cases it is more economical than manual starting; it permits the starting means to be located near the motor and reduces wiring expense. It is often more convenient, as it enables the motor to be started and stopped from several places. Push buttons can be located wherever most convenient to the work. If the application involves a personal hazard it is very desirable to have ready means of stopping the machine from all positions of the operator. All of these considerations are tending to increase the number of automatic starters in proportion to the total number of starters used.

VOLTAGE CONTROL

This method of controlling a direct-current motor has come rapidly to the front in the last year or two. It consists in providing an individual generator for each motor, the motor being controlled by changing the value and direction of the generator field. This system was first advocated by Mr. H. Ward Leonard about 25 years ago, but its development was retarded by certain inherent difficulties experienced in its application. It is the scheme which is recommended for mine hoists where large d-c. motors are used, and it is also the recognized method of controlling the larger motors used for reversible steel mill drive.

Recently this system of control has been successfully applied to electric elevators, electric shovels and it is now being used to some extent on reversing planer equipment. It has some very desirable characteristics and undoubtedly will be applied to skip hoists, which are very similar to elevators.

PAPER MACHINE

The sectional drive for paper machine has come to the front in the last few years. The improvements which have been completed during the past year indicate that it is not only practical, but very desirable to operate paper machines by individual motors applied to each section. This has proven a difficult problem and has been worked on at various times by engineers during a considerable period of time. Its successful solution is a distinct advance in the application of the electric drive for industrial use.

POWER STATION AUXILIARIES

The electric drive has practically superseded the small steam turbine for the operation of power house auxiliaries. The attempt is being made to use a-c. motors for all applications on account of the greater convenience in securing a-c. power and the greater reliability of this source of power as it can be obtained from static transformers rather than rotating machinery. Considerable success has attended the use of a-c. motors and some stations are being entirely equipped with this form of auxiliary drive. The electrical characteristics of d-c. motors for certain applications are so much better that they are in general the ones that are used for these particular applications, and where a power station has a reliable source of d-c. power it is an advantage to operate these auxiliaries with d-c. motors.

OIL WELL APPLICATIONS

The electric drive has superseded the gas and steam engine for oil well pumping, and also the steam engine for oil well drilling on many large properties. The pumping equipment has been universally satisfactory and much more effective than the gas engine. Experiments are still being conducted on the electric drive for drilling purposes.

LUMBER INDUSTRY

The electric drive has been used as a source of power for most of the operations connected with the lumber industry, particularly for all those operations in and about a mill. More recently the electric motor has been successfully applied to logging donkeys and experiments are being continued which engineers believe will result in a further substitution of the electric motor for the steam engine.

WOOD WORKING MACHINERY

Many of the operations in wood working are most economically performed at a high speed. Recently an adjustable frequency system of control has been used, some a-c. induction motors being coupled to an induction generator from which different frequencies can be obtained. This is particularly interesting as one of the few applications so far employing a variable frequency method of control. Undoubtedly, other applications will be made of this method.

is working on it. Also, low-voltage protection which prevents the accidental starting of the machine after failure of power.

CONCLUSION

Our committee hopes that section meetings can be arranged for the discussion of electric application to the industries and that we can work out a plan of cooperation with the local sections to further this work. We shall welcome any suggestions from members calling our attention to subjects of importance or any other matters connected with our committee work.

H. D. JAMES, *Chairman.*

REPORT OF THE INSTRUMENTS AND MEASUREMENTS COMMITTEE

To the Board of Directors:

The Instruments and Measurements Committee submits the following annual report, giving briefly a summary of its activities during the past year, together with mention of the progress and developments of the electrical art included in the field of this Committee.

At the Midwinter Convention, held at New York, a session on Friday afternoon, February 17th, was assigned to this Committee. A most interesting and valuable group of papers was provided and presented. The discussion was very active and was limited only by the time available. The papers were as follows:

Application and Limitation of Thermocouples for Measuring Temperature, by I. B. Smith, Leeds & Northrup Co., Philadelphia, Pa.

The increasing use of thermocouples in electrical measurements makes this paper most timely. The applications and limitations are clearly set forth.

Measurement of Power in Polyphase Circuits, by C. Fortescue, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

The author believes the present method of measuring power in polyphase circuits is not an equitable one and suggests a better.

Volt-Ampere Meters, by R. C. Fryer, Union Gas & Elec. Co., Cincinnati, O.

There is a decided tendency to change rate systems from kilowatt demand primary charge to a kilovolt-ampere basis. The author describes the various methods available for measuring kilovolt-amperes. This is the first paper on this subject presented before the Institute.

Expansion of Oscillography by Portable Instrument, by J. W. Legg, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

Latest developments have made the oscillograph a really portable device and it is now coming into its own as an instrument for assisting the operating man in solving many heretofore unknown problems. Mr. Legg had one of the devices at the meeting and after the session adjourned spent considerable time in demonstrating it to the members.

Measurement of Transients, by F. E. Terman, Leland-Stanford University.

The subject of transients is always an interesting one. The author presents one method of obtaining information on this subject.

Balance Methods in A-C. Measurement, by P. A. Borden, Hydro-Electric Power Commission, Toronto, Ontario.

The author describes a method of obtaining more accurate measurements of alternating-current quantities.

At the annual convention in June, the Committee has prepared and there will be presented one paper as follows:

The Standardization of Electrical Measuring Instruments, by H. B. Brooks, Bureau of Standards, Washington, D. C.

Your Committee in previous reports has mentioned some preliminary investigations made on the subject of Instrument Standardization, but it was not until this year that it was decided to go ahead with the actual work of preparing what is hoped will develop into an American Standard. A Subcommittee, consisting of Messrs. H. B. Brooks, Chairman, F. P. Cox, Paul MacGahan and G. L. Crosby, was appointed and has held several meetings. The first portion of this work has been completed this year and is presented in Mr. Brooks' paper. It deals with definitions, terminology, etc. The Committee plans to continue this work and to issue from time to time additional sections until we have a complete American Standard. In its work the Committee has studied the English, French and German specifications. In order to bring the first part of the specifications more definitely before the members, the Committee has arranged for a paper to be presented in June, as mentioned above. It is hoped that this paper will receive the closest attention and that the discussion on this part of the report will lead to a satisfactory agreement among the members.

DEVELOPMENTS

The developments during the past year in watthour meters has been chiefly in that portion dealing with demand measurements for alternating-current meters. Three of the manufacturers—General Electric, Sangamo and Westinghouse—have placed on the market a register which may be applied to a standard watthour meter and which will give the integrated kilowatt demand in any specified time interval in addition to the usual kilowatt hours. This development has simplified demand measurements in the alternating-current systems.

The Warren synchronous motor (General Electric Company) has been mentioned in the 1919 and 1920 reports. The Committee can now add that two other manufacturers (Sangamo and Westinghouse) have brought out synchronous motors. The tendency of the art, therefore, seems to be to get away from spring-

driven clocks for the measurement of time in various electrical measuring devices and use instead a synchronous motor. It is expected that the future will see continued developments along these lines.

Meters for the measurement of volt-amperes are appearing on the market and have been described in Mr. Fryer's paper, presented at the Midwinter Convention. Your Committee anticipates that the next few years will see continued development along these lines.

In the instrument field for commercial service, the chief tendency shown in the past year has been toward the more general use of smaller instruments. This has been brought about largely by the necessity to conserve space on large switchboards. This demand is being met by practically all of the manufacturers of instruments.

In the 1921 report, a method of testing current transformers developed by Dr. Silsbee of the United States Bureau of Standards is mentioned. This is being offered to the trade by the Leeds & Northrup Company, Philadelphia, Pa. The Committee has been advised that this year another transformer testing device has been placed on the market by the Esterline-Angus Company of Indianapolis.

Several other devices for Laboratory use have been reported to your Committee but these are more in the nature of improvements to existing apparatus and, therefore, have not been described in detail.

In order that the activities abroad in the instrument field may be brought before our members in convenient form, the Committee this year arranged to review and abstract articles appearing in the foreign technical press. This important work has been under the direction of Mr. Iving B. Smith, committee of one, and his report which has been approved by the Main Committee is attached. It is suggested that future Committees continue this work, so that this part of the annual report will constitute in time a valuable historical record of the work in foreign fields.

Subcommittee on Instrument Development in Europe During the Past Year

IRVING B. SMITH

CURRENT AND VOLTAGE MEASUREMENT

Moving Iron Instruments. A comprehensive discussion of the various types of moving iron ammeters, voltmeters, frequency meters, ohm meters, capacity meters and wattmeters. There is considered the relative performance of the different types on direct and on alternating current, the compensation for hysteresis, for frequency variation, temperature variation, influence of external magnetic fields and form of scales.

Dutilh (*Soc. Franc. Elect.* Bull. 1 pp. 387-409, Nov., 1921).

New High-Pressure Voltmeter. A gold leaf electroscope arranged to indicate voltage. The leaf is en-

closed in and electrically connected to a metal case supported by an insulator. A beam of light permits measuring the deflection of the leaf. An earthed plate is placed at a greater or less distance according to the voltage to be measured, and acts on the leaf through an adjustable window. The law relating to the angular deflection (X) of the leaf to the potential (Y) was found to be of the form $Y = ax^2 + bx + c$. The theory of the apparatus is given. Its chief advantages are ease of operation and safety in use.

L. Amaduzzi (*Elettrotecnica* 9. pp. 52-56, Jan. 25, 1922).

Shunted Dynamometer Ammeters. This paper describes a dynamometer ammeter, suitable for a-c. or d-c., reading up to 300 amperes, made by the firm of Carpentier, the instrument possessing several novel features. The fixed coil and the moving coil are put in parallel across a shunt which carries the main current and has a potential drop up to 0.5 volt, the circuits of the two coils having time-constants of about the same order. In order to increase the couple in ammeters intended for less precise work, the coils may contain a laminated iron core. Each coil is in series with a suitable manganin resistance, and in order to reduce the temperature coefficient of the instrument a nickel shunt is connected in parallel with the moving coil and a portion of its manganin series resistance. The instrument is found to be very effectively compensated for changes of temperature, and frequency errors are negligible. To render the ammeter unaffected by external magnetic fields when used to measure direct currents, it is enclosed in a sheet-iron case. The current range is varied by changing the shunt. A description is also given of dynamometer testing sets arranged to measure voltages and currents on alternating current with a precision comparable with that obtained with moving-coil instruments on direct current. A universal dynamometer to measure voltage, current and power is also described. The paper is illustrated by photographs of the instruments, and diagrams of connections are given.

L. Joly (*Soc. Franc. Elect.*, Bull. 2 pp. 291-301, June, 1922).

Modification of Campbell's Arrangement for Measuring Currents of Telephonic Frequency. For measuring currents of telephonic frequency, the simplest arrangement is that devised by A. Campbell. This arrangement is, however, not suitable for measuring lower frequencies in most cases. It is shown how the original arrangement can be modified so as to be suitable for the measurement of frequency over a wide range. The generalized frequency bridge is thus obtained and its principle explained. Some special cases of this generalized bridge are found very simple and satisfactory for the purpose.

S. Chiba (*Inst. El. Eng. Japan*, J. No. 405, pp. 294-300, April, 1922).

CAPACITY MEASUREMENT

Valve Method for Determining Capacity. A small transmitting valve or a receiving valve has its grid and filament connected together. The filament current is measured by an ammeter in circuit. The condenser, whose capacity is to be determined is included in the anode circuit, and a static voltmeter (a Wulf quadrant electrometer) is joined in parallel with it. A sensitive mirror galvanometer serves to measure the anode current. An anode voltage sufficient to give the saturation current in the valve is used; this voltage depends on the filament current; in the experiments here described anode voltages of 300 volts were used, the saturation voltage being about 30 to 50 volts.

The condenser is first short-circuited. On removing the short-circuiting connection the condenser accumulates a charge proportional to the time. The charging current will remain constant so long as the difference between the anode potential and the back e. m. f. of the condenser exceeds the saturation voltage. Measurement of the time t required for the anode current I_a to charge the condenser (of capacity C) to the measured potential V , allows C to be determined at once from the relation $C = I_a t/V$. The method can be used for widely different capacities. In the experiments here described the capacities varied from 0.01 to 1.0 microfarad.

Karolus and (Prince) Reuss. (*Phys. Zeits.* 22, pp. 362-363, June 15, 1921).

Development of Maxwell's Capacity Bridge. It is shown that in a general network of electric conductors, in which there is a galvanometer, together with one or more sources of e. m. f. and a condenser having one set of plates permanently connected to a junction, while the other set is alternately connected n times per sec. to one or other of a pair of junctions, when the variables are adjusted so that there is no galvanometer deflection, the permanently-connected plates of the condenser may be connected to any point in the network without disturbing the zero galvanometer deflection. The theorem is extended to include inductances in the network, and is illustrated by its application to Maxwell's bridge method for determining the capacity of a condenser in electromagnetic units.

V. A. Bailey (*Phil. Mag.* 43, pp. 1107-1112, June, 1922).

CARBON DIOXIDE MEASUREMENT

Carbon-Dioxide Meter. A small motor pumps the flue gas into a measuring chamber and rotates it rapidly. Within the chamber a measuring wheel is taken along by friction. At the same time air is pumped into an identical chamber rotating a similar wheel in the opposite direction. The difference in the two torques can be calibrated in terms of $C O_2$.

W. Waldhansen, A. E. G. Mitteilungen, Aug., 1922.

Carbon-Dioxide Recorder. Two platinum spirals in two separate cells form 2 arms of a Wheatstone's

Bridge. One cell saturated air. Galvanometer of moving coil type. Can be secured either as a recorder or an indicator.

Cambridge & Paul Instrument Co., London, Eng., Nov. 10, 1922.

DIELECTRIC CONSTANT MEASUREMENT

Valve Method of Finding Dielectric Coefficient of a Liquid. Two oscillatory circuits are loosely coupled and their tuning is adjusted until suitable beats are obtained in the anode circuit of one of them. These beats are detected by utilizing condensers, a potentiometer, and an aperiodic galvanometer suitably connected. By altering the dielectric of the condenser across the oscillatory circuit the beat rate changes. The known condenser variation required to restore the original beat rate enables the dielectric coefficient to be computed.

R. Whiddington (*Cambridge Phil. Soc. Proc.*, 20, pp. 445-446, Nov., 1921).

FLOW MEASUREMENT

Recording Flow Meter. A device of H. Tinsley & Co. for recording electrically and at a distance, the rate of flow of water over a weir. Also arranged to integrate the total flow. The method depends upon the depth of immersion of electrodes placed in the water above the weir. The higher the water level the deeper the immersion, and the less the electrical resistance. By specially shaping the one electrode the conductivity may be made a measure of the flow of water. A second similar set of electrodes with constant depth of immersion, excited by the same d-c. voltage, forms part of the "control" circuit. The recording instrument is a "thread" recorder operated by an ohm meter arrangement of circuits connected to the two electrode systems. The deflection is proportional to the rate of flow of water. A simple type of intermittent integrating mechanism is added. The apparatus can be placed at a very considerable distance from the weir, as the currents are very small and the line resistance may be made negligible.

J. of Scientific Instruments, May, 1922.

FREQUENCY MEASUREMENT

Deflection Frequency Meter. The frequency meter described has a very open and long uniform scale. The principle employed is that of a circuit made resonant for a particular frequency, say 50 cycles per sec. Any departure from this frequency causes a deflection of the moving element, which is fitted with soft-iron vanes in the shape of two quadrants set at 90 deg. to one another and subjected to the influence of coils in two parallel circuits (the l circuit and the r circuit), the current in the former of which lags by 90 deg. behind that in the latter. The instrument is now made by Messrs. Nalder Bros. and Thompson, Ltd.

C. L. Lipman (*Electrician*, 87, pp. 458-459, Oct. 7, 1921).

GALVANOMETERS

The Moll Galvanometer is a moving coil instrument with a compact electromagnetic field instead of the customary permanent magnet. It is quick in action and suitable for thermopiles.

J. Scientific Instruments, May, 1922.

High-Sensitivity Galvanometer. Sullivan Type of increased sensitivity made by H. W. Sullivan, London, Eng. 10,000 m/m per micro-ampere for a period of 24 sec. and a resistance of 8000 ohms.

Moving-Coil Galvanometer of High Sensitivity. The theory of the moving-coil galvanometer is considered in this paper, and it is shown how to make a reflecting type of instrument as sensitive as possible. The conditions for maximum sensitivity are $K/K_0 = r/r_0 = H/H_0$, where K = total moment of inertia, K_0 = moment of inertia of coil alone, r = total resistance, r_0 = resistance of coil, H = intensity of magnetic field, H_0 = smallest value of H for which motion is aperiodic. By using a quartz fiber suspension and extremely thin electrolytically-deposited silver strips, hanging loosely on either side of the fiber to produce the resisting torque, a sensitivity of 21 mm. per microvolt can be obtained.

F. Zernike (*K Akad. Amsterdam*, Proc. 24, 6 and 7, pp. 239-245, 1922).

New High-Frequency Vibration Galvanometer. By means of a mechanical device, the vibrations of the reed of a Brown telephone receiver are optically magnified to such an extent that 1000-cycle alternating currents of a few microamperes may be easily measured. In combination with vacuum amplifiers, currents several thousands times smaller may also be measured.

L. V. King (Roy. Soc. Canada, *Trans.* 15 Sect. 3, pp. 143, 1921).

New Form of Thermo-galvanometer. A simplified form of thermo-galvanometer in which the magnetic system of an ordinary Deprez d'Arsonval galvanometer is employed. The moving part consists of two loops in series, one consisting of two thick wires of different metals, the second of two very fine wires of the same metal. The two loops are joined in series so that when the current passes through them, the heat produced in the fine-wire loop, owing to its ohmic resistance, produces a difference of temperature between the two ends of the thick-wire loop. This causes a thermoelectric current to flow round the loop, superimposed on the main current, and thus a deflection is caused. A sensitivity of 1 mm. per milliamperes is attainable with single loops, but the same principle can be applied when multiple loops are used. If one of the metals used in the thermoelectric loop be iron, it is necessary to compensate for the inequality produced in the magnetic field.

A. Competti (*N. Cimento*, 22, pp. 321-322, Nov.-Dec., 1921).

Quick-Action Registering String Galvanometer. A detailed description of the instrument, including reproductions of the records given by it. An investigation

was made of the effect of temperature, and of secular change of the tuning-fork used for regulating the film speed. It was found that the greatest variation in the number of vibrations per sec. was less than 1 in a thousand. It was found also that the absolute error of a single exposure point was less than 0.001 sec.

E. V. Angerer (*Zeits. Instrumentenk.* 42 pp. 1-6, Jan., 1922).

HUMIDITY MEASUREMENT

New Electric Hydrometer. The instrument, which is on the market, consists of a number of thermocouples in series, with alternate junctions in juxtaposition as in a thermopile, one set being covered with muslin which is kept moist with distilled water while the other set is exposed to the air. This arrangement is connected with a galvanometer and acts as a wet-and-dry-bulb hygrometer, the psychrometric difference being indicated by the deflection of the galvanometer. In addition the air temperature is measured by an electric resistance thermometer. The psychrometric difference and the air temperature are actually recorded by the movement of two pointers across a dial on which is engraved a monogram from which the relative humidity is easily read. The recording portion may be at a distance from the psychrometer, and indeed may serve several, being connected with each at will. For use in cases where the air temperature is not required the instrument has been adapted to read relative humidity directly off a single scale, while an autographic recording device has also been devised.

J. Cartus (*Zeits. Vereines deutsch. Ing.* 65, pp. 767-768 July 16, 1921).

INDUCTANCE MEASUREMENT

Direct-Reading Inductance Meter. The method consists in measuring the potential difference at the terminals of the inductance, alternating current being supplied by a magneto, and the potential difference being rectified before being applied to a direct-reading voltmeter. The inductance to be measured is in series with a permanent inductance, which is relatively large. Under these conditions it is shown that the reading of the voltmeter is very approximately in proportion to the inductance under test. The effect of the resistance of the inductance on the result is considered.

R. Barthelemy (*Rev. Gen. d'El.* 11, pp. 419-424, March 25, 1922).

MAGNETIC MEASUREMENTS

Flux Density in Air. Essentially an analytical balance for balancing the force deflecting a short conductor in a magnetic field. Read by means of beam of light and mirror. Claim remarkable sensitivity and accuracy being able to detect a change of 1 line per sq. cm.

W. P. Canby, *Jour. of the Inst. of Elec. Eng.* (British) Jan., 1923.

Magnetic Testing of Permanent Magnets. The paper describes a method of calibrating Hartmann and Braun's apparatus—used originally for measuring apparent remanences—so that it could be employed for determining the part of the hysteresis curve lying mostly in the upper left-hand quadrant. The true remanence, coercive force, and reversible permeability of a number of short cylindrical bar magnets of different qualities are measured by using the method.

J. Wurschmidt (*Zeits. f. Physik.* 10. 2. pp. 91-110, 1922).

LIGHT MEASUREMENT

A Universal Photometer without Diffusing Screen. The principle of the apparatus, the construction of which is illustrated and described in detail, is as follows. A small real image of the source to be measured, placed at a suitable distance, is projected on the eye of the observer, who thus sees a lens uniformly illuminated and forming one of the photometric surfaces. The second photometric surface is formed similarly by the light from a small comparison lamp. The two surfaces are brought into juxtaposition by means of a Lummer-Brodhun cube. Equality of brightness is obtained by interposing a wedge of absorbing material or suitable screens. The apparatus is contained in a small box easily transported. The method has the advantage that any one of a number of sources (such as individual lamps in a room or a street) can be studied separately. In addition it eliminates the great loss in brightness inseparable from the use of diffusing screens. The apparatus can be applied to measure the brightness of a surface, and it has various special applications, notably the determination of the loss of light in optical instruments.

C. Fabry & H. Buisson (*Rev. d'Optique* 1, pp. 1-12, Jan., 1922).

POWER FACTOR MEASUREMENT

Power Factor Meter. The combined electromagnetic effect of the current and pressure windings is such that for any power factor the system takes up a position of neutral equilibrium. The reading is independent of load. Made by Nalder Bros. and Thompson, Ltd.

London Electrician, Jan. 26, 1923.

POWER MEASUREMENT

Remote Power Indicator. The Cambridge & Paul Scientific Instrument Co. produce the Fawsett Indicator used for automatically indicating the power in a three-phase circuit at a distance of several miles. The actual operating circuit is a thermo-electric one making use of a uni-pivot d-c. galvanometer which may be scaled in thousands of kilowatts. Pilot wires laid with the transmission cables may be made use of to carry the current.

London Electrician 88, pp. 71, Jan. 20, 1922.

Differential Electrodynamometer. Method used at the Laboratoire Central d'Electricité for standardiza-

tion of a-c. wattmeters and for power measurements consists essentially in balancing the power to be determined (or a known fraction) against another power which can easily be measured, for example the power dissipated in a non-inductive circuit.

The method is reduced to the measurement of pressure and a knowledge of the value of several resistances. It is a null method not requiring a knowledge of the frequency.

P. de la Gorce (*Comptes Rendus* 174, pp. 607-609, Feb. 27, 1922).

Electrostatic Wattmeter. After a historical review of the quadrant electrometer and its application to the measurement of alternating currents and dielectric losses, the author describes recent improvements by means of which he obtains a sensitiveness of over 400 mm. at 2 meters with 100 volts on the needle and 0.1 volt between the quadrants. This instrument has a good control of the electrical and mechanical zeros. The use of the instrument at 0.1 per cent power factor is considered, and it is shown that an accuracy up to 5 per cent is attainable, using a good wave form and avoiding errors due to surface leakages from the leads and operating switches. It gives results of value on capacities as low as 1/1000 microfarad, working on a 100-volt circuit at 50 periods. The mathematical theory of the instrument is given, and its application to modern precision measurements (as, for example, the measurement of induction) is described.

G. L. Addenbrooke (*Electrician* 88, pp. 466-469, April 21, 1922).

POTENTIOMETER

A-C. Potentiometer. Consists of two potentiometers supplied with alternating current in quadrature with each other. In series with the first potentiometer is a reflecting dynamometer. This allows comparison between the effective values of alternating and direct current. Arrangement is provided for securing perfect quadrature.

H. Tinsley & Co., London, England.

A-C. Potentiometer. Apparatus for measuring the ratio of transformation and phase angle of transformers. Diagrams of theoretical and practical connections are given.

Elettrotecnica 9, pp. 344-346, May 25, 1922.

A Portable Deflection Potentiometer. The author describes a potentiometer in which a millivoltmeter is used instead of a zero galvanometer. The only adjustment of the potentiometer resistance required once the instrument is set, is a rough one to bring the reading conveniently on the scale of the millivoltmeter. Two potential points are taken off the potentiometer resistance, and the derived circuit from them contains the standard cell, or alternatively the e. m. f. to be measured, and the millivoltmeter. In the first setting, the two zero potential points, between which the resistance is r , are used and the series rheostat is adjusted

so that the millivoltmeter reads zero in the ordinary way. The e. m. f. to be measured then replaces the standard cell and the deflection of the millivoltmeter is noted after altering the resistance between the potential points to r' is necessary. The voltage to be measured is then $r' e/r + u + i r' (R - r)/R$ where e is the e. m. f. of the standard cell, u is the reading of the voltmeter, i the current in the derived circuit, and R the resistance of the main circuit). It is shown that the last term may be neglected without appreciable error, and $r' e/r$ is a difference of potential proportional to r' the potentiometer dials may be graduated directly in these terms, so that the value of the e. m. f. to be measured reduces to the sum of the readings of the millivoltmeter and the potentiometer dials. The whole of the dial and other switches, resistances, etc., are arranged in a compact case, which is described and illustrated in the paper. A special form of voltage multiplier enables voltages up to 900 volts to be measured and the resistance that this should have for minimum error is discussed. The exact procedure in use is detailed both for voltage measurement and for that of currents by means of shunts. An accuracy of 1 in 1000 is obtainable in all cases, and in favorable cases a much higher accuracy is obtainable.

A. Iliovici (*Soc. Franc. Elect.*, Bull. 2. pp. 117-136, March, 1922)

TEMPERATURE MEASUREMENT

Optical Pyrometer. A disappearing type of optical pyrometer produced by H. Tinsley & Co. in cooperation with the National Physical Laboratory. A Wheatstone's Bridge arrangement of connections permits of offsetting the scale zero to such an extent as to permit the full scale length to cover any desired range of temperature. Direct reading in temperature with one or more ranges.

J. Scientific Instruments, May, 1922

Total Radiation Pyrometer. Produced by the Foster Instrument Co. and arranged to indicate record or control high temperatures. It is proposed to so construct the control device as to permit holding to any desired time-temperature program.

J. Scientific Instruments, May, 1922.

Total Radiation Pyrometer. Describes a new form of radiation pyrometer in which an image of the radiator is formed on a blackened plate to which are attached two fine thermo-junction wires. The observer has an eyepiece by means of which he ensures that the plate is more than covered by the image of the radiator, and a galvanometer attached to the thermo-element then gives a measure of the heating effect of the image on the plate, i. e., of the temperature of the radiator. Full deflection is generally reached in about 6 to 8 seconds from exposure to the radiation. The instrument is termed an "ardometer."

G. Keinath (*Elekt. Zeits.*, 42, pp. 1384-1387, Dec. 1, 1921).

RESISTANCE MEASUREMENT

New Ohm Meter, the "Meg." Produced by Evershed and Vignoles, London, England. It does not replace the "Megger" entirely but has some advantages in portability and cost. Tests on 500 volts.

Direct-Reading Ohmmeter. A high resistance is placed across the line with a sliding contact near the middle. Connecting a sensitive voltmeter between slider and ground, a point is found giving full scale deflection on the voltmeter. A fixed resistance is then shunted across the voltmeter resulting in the voltmeter reading directly the resistance in ohms to ground.

C. Dufrene (*Revue Generale de l'Electricite*, April 1, 1922).

Direct-Reading A-C. Ohmmeter. The author previously described the use of a magneto in conjunction with a synchronous commutator and moving coil voltmeter for the direct reading of inductance. He applies the same apparatus in the direct measurement of capacity and low resistance by alternating current. It may be used to measure earth resistance with electrolytic capacity and subject to parasitic currents. The measurement is independent of the speed of the magneto. The method has been used for capacities from several microfarads down to two or three thousandths of a microfarad.

R. Barthelemy (*Rev. Gen. d'el.* pp. 891-894, June 17, 1922).

Leakance Bridge. Wagner's method of measuring leakance is only applicable when the cable sheath is insulated from earth. The present article describes (1) a form of bridge in which the effective capacity and leakance under working conditions can be accurately determined when the cable is still on the drum (i. e. with the sheath partially earthed), and (2) a double bridge for similar measurements on cables after laying. The article contains a useful discussion of the action of the earth-capacities of various parts of the bridges and of the generator circuit and shows how their effect is eliminated.

F. Fischer (*Telegr. u. Fernspr. Techn.* 10, pp. 137-140, Oct., 1921).

A-C. Bridge for Telephone Cables. In measuring the a-c. resistance of telephone cables difficulties arise because of the capacities against ground. An improved Wien bridge is suggested wherein an auxiliary resistance which duplicates the bridge branches, makes the arrangement symmetrical against ground. Great accuracy is claimed.

K. Kupfmüller & P. Thomas (*Elektrotechnische Zeits.*, April 6, 1922).

Thomson Bridge. In the usual connections for the Thomson Bridge errors may arise due to yoke resistance and to variable contacts in ratio coils. The author shows how a second measurement may be made and all of the above errors eliminated.

R. Hiecke (*Elek. u. Maschinenbau* 40, pp. 158-161, April 2, 1922).

SPEED MEASUREMENT

Stroboscope. The stroboscope method of calibrating tachometers and regulating governors is in use and has been found to give high accuracy with little trouble.

Oscilloscope. While this is not essentially a speed measuring device, it is for use in the examination of objects when under rapid motion. It depends for its action upon the principle of the stroboscope. Instead of a shutter an "Osglim" lamp and induction coil is used.

A double set of gears permits driving the interrupter from the device whose motion is being studied. In this manner the stroboscope is either maintained in synchronism with the machine being tested or else by means of another set of gears. A slow motion effect may be produced enabling one to study the full cycle of operation of any moving part. It is put out by Herbert Kennedy & Co., Ltd., London, England.

INSTRUMENT TRANSFORMERS

Current Transformer. Everett Edgecumbe Co., England, have produced a portable current transformer having a large number of ranges. It is combined with a small testing set.

London Electrician, Jan. 19, 1923.

Short-Circuit Proof Current Transformer. Paper describes the latest types of "bar transformers" for currents of 300 amperes and up, suitable in secondary energy supply to operate a wattmeter, a relay and a meter. For currents between 10 and 300 amperes a similar type but with a loop as primary is described. This latter type is overload proof. A small spark gap built into the transformer gives protection against sudden overvoltages. Some of the 300-ampere, single-bar transformers have withstood a dead short circuit from a 60,000 kv-a. generator in which a crest value of 114,000 ampere was reached before the circuit breaker opened.

(*Siemens Zeits.*, May and June, 1922), W. Skirl.

Transformers for Measuring Apparatus. Current and potential-transformers for ammeters, voltmeters, wattmeters, and relays must satisfy conditions quite different from those of ordinary transformers. These conditions are separately analyzed, and it is shown that they are satisfied in the transformers of the Societe de la Metallurgique Electrique. Special attention is given to transformers for relays in order to obtain a given time-lag.

V. Candie (*Rev. Gen. d'El.* 11, pp. 193-201, Feb. 11, 1922).

High-Voltage Electric Meter with Fault Indicator. To give warning when one of the fuses on the potential transformer burns out or fails to make circuit, auxiliary windings are placed over the usual potential coils. These serve to light two miniature lamps to unlike intensities if a fuse is out. It is claimed that without

such indication a meter may be registering as much as 70 per cent low for long periods.

A. Kaeppele (*Elektrotechnische Zeits.*, March 9, 1922).

TESTING TRANSFORMERS

High-Voltage Testing Transformer. Describes a 400,000-volt testing transformer set. Based upon the Dessauer principle, one single-phase transformer of 200,000 volts and two single-phase transformers of 100,000 volts each, are arranged in series with their low-voltage windings excited from two-insulating transformers, resulting in a total potential against ground of 400 kv. This simplifies the securing of the insulation of the individual transformer windings against core and ground and guarantees at least a partial testing voltage in case of a breakdown of one of the transformers.

D. Vogelsang (*Elektrotechnik und Masch.*, May 28, 1922).

A 350,000-Volt Testing Transformer. The transformer described is designed to give currents up to one ampere at 350,000 volts, 50 cycles, in view of the appreciable capacity currents required in cable testing at these high voltages. The oil-immersed type was chosen in preference to the open type as affording greater security from the effects of damp, etc., although the latter would have been cheaper and in some ways more convenient. One terminal of the high-tension winding is permanently earthed to the case to which one end of the primary winding is also connected. The primary is supplied at 5000 volts through an auxiliary transformer, on the low-tension side of which all voltage regulation is effected. The secondary is divided into sections so that voltages of 87,500, 175,000 or the full 350,000 can be obtained. During the tests a spark-gap method was used to measure the secondary voltage. Special care was taken in the arrangement of the insulation, which is partly of oil and partly by screens of solid insulating material, as well as the coverings on the conductors composing the coils. The disposition of the coils and insulation is such that the positions of the equipotential surfaces can be calculated easily, and the screens and surfaces where there is a change of insulating material are arranged as far as possible to lie on equipotential surfaces. The magnetic circuit consists of a central core and two return paths. Concentric windings of circular form are employed, with the low-tension windings inside the high-tension windings, and much heavier insulation is provided for the turns near the high-tension terminal than for the rest of the winding; these are altogether of much more substantial construction. The different layers and sections of the windings are separated by carefully placed screens. A special feature of the apparatus is the large, single, high-tension exit terminal, which is of the condenser type, with five concentric metal sleeves separated by a special insulating material. The projecting portion is enclosed in a sort of cylindrical chimney filled up with oil, which projects about 5 feet above the

top of the main case. Excluding this chimney, the case which is cylindrical is about 9 ft. high and about 8 ft. in diameter, and the total weight of the apparatus is 15 tons.

R. Massot & P. Bunet (*Rev. Gen. d'El.* 11, pp. 752-757, May 20, 1922).

TIMING APPARATUS

Electric Timing Device. For short intervals of time. An inductive resistance in a Wheatstone's Bridge employed for calibrating an electrical chronometer.

J. of the Inst. of Elec. Eng. (British), Dec., 1922.

VIBRATION MEASUREMENT

Vibrograph for Turbo-Generator Shafts. Describes the construction and method of use of a vibrograph designed for use on large turbo-generators. The description given is fully illustrated by diagrams, and examples of the results obtained, showing the effect of loading at various speeds, are reproduced in the paper.

J. Geiger (*Zeits. Vereines deutsch. Ing.* 66, pp. 437-330, May 6, 1922).

Measurement of Vibrations of Structures. Describes apparatus designed for studying the vibrations in a building, etc., from the point of view of acceleration. The principle of the method consists in suspending a heavy mass M in such a manner that it makes a very light contact with a surface. The force of contact is adjusted to such a value that the vibration forces are just insufficient to produce separation of the mass from the surface. The additional force f required to produce this separation under static conditions is determined by means of a subsidiary experiment, so that the acceleration y , which is due to the vibration, is given by $f = M y$. Instruments are described for measuring vibrations in the horizontal and vertical directions, and the method of determining the instant of separation is discussed.

P. Prache (*Soc. d'Encouragement*, Bull 134, pp. 177-186, Mar., 1922).

G. A. SAWIN, *Chairman.*

REPORT OF THE COMMITTEE ON TRANSMISSION AND DISTRIBUTION

To the Board of Directors:

The Report of the Committee on Transmission and Distribution for the year 1922-1923 is submitted under the following headings:

1. Report of the Cable Research Committee.
2. Review of Construction Problems in Overhead Transmission and Distribution.
3. Review of Construction Problems and Tendencies in Underground Transmission and Distribution Practise.
4. Testing of Underground Transmission and Distribution Cables.
5. Review of Inductive Coordination.
6. Review of Papers Submitted during the Year.

As has been the custom in previous years, the report of your committee summarizes under the various headings the advances made in the transmission and distribution field during the past year together with future improvements to be expected but not, as yet, fully developed.

REPORT OF THE CABLE RESEARCH COMMITTEE

Maximum Permissible Temperature for Impregnated Paper Insulation. The investigation on the maximum permissible temperature for impregnated paper insulation, which is being conducted by the Massachusetts Institute of Technology for the Research Committee is progressing favorably, and the preliminary investigations have been practically completed. During the course of these investigations it was discovered that none of the existing machines or devices for testing paper were sufficiently accurate to serve as a measure of the depreciation of the paper with heat. Accordingly, the college staff in charge of these investigations devised a new machine for testing the folding endurance of strips of paper, which appears to give very consistent results.

A number of the cable manufacturers have placed orders for similar machines. It is expected that the heat runs on the samples that are available will start very shortly, and a portion of the results should be available during the course of the year. In this connection it is of interest to note that a report recently presented to the Institution of Electrical Engineers, (English) has resulted in raising their maximum permissible temperature from 50 deg. cent. to 65 deg. cent. Private information from some English engineers indicates that a number of the leading engineers in England consider that a further increase is warranted, particularly for low-voltage cables.

Available Supply of Manila Hemp Rope Fiber Paper.

All recent American specifications for high-voltage cable include a requirement that the paper shall consist solely of manila hemp rope fiber stock. Some of the cable manufacturers have found difficulty in getting as much paper as they desired, and apparently the difficulty is due primarily to the shortage of second-hand manila hemp rope fiber ship's hawsers, which is the material from which the cable paper is made. The shortage is due in part to the gradual change from manila hemp rope fiber hawsers to steel hawsers, and partly also to the considerable reduction in international shipping. These causes may result in a gradually diminishing supply of raw material over a period of years, and with the increasing use of high-tension cable, it may be desirable to investigate the use of other fibers for making cable paper. Some foreign companies are using wood pulp paper, or a mixture of wood pulp and manila hemp rope fiber.

Previous reports have related the improvements in the quality of paper insulation that have been secured in the past few years, and the reductions in the thick-

ness of insulation that had been found to be satisfactory with the modern grade of impregnated paper insulation. One company has reduced the thickness of insulation on cable for all voltages by about 50 per cent and the experience in service with the cables having this reduced thickness of insulation indicates that the cable is just as satisfactory in all respects as the older cable with thicker insulation. It is suggested that the purchasers of cable could do much to relieve any shortage in paper that might occur by making a similar reduction in the thickness of the insulation which they specify, as this would reduce the amount of paper required for cable insulation by about one-half.

Dielectric Strength. The leading cable manufacturers have made some marked improvements in the dielectric strength of their insulation, and the present indications are that they will ultimately be able to offer to customers high-voltage cables with just as low a dielectric power factor as any heretofore furnished and at the same time a materially higher dielectric strength. Improvements of this kind should very shortly result in the manufacture of cables for materially higher voltages than any that have heretofore been considered practicable.

One large company is installing this year several miles of single-conductor cable for operation at 44 kv. Another company is installing some single-conductor cable for operation at 66 kv., and a third group of companies is making plans for the trial operation of a short length of single-conductor cable at a much higher voltage. Several of the leading cable manufacturers will cooperate in this experiment. One company that has now a number of miles of 33-kv. cable in service will make a considerable addition to this class of cable during the year, and as the operating results to date do not indicate that the cable is operating at its maximum voltage limit, it is proposed to operate one or two lines about 14 miles in length at 44 kv. The transformers for this trial operation will be so wound that they will permit keeping full load on the cables at either 33 kv. or 44 kv.

In England one company has on order some 3-conductor cable with round conductors, intended for operation at 44 kv., and guaranteed for this pressure. Arrangements are being made, however, for the trial operation of this cable at 66 kv., and in case this experiment is not successful, a trial will be made at 55 kv. Apparently this company, like one of the large American operating companies, is of the opinion that the upper voltage limit of a cable can be definitely determined only by experimental operation.

Investigation of Dielectric Loss and Ionization. An arrangement has been made by the Research Committee with the Harvard Engineering School to make an investigation into the subject of ionization loss and ionization in high-voltage cables, both single-conductor and three-conductor. This subject is also receiving

considerable attention from the leading cable manufacturers, and apparently the investigation is very necessary, for until the nature of the so-called ionization loss can be definitely determined, and this loss materially reduced or eliminated, this particular property of high-voltage cables may be the limiting feature in raising the operating voltage, and particularly so in those portions of the country where the ground temperature during the winter months is below the freezing point.

High-Voltage Tie Lines between Generating Stations. Two of the larger operating companies with stations on both sides of the cities which they serve are seriously considering plans for high-voltage tie lines between their large generating stations, so that these tie lines may make available, in case of an emergency, the spare generating capacity in any one of the several generating stations. In this way spare capacity in one station would be made available at any portion of the system, and the calculations indicate that the reduction in generating capacity would more than offset the cost of such a tie line. The preliminary plans for these tie lines contemplate the line being carried through the outlying districts of the city, in which portions the line when first installed may be in part overhead, but it is assumed that as the cities expand, due to their normal growth and development, these overhead portions may have to be placed underground.

High-Voltage Cable Joints. In impregnated paper insulation, the dielectric strength at right angles to the paper is very much higher than the dielectric strength along the surface of the paper. It is for this reason that the lead sheath of the cable must be trimmed back a considerable distance from the exposed ends of the copper in making the joints. As the voltage increases the length of the joint will have to increase proportionately, and in the case of some of the higher voltages now being considered, the joint may be four or five feet long. Even this length would be materially shorter than that used in England for cables which are armored and buried directly in the ground.

This indicates the desirability of some research in connection with high-tension cable joints for the purpose of determining if changes in the present methods of joint construction can be made which will materially reduce the length of the joint now indicated as necessary for the higher voltages. If such a reduction in length is not possible, then it may be necessary to devise new types of conduit and manhole construction for the installation of the very high-voltage cables.

Dielectric Loss Guarantees. In this country, the leading cable manufacturers have recently been making high-voltage cable with dielectric losses that compare very favorably with the best results obtained abroad. Private advices from foreign engineers, however, indicate that the American manufacturers are maintaining a somewhat wider margin between their average dielectric loss results, and their guarantees, than is

given to methods of avoiding corrosion in the contact-making surfaces of air break switches.

Fuses for higher voltage service are still unsatisfactory in many respects, as has recently been proved by some extensive tests undertaken by operating companies.

Street Lighting Construction. New and improved devices for series street lighting circuits are coming on the market. In overhead work there is noted a tendency toward the abandonment of span construction in favor of long mast arms. The use of insulating transformers for special services, as for instance, where branch loops are carried through trees, or in other hazardous locations, is noted. There is also observed a tendency in some instances toward the employment of pole-type, constant-current transformers of relatively small size, fed from constant potential circuits utilized only for street lighting purposes. This system is said to result in a considerable saving in substation space and pole space and also in fewer outages.

4000-Volt Distribution. While higher voltage distribution continues to increase, nevertheless, 2300-volt and 4000-volt systems remain the general standard for urban distribution. Although 4000-volt, 4-wire distribution has been practised in this country for 25 years or more by some companies, there has recently been noted a tendency toward changing over many 2300-volt, 3-phase, 3-wire or 2-phase, 4-wire to 4000-volt systems, particularly in some of the larger cities which have heretofore preferred the older systems. This movement will probably result in more uniform practices in 4000-volt distribution.

Rural Lines. The rural line problem continues to be one in which economic considerations are paramount. Various means have been suggested whereby this much desired service can be rendered at reduced cost, but always it is necessary to give the closest attention to the maintenance of safe construction. The possibilities of long span construction, having regard to the necessities of climatic conditions, are being recognized, and some cheap but satisfactory lines have been constructed.

REVIEW OF CONSTRUCTION PROBLEMS AND TENDENCIES IN UNDERGROUND TRANSMISSION AND DISTRIBUTION PRACTISE

It has been apparent during the last year that there is an increasing interest in problems connected with the construction and operation of underground systems. This has been brought about by the fact that such systems are becoming larger and the voltages being used are becoming higher.

Some of the causes of trouble on underground cables have been studied and definite remedies have been found. For example, expansion and contraction of cables under various load conditions have been determined and it has been found and quite generally recognized that the most effective way of overcoming troubles

from this source is to construct the duct entrances into manholes in such a way as to avoid undue wear and exposure of cables. The use of concrete duct end bells, permitting cables to be fireproofed well into the ducts and providing broad bearing surfaces for the cables have been found particularly advantageous.

The heating of duct runs is another subject which has been given much attention and it is now generally recognized that duct runs should be so constructed that no cable will be required to dissipate its heat solely by conduction through other ducts. This has had a material effect upon shape of conduit runs, and it is now standard practise for some companies to build their duct runs 2 wide and 4 high, and in some cases build them in the form of a *U* so that each duct can radiate heat directly to the surrounding earth.

The use of the kenotron for routine testing of high-voltage cables with direct-current promises to result in the ability to detect incipient trouble in cables so that weak spots may be removed and the troubles due to cable failures in service largely eliminated. During the year 1922 one company was able by means of such testing to almost eliminate failures in service on a number of 6600-volt rosin oil cables. The method used by this company consists in applying periodically a moderately high-voltage direct current and measuring the variation of current with time. Normally the current decreases very rapidly and approaches a constant value but should it first decrease and then begin to increase it is taken as an indication of incipient trouble and the cable is broken down and replaced at some convenient time. If further investigation proves this to be a general characteristic of all paper-insulated cables, this method of testing should be very important and an extremely valuable one, since the indications are positive, while the application of high voltage which either does or does not break down the cable is undoubtedly a less useful test.

In recent years, but particularly during the last few months, a great deal has been done to improve the reliability of service on a-c. underground distribution systems through the adoption and use of various schemes for connecting distributing mains in multiple. This idea has been developed to the point where the reliability of service from a-c. networks is equivalent to that of generating stations and some companies have even gone so far as to recommend the abandonment of d-c. distribution systems. Recent progress has been such that a number of companies have definitely decided to curtail the growth of their d-c. systems.

TESTING OF UNDERGROUND TRANSMISSION AND DISTRIBUTION CABLES

There have been no innovations or marked changes in the standard practise for testing underground cables since the last report of this Committee, and the general practise continues substantially as described in that report.

The manufacturers are giving more attention to the development of tests for the control of raw products. The rapid increase in operating voltages emphasizes the importance of absolute knowledge of the quality of the materials going into cables and therefore the necessity for careful control of the materials and manufacturing processes.

It is understood that the principal research work of the manufacturers during the past year has been devoted very largely to investigations of those factors which cause variations in the quality of cables and in test results, particularly on high-voltage cables. It is obvious that the advancement of the art must include not only improved average quality but greater uniformity in quality for as operating voltages increase, a lower "factor of assurance" may have to be accepted. A lower "factor of assurance" may be permissible if it is accompanied by a smaller variation in the quality as shown by greater uniformity in the results of the various tests which are made. But much research work is still necessary before it will be possible to secure a thorough understanding and accurate control of the obscure and apparently very sensitive causes of variations which are now experienced.

There has been no change in the standard acceptance testing methods. Most cable, particularly that for high-voltage service, is being purchased under the N. E. L. A. specifications for paper-insulated underground cable or specifications very similar to them, the acceptance tests being carried out as prescribed in those specifications.

There is, however, a feeling on the part of some engineers that in puncture tests of samples graduated time tests should be made. It is well known that the puncture voltage obtained when raising the voltage by 30-second steps, as prescribed by the existing specifications, will be considerably higher than the maximum voltage which the cable will withstand indefinitely. While the determination of the latter value is only practicable in connection with large and important installations, the 30-second period might properly be increased considerably.

The opinion has also been expressed by some engineers that specifications should include a test for thermal resistivity similar to that provided in certain English specifications.

REVIEW OF THE INDUCTIVE COORDINATION

Probably the most outstanding result of the year in inductive coordination was the publication on December 9th, 1922 of the third report of the Engineering Subcommittee, Joint General Committee of the Bell Telephone System and the National Electric Light Association. This report contains preferred detailed practises covering the physical relations between electrical supply and signal systems which, taken with the second report of the Joint Engineering Committee containing detailed principles, forms a basic code for guidance in the

cooperative settlement of specific cases. Due to the complexity of the subject and, in many instances, lack of supporting technical data, these reports necessarily treat the subject in a qualitative manner.

The joint work has now entered upon a third stage of development; namely, the determination of limits or tolerances for inclusion in a subsequent addition of the practises. A Joint Subcommittee on Development and Research, working under the supervision of the Joint Engineering Committee has been organized and is actively working on the determination of mutually satisfactory values for quantitative limits or tolerances in the practises. This Subcommittee is also cooperating for the improvement and extension of remedial measures in general.

REVIEW OF PAPERS SUBMITTED DURING THE YEAR

In the June 1922 issue of the JOURNAL an article on "Rating of Cables in Relation to Voltage" was presented by the Subcommittee on Wires and Cables of the Standards Committee.

After a brief discussion of the need of a comprehensive research on fundamental cable problems, this paper presents summaries of various papers and articles dealing with geometric relations which affect dielectric stress; dielectric failure of air; ionization of gas in solid insulation; dielectric failure of transformer oil; electric properties of petrolatum; residual charge, power factor and associated effects; grading of insulation; and miscellaneous data.

A paper on "Potential Gradient in Cables" was submitted by Messrs. W. I. Middleton, C. L. Dawes, and E. W. Davis in the August, 1922 issue of the JOURNAL.

This paper deals with a discussion of the logarithmic formula as applied to the variation of stress in single-conductor cables, its modifications and the effect of internal heat on the potential gradient. Considerable experimental data and curves, accumulated from many breakdown tests, are given. Results of tests on cables with large ratios of dielectric diameter to conductor diameter are included with the modification of the logarithmic formula as applied to them. Results of breakdown tests on three-conductor cables are also shown and the calculated rupturing stresses are compared with those for single-conductor cables.

In the same issue of the JOURNAL, Mr. Donald M. Simons has contributed an article entitled, "Rating of Cables in Relation to Voltage."

This paper is a bibliography on dielectrics and includes references to articles in periodical literature dealing with the physics of dielectrics from the view-point of energy loss and electric strength.

In the June 1922 issue of the JOURNAL, Mr. D. W. Roper presented a paper on "Dielectric Losses and Stresses in Relation to Cable Failures."

A compilation of the cable failure records covering a period of 18 years on the transmission lines of a large operating company was used by the author in the prep-

aration of this paper. All failures caused by external injury to the lead sheath, lightning, failure on test and all joint troubles are eliminated. The author discusses the remaining failures from the viewpoint of dielectric loss and curves showing the relation of current per conductor, temperature, and watts loss per foot are given. Curves showing the interrelation between critical current, critical temperature and dielectric loss are shown for several sizes of cable. The relation between insulation thickness and dielectric stress is discussed and the present practise of American and foreign cable manufacturers in the matter is pointed out. The conclusion of the writer is that the cable failures considered have been largely dielectric loss failures. It is also pointed out in conclusion that high-voltage cables having a low dielectric loss can be safely operated at temperatures materially higher than are possible with high-loss cables.

A paper entitled "A New Method for the Routine Testing of Alternating-Current High-Voltage Paper Insulated Cable" was presented by Messrs. Howard S. Philips and E. Dean Tanzer in the March, 1923, issue of the JOURNAL.

In this paper the authors present a method developed for the routine testing of cables. The need of a satisfactory routine test is discussed and the development of this method of testing is described. The method of applying this test is explained and the highly successful results obtained by a large operating company in indicating incipient trouble on rosin oil cables prior to failure of the cable is pointed out. Various charts showing results obtained on cables in good condition and those having incipient trouble are given. In conclusion the advantage of this test and the need for further investigation is brought out.

In the June 1922 issue of the JOURNAL, Mr. Donald M. Simons submitted an article entitled "On the Minimum Stress Theory of Cable Breakdowns."

This paper presents a discussion and further investigation of Fernie's theory and data that cable breakdowns are governed by the dielectric stress at the sheath, or in other words the minimum stress. Assuming that the inner layers of insulation may be over-stressed without complete rupture of the cable due to the stable equilibrium of the remainder of the insulation and also that insulating materials have a critical breakdown gradient, the author shows that the direct result of these two hypotheses is that the minimum stress at breakdown is a constant though it is not in itself the criterion.

In the February 1922 issue of the JOURNAL, Mr. Robert J. Wiseman presented a paper entitled "The Apparent Dielectric Strength of Cables."

After a brief discussion of theories previously advanced in connection with the dielectric strength of cables, the author presents the assumption that that which has been considered the dielectric strength of the dielectrics is not the "true dielectric strength" but an

"apparent dielectric strength" which is a function of the radii of the conductor and insulation. Reasons supporting this assumption are pointed out and discussed. Comparison is made of the dielectric strength of cables computed from the same data from four different viewpoints, namely the minimum stress theory, the average stress theory, the increase in conductor diameter theory when $R/r > 2.72$ and the ionization theory. The results are shown and discussed and it is pointed out that the ionization theory appears to apply most satisfactorily.

In the June 1922 issue of the JOURNAL, an article on "Effects of the Composite Structure of Impregnated Paper Insulation on its Electric Properties" was submitted by Messrs. Wm. A. Del Mar and C. F. Hanson.

Electrical networks representing the conditions in cable dielectrics are presented and discussed and a quantitative expression is obtained of the power factor and dielectric loss in terms of the resistivities and specific capacities of the elements of the insulation. The electrical function of the paper in impregnated paper insulation is also discussed and experiments are cited which indicate that the failure of such insulation is due to ionic motion of the oil. The conclusion is drawn that in designing and using high-voltage cable particular care should be taken to impose every possible restraint upon ionic motion in the oil and practical means of accomplishing this are given.

The October 1922 issue of the JOURNAL contained an article entitled "Electrical Characteristics of Transmission Systems" by Mr. Herbert Bristol Dwight.

The author describes and explains a method of making electrical calculations for long constant-voltage transmission lines, taking into account the effect of step-up and step-down transformers and making a direct calculation for the complete system without any trial-and-error procedure. The author uses as a specific example a 220,000-volt, 60-cycle line 200 miles in length with assumed average values of transformer core and condenser losses and gives the solution of the line characteristics. A circle diagram of the line, based on this method and giving results for all loads, is also shown.

"A Graphic Method for the Exact Solution of Transmission Lines" is the title of an article contributed in the November 1922 issue of the JOURNAL by Mr. Collis H. Holladay.

This paper presents a quick method of constructing the vector diagram of a power line, from which it is possible to read directly the voltage, current, power and power factor at either end of the line. The method of constructing the diagram is described and explained. To illustrate the procedure by this method, the calculation for a three-phase line is presented.

Mr. H. Goodwin, Jr., presented a paper on "Qualitative Analysis of Transmission Lines" in the January 1923 issue of the JOURNAL.

The process proposed in this paper is called "Qualitative Analysis of Transmission Lines" because of its

ture. It is also pointed out that in the overpotential test, involving as it does a higher intensity of applied pressure, the insulators passing the test have not been weakened and a part of their useful life sacrificed.

In the October 1922 Issue of the JOURNAL a paper on "Test and Investigations on Extra High-Tension Insulators" was submitted by Messrs. C. Coleridge Farr and Henry E. R. Philpott.

In this paper, the viewpoint of the purchasing engineer is taken with special reference to methods of test for acceptance and tests for porosity and deterioration of insulators. The author's experience with insulators on a 66,000-volt line in New Zealand is described and tests to overcome the many failures due to inherent faults that are either overlooked or "get by" the factory tests are discussed. The methods of test suggested are a measurement of insulation resistance with a 1000-volt megger, a bare flashover pressure at 50 cycles for 15 seconds, a bare flashover at high frequency for 15 seconds, and a porosity test consisting of a hydrostatic pressure of 2000 pounds per square inch applied to the insulator through a strong aqueous solution of fuchsin for approximately a week. A general discussion of these tests is given with the results of their application to several types and makes of insulators including those of British, American, New Zealand, Australian and German manufacture. The conclusions drawn are that insulators for extra high-tension work, before being put into service, should be subjected, individually in the case of suspension units and on each shell in the case of pin insulators, to flashover pressure for a definite period at both high and low frequency; that a percentage of each shipment of insulators should be subjected to a hydrostatic pressure test for porosity; and that insulators can and are being made which will not be overstressed by such tests.

In the December 1922 issue of the JOURNAL, Mr. Karl Willy Wagner presented a paper on "Physical Nature of the Electrical Breakdown of Solid Dielectrics."

This paper deals with the electrical rupture of solid insulating materials and advances the theory that the electrical rupture of solid dielectrics is a phenomenon of overheating by current. After pointing out the general outline of the theory, the author describes the various experiments he has conducted to disclose the nature of the rupture phenomena. The results of these tests are shown and their support of the author's theory discussed.

Mr. Malcolm MacLaren contributed an article on "Lightning Disturbances on Distribution Circuits" in the March 1923 issue of the JOURNAL.

A general survey of the nature and distribution of failures and interruptions due to lightning upon the circuits of a large city supply system is presented in this paper. The subject is treated under three principal divisions, namely, troubles on the 115 to 230-volt circuits, the 2300-volt circuits and the 13,200-volt cir-

cuits. It is shown that line failures on the low-voltage circuits are so infrequent as to be practically negligible and that the blowing of fuses and injuries to equipment on the customer's premises are infrequent with the exception of the house meters. Trouble from meter burn-outs increases with the length of the secondary circuits. It is recommended that a simple spark gap or other equivalent type of arrester be installed on the customer's premises as a part of the equipment in the service box.

For the 2300-volt circuits it is shown that lines running over high ground and open country are more subject to transformer burn-outs and blowing of fuses. It is also shown that damage to exposed lines decreases as the number of arresters increases and that the effectiveness of the protection is decreased with high resistance in the ground connection.

For 13,200-volt aerial circuits it is shown that on lines at a considerable distance from generating points most of the damage from lightning is in insulator breakages but where the line reactance is not sufficient to prevent flow of heavy dynamic current, at the time of discharge, the conductor is often fused, allowing the line to fall. It is recommended that arresters be distributed along the line at not more than two mile intervals and that near generating stations the three arresters of a group be mounted on successive poles and provided with independent ground connections.

"Corona in Air Spaces in a Dielectric" is the title of a paper presented in the September 1922 issue of the JOURNAL by Mr. J. E. Shrader.

This paper deals with the investigation of the formation of corona in air spaces in various dielectric materials, with air spaces excluded as much as possible and also with air spaces of definite thicknesses, extent and location at atmospheric pressure. The author shows the results of this investigation by curves and the variation of power factor with potential gradient. The conclusion drawn is that the potential gradient to produce corona depends on the thickness of the air space and also upon its extent.

In the same issue of the JOURNAL, was an article on "The Action and Effect of Moisture in a Dielectric Field" by Mr. Delafield Du Bois.

In order to get a picture of the action of moisture in a dielectric field the author has assumed a simple hypothetical case and attempts to follow it to its logical conclusion. A pure dielectric of a homogeneous and plastic nature between parallel electrodes and subject to electric stress is assumed. A very small globule of conducting moisture is then assumed to be placed in the dielectric and its action analyzed under constant potential stress and alternating stress.

Following up the analysis the author finds that such a dielectric containing particles of moisture would show absorption and residual charge and many other characteristics of actual insulation. It is also found that

certain unusual test data, obtained while testing cables, could be explained in accordance with his analysis.
E. B. MEYER, *Chairman*.

REPORT OF THE LIGHTING AND
ILLUMINATION COMMITTEE

To the Board of Directors:

Following the established practise, the first part of the Committee's report reviews the year's activities of the Committee, while the latter part is devoted to the progress of the art.

COMMITTEE ACTIVITIES

In the organization meeting held October 19th, 1922, plans for the year were outlined and the work of the Committee assigned to individual members.

In the second meeting held on February 14th, 1923, the progress of the work was approved, and the possibility of starting new activities discussed. Prof. Scott pointed out the desirability of encouraging further publicity along the line represented by Illumination Items. At the request of the Committee, he is looking into the question with the view of recommending activity on the part of the Committee.

The leading established activities of the Committee are the arrangement for convention papers and the department of Illumination Items, contributed to the JOURNAL of the American Institute of Electrical Engineers.

Convention Papers. Dr. Shackelford, with the assistance of other members, has taken charge of the Committee's work in supplying suitable papers for conventions. The interest of the Association membership in lighting is such that it has seemed desirable to provide papers of broad general interest rather than those appealing particularly to specialists. Likewise, it has seemed preferable to present a small number of papers at each convention rather than grouping a larger number less frequently, and such a plan has been followed by the Committee.

At the Pittsburgh convention, a paper on Theatre Lighting by Messrs. Mott and Jones was presented. A paper on Incandescent Lamp Quality by Messrs. J. W. Howell and H. Schroeder is arranged for the June convention.

Negotiations are well under way with a number of authors for papers ranging from street lighting to railway signal lighting. These will be available for next year's committee, and are likely to provide for all the convention time available to this phase of the Association's activities.

Illumination Items. Last year's Committee initiated the plan of contributing a section to the JOURNAL made up of short articles on timely topics, presented in a form to interest engineers who do not specialize on lighting. This department has been continued during the past year and the inquiries received seem to indicate an

increasing interest on the part of the readers of the JOURNAL. Mr. W. M. Skiff has taken charge of collecting the material for this purpose, and he has been assisted in this connection by various members of the Committee. In the twelve numbers of the JOURNAL, including that of May 1923, fifty columns of articles have appeared. Ample material has been maintained on hand at the General Office. In addition, many shorter articles have been placed at the disposal of the Editor for use as fillers.

LIGHTING PROGRESS

There has been a considerable revival of interest in lighting growing more and more apparent since the first of the calendar year. Many new installations are being made and old ones are being revamped, these changes being accompanied with a tendency toward higher standards of illumination.

Perhaps the best numerical indication of lighting activity is the relative sale of incandescent lamps. The year 1921 recorded a slump of about 20 per cent in the number of so-called "large" incandescent lamps sold, as compared with 1920.

The figures for 1922 show a full recovery. While the number of lamps sold, viz.: 203,000,000 is slightly less than in 1920, the total wattage and lumen capacity is higher.

The relative quantities of large lamps sold for the last three years are as follows:

	Year		
	1920	1921	1922
Relative number of incandescent lamps.....	100	78.5	97.5
Relative total lumens or candle-power.....	100	85.6	118.
Relative total watts.....	100	81.	102.5

In addition to the large lamps, about 85,000,000 miniature lamps were sold in 1922.

Illuminants. There was considerable development in manufacturing methods and ingenious machinery for incandescent lamps, which, among other things, make for simplicity and flexibility in meeting changes in demand. Along with these improvements, it has been found more practicable to make tipless lamps and some types are being changed to this form.

The specifications for incandescent lamps have been changed to average lumens throughout life. Since lamp quality is independent of rating, this provides a measure of excellence, which is universally applicable, and therefore, is a strong influence toward the production of better lamps.

Slight changes have been made in the larger sizes of sign lamps to increase the end-on candle power.

There has also been some development in the application of tints and colors to lamps by the coating with refractory material forming a diffusing surface.

A number of 30,000-watt incandescent lamps were made and used for experimental purposes. These demonstrated the practicability of building much higher power lamps than at present, but in the absence

of a sufficient demand, they are not being commercialized at the present time.

Arc lamps are still being used to quite an extent in street lighting, especially for the "white way" lighting and some improvement has been made in electrodes and in light controlling equipment, resulting in increased effectiveness.

There has been considerable experimentation along various lines of so-called gaseous conductor illuminants, although no predominating practicable development has been reported.

Lamp Equipment. The term "luminaire" as a broad designation for a lighting fixture or lighting unit was mentioned in last year's report. It has been approved by a number of electrical groups and is receiving considerable use. It is still too new to tell whether or not it will ultimately predominate in this country. Reports from Europe indicate that it is looked upon with favor there, and so has the possibility of world-wide adoption.

A considerable number of new equipments have been developed and put on the market. Few of these embody radical changes or new lighting principles.

A new type of industrial unit consists of a combination of diffusing globe with a steel reflector. This unit gives excellent diffusion, minimizes glare and has a relatively high utilization of light. The enclosing globe not only permits the use of clear bulb lamps, but also minimizes dust accumulation and facilitates cleaning. While its higher cost may prevent its application to as broad a field as the *R L M* reflector, its merit seems likely to assure wide use in the better classes of installations. This luminaire is being furnished by several manufacturers under the trade-name of "Glassteel."

Several new forms of prismatic reflectors have been developed.

The tendency toward the use of squat globes having a large diameter compared to the depth, seems to be extending rapidly, a number of new makes having been brought out.

The luminaires having imitation candles or otherwise employing diffusing round bulb lamps, are still being shown prominently for home lighting. Quite a variety of supplementary glassware is being presented to further diffuse the light of such equipment. Where this glassware is applied, it is quite practicable to use clear bulb regular lamps and thus save the additional cost of the somewhat special round bulbs.

The portable floor and table lamps are finding considerable use in home lighting and, to some extent, are being applied in other classes of artistic lighting. The indirect and semi-indirect types of portables are being utilized in rapidly increasing numbers.

Some of the recent developments in glassware and shades indicate a growing interest in tinted light.

Street lighting practise indicates the growing popularity of the ornamental types having single light pole top lanterns. Where formerly the use of such equip-

ment was more or less limited to so-called "white-way" districts, they are today being used throughout the cities and notably in residence sections. The four and five light ornamental standards which were so popular a few years ago, are in many instances being changed over to the single light arrangement, some manufacturers having developed parts to facilitate the transformation. For highway lighting, in addition to the unit reported last year, at least two new equipments have since been developed. A rapidly growing demand has been reported.

To facilitate the selection of street lighting units, several manufacturers have made extensive installations of various ornamental equipments from which an excellent idea of appearance may be obtained, either lighted at night or cold in the daytime.

A number of developments are being made to increase the flexibility of control of electric lighting circuits, these include mercury switches for distant operation and carrier-current control.

Practise. The practise in lighting is still advancing rapidly toward higher illumination levels and better diffusion, with the result that effectiveness of illumination is being more harmoniously combined with artistic effects. Each advance suggests greater possibilities of the future.

School lighting is still one of the active fields. While most of the new installations represent acceptable practise, there is still a need of revamping of most of the older installations in the interest of conserving the eyesight of pupils, especially during evening sessions.

More interest in improved home lighting has been shown during the past year than ever before.

Store lighting is always a leader in practise, due to its close relation to profitable merchandising. During the year, attention has largely centered around the show window. Investigations reported have shown, by actual statistics, the increased drawing power of brightly lighted windows and of colored light. It has also been shown that higher intensities than previously used are effective in overcoming the distraction of external reflections in window glass, both by day and by night. The new practises are making liberal use of color and spotlight effects, used much as they are applied in theatrical stage lighting.

The year has witnessed considerable activity in theatre lighting and art gallery lighting, both of which have been subjects of papers and reports. Rather novel lighting effects were employed by a German Opera Company which toured the eastern part of the country during the past season. Most of the equipment employed is not applicable to the conditions existing in the United States, although certain features are of considerable interest.

Surveys of industrial lighting practise have been reported, including food industries, laundries, textile mills, etc.

The United States Public Health Service has con-

ducted an investigation of lighting conditions in the post offices. Results have been reported in the technical press and elsewhere. They indicate that the standards now in use are considerably below those necessary for welfare and economy of operation.

The sign lighting field has been stimulated quite remarkably during the past year and a number of stupendous signs, involving rather novel features, have been erected. The power requirements of these are especially heavy in the brightly lighted metropolitan areas, due to the rather large lamps necessary to produce a conspicuous effect. Some of the signs represent lighting loads equivalent to those of towns of one or two thousand population.

Due to data presented on the relation of wall finishes to lighting effects, a number of the paint manufacturers have actively taken up the problem of painting for light and are promoting recent improvements.

Street lighting is still receiving considerable attention. The mounting number of traffic accidents is evidence of the need of better illumination, while the value of improved appearance is better appreciated. Highway lighting has been extended with remarkable rapidity. It is making night driving on interurban highways safer and more convenient. Where travel is heavy, headlights alone are not entirely adequate.

Many special applications have shown increased activity, among these may be mentioned railway signaling and aerial navigation.

For quite a number of years, horticulturists have evinced considerable interest in the application of artificial light to the control of plant growth. As the result of these investigations, the art appears to be approaching a practical state. A very comprehensive and elaborate project is nearing completion. An experimental laboratory has been so designed that factors, such as temperature, moisture and carbon dioxide contents, as well as the artificial lighting, can be accurately controlled. In this instance, it will be possible to obtain higher intensities of artificial light over relatively large areas, than ever before used.

Codes and Standards. Last year mention was made of the adoption of the Illuminating Engineering Society's Industrial Lighting Code as an American Engineering Standard. Since then the Motor Vehicle Lighting Code and the System of Nomenclature and Photometric Standards have been similarly approved.

The State of Massachusetts determined to set about enforcing the motor vehicle rule that tail lights must be such as to render registration plate numerals visible at 60 feet. An investigation revealed that practically none of the equipment in use was complying. At the request of state officials, a joint committee of the Illuminating Engineering Society and the Society of Automotive Engineers formulated specifications. The enforcement in Massachusetts started January 1, 1923, and it is understood that similar action is being under-

taken in each of the states represented in the conference of motor vehicle administrators.

Committees of the Illuminating Engineering Society are revising the School Lighting Code put out in 1918 by that organization. A sectional committee is being organized under a joint sponsorship of the American Institute of Architects and the Illuminating Engineering Society to consider establishing the School Lighting Code as an American Engineering Standard.

Another lighting project which is active in the American Engineering Standards Committee is that of colored signal lights for traffic and other purposes. A conference of all interested groups, which was held last summer, showed a strong demand for such action.

The world standardization of incandescent lamp bases was the subject of extensive discussion at the recent meeting of the Electrotechnical Commission held at Geneva. The tendency seems to be toward the adoption of the Edison base, which has been known abroad as the American base. The changes involved are principally with regard to details of screw threads of both lamp bases and sockets.

The meeting of the International Commission on Illumination is scheduled to be held in the United States in 1924. Preliminary plans have been made, although arrangements have been somewhat delayed by the unsettled conditions abroad.

Education. Lighting education is playing an important part in the "Electrify" movement of the Joint Committee of the electrical industry, to inform the American Public regarding the advantages of electric service. In connection with this movement, a rather comprehensive book on incandescent lighting practise has been issued.

The Lighting Sales Bureau of the National Electric Light Association has felt the need of more trained illuminating engineers in the employ of central station companies. A committee has been organized to encourage the employment of such engineers and provide, in cooperation with the Illuminating Engineering Society, for a suitable training course.

The Chicago Section of the Illuminating Engineering Society, in cooperation with the Armour Institute and the architectural societies, conducted a course on lighting for architects in Chicago and the Illuminating Engineering Society has organized a general committee to encourage and guide similar activities elsewhere. This committee has outlined courses for architects and contractors.

To educate school children in the correct use of the eyes, field representatives of the Eyesight Conservation Council of America have been giving illustrated talks in the grade and other schools in various sections of the country. The relation of lighting to eye protection is being stressed.

Evidence is plentiful of the expanding public interest in better lighting. Not the least of this is the insistent demands upon the few lighting service departments for

demonstrations and lectures. These requirements are taxing the capacity of the limited number of illuminating engineers available. The demonstration method of creating interest and giving instruction has proved its value.

One manufacturers' organization has been very successful in impressing the principles of good lighting by means of dialogues depicting their application to particular situations.

All in all, the year may be characterized as one of healthily increasing progress.

G. H. STICKNEY, *Chairman.*

REPORT OF THE POWER STATIONS COMMITTEE

To the Board of Directors:

SCOPE OF THE COMMITTEE

"The duties of the technical committees" having been defined by the Secretary of the Institute as "the promotion and coordination of Institute activity in their respective field," the scope of the Power Stations Committee has comprehended four main activities:

First. Routine analysis and recommendation of papers submitted by the Meetings and Papers Committee.

Second. Securing of papers on subjects related to the committee's jurisdiction for publication in the A. I. E. E. JOURNAL.

Third. Special research investigation with reports and papers resulting therefrom.

Fourth. Resumé of the year's progress on power station work.

ACCOMPLISHMENT

During the past year the first activity has been carried out as occasions presented. As to the second, various papers have been secured on the initiative of the committee. As to special research work, of the various suggestions made it has been found that only a few could be favorably considered at the present time, although it is believed that this work of the committee will in future years bring substantial results to the Institute and its membership.

Emphasizing the point raised in last year's report of this committee, that A. I. E. E. committees should deal rather with the scientific and technical aspects of problems, while leaving to other national societies, like the National Electric Light Association, American Electric Railway Association and the Association of Edison Illuminating Companies, new developments and their application, it is believed that much greater benefit to the Institute and its membership may be secured through the agency of this committee if it may receive from the membership at large suggestions covering (a) desirable papers for presentation to the Institute, (b) special lines of technical research such as might be carried out most readily in specially equipped laboratories, (c) test results or (d) information best procur-

able from operating power stations. Should such suggestions through inadvertance cover subjects more properly handled through other societies' committees, there is provided through the Committee on Coordination a medium for the proper allocation of the work, at the same time affording to all Institute membership an opportunity to secure assistance possibly unavailable without such freedom of suggestion. In like manner the related committees of the other societies have arranged to refer to the Power Stations Committee problems requiring special technical or scientific treatment.

RESUME OF THE YEAR'S PROGRESS IN POWER STATION WORK

It is scarcely possible to attempt to review power station progress without trenching upon ground covered by the 1923 reports of the Electrical Apparatus and Prime Movers Committees of the N. E. L. A. and the Power Generation Committee of the A. E. R. A. to which particular reference is made for a wealth of information and detail. Certain points, however, will be emphasized here.

TEMPERATURE INDICATORS

Temperature indicators installed for many years back have been of the resistance coil or thermocouple type, arranged for occasional use or at periodic intervals. Later switchboard type instruments for indicating temperatures were used in many stations, but recently an insistent demand for an accurate curve drawing instrument has been met and many are now in operation both on steam and water wheel driven units. Troubles of various sorts with the detecting coils or couples appear to have been largely overcome by more careful and substantial construction and stronger armor particularly at lead exits.

TEMPERATURE STANDARDS

Papers and discussions presented at last year's A. I. E. E. Convention as a result of cooperative tests by manufacturers and operators on various large generators presage an early revision of existing standards so that the present maximum temperature of 150 deg. cent. for class B insulation will be reduced to 125 deg. cent. and a single type detector standardized consisting of a twenty inch resistance coil instead of the present choice between coil and couple. In case of turbine generators this seems likely to be accompanied by a change in design employing radial ventilation.

TURBINE GENERATOR UNITS

For the past two years very complete analyses of the performance of the seventy odd largest steam turbines units have been made by which both users and manufacturers of turbines and generators, alike, have benefited through elimination of defects shown to be inherent, and through improvement in design for future construction.

The advance in the size of generators is notable in

those being produced for the Hudson Street Station of the Brooklyn Edison Company and the Crawford Avenue Station of the Commonwealth Edison Company having a capacity of 62,500 kv-a. at 80 per cent power factor. While not immediately affecting generator design or characteristics, it is not improbable that the present tendency toward higher steam pressures and superheats, and suggestions looking toward furnaces in which refractory material is substantially replaced by water tube surfaces, may bring about a unit type of power station from the boiler to the bus which will have material influence on generator design. For several new stations main turbines are under construction for operating pressures of 550 pounds per square inch and total temperatures of 725 deg. fahr., and smaller trial turbines are being built for pressures of 1000 to 1200 pounds.

The lubrication of steam turbine generator units has long been a source of anxiety to many of the most careful operators. Until recently the subject has not been approached in the spirit of scientific analysis which its importance warranted. Within the past year through the agency of the Prime Movers Committee of the N. E. L. A. arrangements have been perfected in cooperation with the representatives of the Bureau of Standards, manufacturers of lubricating oil, and the turbine builders whereby a tentative set of specifications previously drafted will be tested by oils taken from many of the most important units in the country to determine whether these specifications impose all the necessary and sufficient conditions for purchase. It is believed that this step marks a distinct advance in the state of the art and will produce information of permanent scientific value for power stations.

WATER WHEEL GENERATORS

The race for size is close between the water wheel and the turbine driven type; the year sees the construction of both types in the gigantic capacity of 65,000 kv-a. and voltages around 12,000. In the case of the Niagara Falls Power Company's machines guarantees for generator efficiencies have reached the remarkable figure of over 98 per cent so that in combination with their transformers an efficiency of 97 per cent is obtained. This installation is noteworthy, among many other features, in suspending with the added weight of the water wheel from a single Kingsbury bearing 69 inches in diameter a total weight of over 1,100,000 pounds; there is further interesting provision in the case of each main unit for mounting an auxiliary a-c. generator on the shaft to supply power to an auxiliary bus from which through a motor generator set excitation to the main unit is secured.

FLY WHEEL EFFECT IN WATER WHEEL DRIVEN A-C. GENERATORS

In the application of the a-c. generators for water wheel drive, the flywheel effect (WR^2) required for speed regulation or other reasons is an important factor

in the first cost of the generating equipment. As it is important to keep the initial investment in a hydroelectric installation to a minimum, a more general appreciation of the effect of WR^2 on the initial cost will be beneficial to the industry, particularly in the case of moderate and small capacity low head propositions.

Standard designs provide a value of WR^2 which general experience has proved satisfactory. By various means, involving either the addition of weight to the generator rotor, the use of flywheels or possibly a combination of both practically any requirement within reason can be met, but the investment is correspondingly increased, not only due to the increased cost of materials entering into the unit but also due to the special design involved.

The value of flywheel effect required in a water wheel generator installation is primarily a question of application and not one of generator design. The generator design, however, is affected. A study of the application involves a knowledge of the hydraulic setting, the electrical system layout, number and size of units, ratio of actual load fluctuations to size of system and the service expected of the generator. With these factors in mind the value of flywheel effect needed or the effectiveness of the value recommended by either the generator manufacturer or the water wheel builder can be determined. Such an analysis is particularly pertinent to the moderate capacity open flume setting where it is primarily a question of speed regulation, and the matter of stresses in penstocks or wheel casings are not controlling, as in such cases it is often found that the operating condition of from 10 to 30 per cent load change rather than the 100 per cent load change, which common practise takes as the basis for guarantees on speed regulation, a difference of from 1 to 1½ per cent in speed regulation will often show from 5 to 15 per cent saving in cost in the generating unit.

It is recommended that this matter receive more generally the consideration that experience warrants should be given to it, as by so doing it will clarify what is often a more or less obscure factor, but one that is always involved in hydroelectric applications.

SMALL ALTERNATING-CURRENT VERTICAL WATER WHEEL GENERATORS

In the past few years the smaller isolated, automatic, low head hydroelectric station has become of increasing importance, as it offers an economic and cheap means of developing the country's water power in many parts of the country. Also in some locations the larger developments have been made, but there still remains a large number of small developments awaiting suitable equipment for an economical utilization of the power. Many of these smaller developments are located close to load centers and, therefore, tend to more economical development than the larger water powers located at distant points with their attendant high cost of transmission.

The vertical unit has established itself as the most practical arrangement for the small and moderate-capacity low-head hydroelectric plant. Very definite requirements are placed on the generator for these installations. It must be economical in first cost and performance, of design proportions and arrangements to fit the modern hydraulic setting, and it must have the same factor of safety in design and reliability in operation required of the larger units.

Complete lines of such small vertical water wheel generators have been designed.

FIRE FIGHTING

The occurrence of frequent generator fires in past years led many companies to install apparatus for fighting fires, either by water or by steam, with provision or more recent machines whereby automatic differential relay apparatus as installed for the purpose of protection against internal grounds or short circuits by opening armature field circuit breakers could also be made to shut off any outside supply of air and if desired trip the turbine throttle. Within the year by concurrence between the Fire Underwriters Electrical Bureau and representatives of the N. E. L. A. the first steps have been taken toward the establishment of any definite requirements. The present general recommendations are included in the 1923 report of the N. E. L. A. Electric Apparatus Committee.

CLOSED VENTILATION SYSTEMS FOR GENERATORS

During the past year several companies, notably those at Hartford and St. Louis, have conducted extensive tests on the injection of inert gas into a closed circuit system for smothering incipient fires, the gases used being carbon dioxide and nitrogen, with preference at present lying in favor of the former. The earlier closed systems used air coolers of the spray type and so satisfactory has been the performance that one important company has decided in future installations to abandon the use of louvres or doors by which the closed system could at will be converted into one of straight-through ventilation.

The outstanding progress of the year in this field has been the successful operation for several months in the Amsterdam Station of the Adirondack Power and Light Company, as well as several instances abroad for even a longer time, of the so-called radiator- or surface-condenser type of air cooler, where cooling water passing through what is practically a surface condenser absorbs the heat of the generator air; multiple metal disks or fins of about $\frac{1}{2}$ -in. radial depth to the tube and spaced from 5 to 11 to the inch afford a heat transfer sufficiently great to prevent the cost of the apparatus becoming prohibitive. A further advantage is found in the hanging of the condenser units directly below the generators so as to reduce to a minimum the volume of enclosed air with the consequent diminution of the risk of entire combustion of windings in case of fire, and concomitant ease and economy of fighting with inert gas the fire

when once started. Many other installations are either under course of construction or consideration.

GENERATOR VOLTAGE REGULATOR

When a station is on hand operation, the field is manipulated to keep a constant alternating-current voltage, and the exciter is kept at a constant voltage. Therefore, if a regulator operated this rheostat through the medium of a motor, the station would function the same as if it were on hand operation.

Heretofore, the difficulty with a regulator that operated the field rheostat directly has been sluggishness and the inability to prevent hunting when the rheostat was operated at a high speed due to the inertia of the moving parts. These difficulties have been overcome and rheostatic type of regulator has been in service for over twelve months in a large steam power station.

It is often desirable to operate a synchronous condenser used for voltage control at the end of a transmission line, over a wide range of lagging and leading kv-a. In order that the condenser may take a heavy lagging current from the line, it is necessary that its field current be reduced to very low values. This low current in turn requires that the voltage across the collector rings of the condenser be reduced to, in some cases, as low as 3 or 4 volts.

The standard broad range vibrating regulator (alternating-current control type) is able to control the exciter voltage down to a point approximately the residual voltage of the machine. If an attempt is made to lower the exciter voltage still farther, the regulator contact remain open permanently, thus inserting the entire rheostat in the exciter shunt field, but the exciter voltage, of course, cannot drop below that corresponding to residual. This residual voltage is, in general, many times that required across the condenser collector rings under maximum lagging conditions.

A special broad range regulator has been developed which is capable of working over the wide range required, consisting of a combination of the standard vibrating regulator, which operates on the exciter rheostat, and a motor operated rheostatic regulator which operates on the main field circuit of the condenser.

In the Hell Gate Station in New York, all main generating units are designed with direct-connected exciters. In order that stable exciter operation can be assured or at least the possibility of unstable operation reduced to a minimum, the exciter is operated throughout its stable voltage range and resistance inserted in the generator field for low voltages. This is accomplished by a unique combination of exciter and generator field rheostats. The rheostat face plate is divided into three sections. The first thirty-eight steps operating in the exciter field rheostat bring the exciter voltage to a predetermined minimum stable operating condition. From this point or over the middle section, the generator rheostat is in operation, and as soon as the generator rheostat is cut out, the exciter voltage is

a change in voltage to 220,000 volts, in order to handle the increased power from Big Creek to the Los Angeles districts. The only equipment necessary to make this change has been additional insulator units with strings equipped with static shields and auto-transformers to step up from 150,000 to 220,000 volts. The transformers will have graded insulation and will be considered as part of the transmission system, there being no breakers on the high-tension side.

SYNCHRONOUS CONDENSERS

In connection with large distribution systems, the importance of good regulation through control of power factor is well recognized. For this purpose, synchronous condensers have come into general use on long transmission lines; well over 150,000 kv-a. in units of from 10,000 to 30,000 kv-a. capacity, have been installed in the immediate past by three Pacific Coast companies alone; the use of all sizes, however, down to as low as 50 kv-a. is rapidly extending.

All synchronous condensers of modern design are arranged for a-c. self starting. On units of 5000 kv-a. and above, considerable saving can be realized by introducing oil pressure into the bearings before starting so as to lift the rotor in the journals. In addition to the saving in size of starting auto transformers the power demand upon the system is materially lessened which may be very desirable with limited generating capacity.

AUTOMATIC EQUIPMENT

The installation of automatic hydroelectric power stations has been signalized the past year by the operation of the Searsburg, Vt. station of the New England Power Company with a generator of 5000 kv-a., the largest unit in such service. This station is completely automatic including operation of hydraulic governors, and is more completely described in articles included in the bibliography.

Further tendencies in this direction are shown by the equipping by the Southern Power Company of some of their larger generators, normally manually operated, with automatic attachments so that the moving of a single switch by the operator serves for a complete shut down of the unit and its auxiliaries. Further possibilities for the power station have been developed during the year in the installation by the Alabama Power Company of automatic switch closing devices by which the circuit breaker is closed several times in predetermined cyclic succession after the initial opening of the circuit for whatever cause.

SWITCHES AND CIRCUIT BREAKERS

The year has seen developed for both manufacturers and operators decided preference for the "dead" type of circuit breaker which is now standardized for the newer and heavier duty apparatus. Previously inaccuracy was the bane of the bushing-type current transformer, but the New Hudson Avenue Station of

the Brooklyn Edison Company is installing on its circuit breakers bushing-type transformers designed to be accurate for both operating and metering purposes.

The truck type of circuit breaker for both power house and substation has seen notable progress during the year in power house installation, as well as the allied type—also to be installed in the new Brooklyn Station—by which the tank, cover and auxiliary mechanism are first lowered so as to disconnect from the bus or feeder, rendering the parts innocuous for inspection or repairs and obviating the use of disconnecting switches.

BUS STRUCTURE

The outstanding development in recent bus and cell structure construction has been isolated phases which were brought about a year ago in the Hell Gate and Calumet Stations with segregations effected in each by horizontal arrangement of the three phases, whereas during the year installations have been made with vertical phase separation in the Cahokia Station of the St. Louis Company, the Hudson Avenue Station of the Brooklyn Edison Company, and in additions to the switching equipment at the Westport Station in Baltimore, O Street Station of the Boston Elevated, and the South Street Station of the Narragansett Electric Lighting Co. in Providence.

REACTORS

No outstanding developments have taken place other than a realization by manufacturers and operators alike that further increases in staunchness and arcing distances must be provided to secure necessary reliability of service; the more recent designs incorporate such improvements.

DISCONNECTING SWITCHES

Aside from designs improved for more staunchness and greater margin of safety for current-carrying capacity as a result of tests which demonstrated a year or more ago the inadequacy of the existing designs, the chief advance has been the development of improved types of mechanical interlocks of disconnecting switches and their associated circuit breakers.

BENCHBOARDS

For the first time benchboards have been constructed of metal instead of slate or stone previously used; with the tendency in large stations for only low voltage control on the board itself, metal construction affords obvious advantages.

TERMINAL ROOMS

While used in some stations for many years, there has only very recently developed a general tendency to provide a terminal room for all control cable and wires reaching to the switchboard so that utmost flexibility, ease and dispatch may be afforded for inspection and repair or replacement of any necessary parts. This appears to be a development of real importance for future power houses of major size.

LIGHTNING ARRESTERS

For power station use as well as substation a new type of arrester is offered called the Autovalve Type consisting of a gap backed by columns of disklike conducting material with intervening strips of mica and functioning by ready discharge of current at over-voltage but arresting a subsequent dynamic flow.

VENTILATION

The subject of ventilation has received during the year special treatment in the reports of the Prime Movers and Electric Apparatus Committee of the N. E. L. A. to which reference is made for considerable data emphasizing the importance of the subject for future power house design, especially where it is desirable to utilize all air flow in the furtherance of better economy in station heat balance. It would appear that this subject has received in the past very inadequate attention and largely by reason of the many inherent difficulties. Much research work appears to be in order.

ILLUMINATION OF POWER STATIONS

During the year a movement has been started through the agency of the Electric Apparatus Committee of the N. E. L. A. and the Society of Illuminating Engineers for a careful and much needed study of the subject, and reports of value may be expected in the near future.

RADIO

The increasing use of transmission of intelligence by radio by power companies for inter-communication between power stations and out districts, and for general purposes of load-dispatching has led to the opinion among many engineers that future system inter-communication will be entirely accomplished by this means, particularly in view of the progress that has been made through carrier service on transmission lines. At the same time the United States Government regulations at present existing impose hindrances and possible embarrassments that merit attention on the part of power stations contemplating the use of such service.

COMMITTEE ON COORDINATION

Last year's report referred to the organization of the Committee on Coordination which has functioned this year through two meetings and requisite correspondence. The chief usefulness of such a committee consists in its ability to function upon occasion on the initiative of some of its represented member societies and it will probably not originate activities, at least, as long as its status remains unofficial.

The personnel of the Committee on Coordination until otherwise determined consists of the chairman of the respective national societies' committees represented and not of certain individuals. As a very helpful step toward justifying its *raison d'être* committee members exchange minutes of their respective national committees with any necessary correspondence. The Chairman of the Power Stations Com-

mittee of the A. I. E. E. is *ex-officio* chairman of the Committee on Coordination.

During the year it became evident that the work of the committee would be greatly furthered if there should be a representative on it from the American Society of Mechanical Engineers, and by the authority of the President of the A. I. E. E., the Chairman of the Power Stations Committee was instructed to present this matter to the officials of the A. S. M. E., who have appointed as their representative the Chairman of their Professional Division.

The present membership of the Committee on Coordination is made up of the following Committee Chairmen:

American Society of Mechanical Engineers, Professional Division

Association of Edison Illuminating Companies, Turbines and Generators

American Electric Railway Association, Power Generation

National Electric Light Association, Electrical Apparatus

National Electric Light Association, Prime Movers

American Institute of Electrical Engineers, Electrical Machinery

American Institute of Electrical Engineers, Protective Devices

American Institute of Electrical Engineers, Power Stations (Chairman)

The Committee is endeavoring at present to arrive at agreement by the represented societies on a definition, suitable for all occasions, of the term "Net Generator Output."

The Committee has also used its good offices directly and through the represented memberships to have taken under further review the tentative regulations proposed by a Subcommittee of the National Board of Fire Underwriters for the Installation or Use of Pulverized Coal Systems, to the end that the state of the art, particularly as affecting power stations, might be promoted rather than retarded by the premature adoption of regulations unnecessarily drastic in the light of scientific knowledge, technical experience, and operating requirements.

Appendix

Important Articles on Power Station Design and operation that have Appeared in American and Foreign Technical Journals.

A—STATION DESIGN AND OPERATION

"The Quality of Hydroelectric Service, Yesterday and Today" by Alex. E. Bauhan. *General Electric Review*, June 1922. This article relates to the quality of service that is to be expected from a properly equipped and ably operated hydro-plant and shows why such service is comparable with and in many cases is better than that rendered by the metropolitan steam plant.

"Hazards in Hydroelectric Plants" by Alex. E. Bauhan. *General Electric Review*, September 1922. Some of the electrical and mechanical hazards present in a low head hydroelectric plant are described as well as effective precautions taken against these hazards.

"Utilization of Surplus Flood Water to Suppress Backwater upon Water Power Developments" by Floyd A. Nagler. *General Electric Review*, October 1922. The author discusses the use of surplus head water to suppress the backwater by the production of a more or less imperfect form of hydraulic jump.

"Operating Pilot Board and Load Dispatching System of the New York Edison Company" by W. H. Lawrence. *General Electric Review*, March 1923. A rather detailed discussion of a very large and complicated load dispatching board system.

"Indicating the Total Power from Several Generating Stations" by H. P. Sparkes. *Electric Journal*, April 1922. The article describes a system whereby the load dispatcher may be instantaneously informed of the entire system load.

"The Hell Gate Station of the United Electric Light & Power Company" by H. W. Leitch. *Electric Journal*, May 1922, *Power*, May 2, 9 and 16, 1922. Description of an ultimate 300,000 kw. steam station having a novel station layout in all respects.

"Switching Equipment for the Hell Gate Station" by C. M. Moss and J. B. MacNeill. *Electric Journal*, May 1922. A complete description of the isolated study of Massachusetts stations emphasizing the advantages of electrical equipment from the upkeep standpoint.

"European Practises Tend Toward Greater Economy" by A. Dyckerhoff. *Electrical World*, March 4, 1922. Standardization of equipment, waste heat boilers, gas turbines, large mercury rectifiers.

"Developments in Power Station Design". *Engineering*, January 13, February 24, May 12, June 2, July 30, 1922. A series of articles dealing with the latest foreign developments.

"First Large Plant Using Pulverized Fuel Exclusively." *Electrical World*, April 15, 1922, *Power*, April 18, 1922. Description of the Lakeside Station of the Milwaukee Electric Railway & Light Company.

"The Blackburn (England) Power Station" by L. C. Kemp. *Electric Journal* (England) January 1922. A complete description of the plant is given in this article.

"Five Systems with an Output of over 1,000,000,000 kw-hr. *Electrical World*, April 29, 1922. Data on output and peak load of the largest generating and distributing systems in the United States and Canada, having yearly outputs in excess of 100,000,000,000 kw-hr.

"Operating Interconnected Hydro Plants for Best System Economy" by J. W. Andre. *Electrical World*, May 13, 1922. A description of the methods in use on the Southern California Edison Company's system, showing how the use of steam standby plants is minimized.

"Calumet to Reinforce Industrial Section of Chicago System". *Electrical World*, June 3, 1922, *Power*, May 30, 1922. A description of the latest Commonwealth Edison Company's station to be put into service.

"Semi-outdoor Hydroelectric Plant with Backwater Suppressor" by John A. Sirnit. The author describes the use of the Thurlow backwater suppressor in the installation of the Alabama Power Company at the Mitchell Dam.

"Gennevilliers Steam Power Station" by G. Mercier. *Revue Industrielle*. Phase layout in this station is given.

"The Queenston-Chippewa Hydroelectric Development" by F. Q. Gaby. *Electric Journal*, August 1922, *Power*, June 27, 1922. The author describes the general details of the entire plant.

"The 55,000-h. p. Turbines for the Queenston Power Plant" by F. H. Rogers. *Electric Journal*, August, 1922. The article describes very completely the most powerful hydraulic turbines in the world.

"The 45,000-kv-a. Waterwheel Generators for the Queenston Station" by H. U. Hart. *Electric Journal*, August 1922. A detailed description is given of the largest waterwheel generators in the world.

"Some Elements of Air Flow in Electrical Machinery" by C. J. Fechheimer. *Electric Journal*, August, September, November, December, 1922, February, March, May, 1923. A rather detailed description of problems of air flow are given.

"Steam Engineering Practise in Modern Central Stations" by T. E. Keating. *Electric Journal*, December 1922. This article discusses a few of the thermal and operating problems that are today under consideration by central station engineers as well as their influence on the economic generation of power in modern steam stations.

"The Tangential Impulse Waterwheel" by Ely C. Hutchinson. *Electric Journal*, February, March 1923. The author describes the modern impulses waterwheel and its adjuncts.

"The Commercial Economy of High Pressure and High Superheat in the Central Stations" by George A. Orrok. *A. S. M. E. Transactions*, December 4, 1922. The effect of regeneration as well as the effect of increased temperatures and pressures is covered.

"The Choice of Steam Conditions in Modern Power Stations" by L. E. Kemp. *Electrician*, June 30, 1922. This article gives an analysis of the problem from the English point of view.

"Operating Expenses of Six Plants" *Electrical World*, January 21, 1922. A March and April, 1922. A very complete description of the large plant now supplying base load power to Paris. This plant represents the best European practise as pertaining to "Superpower" stations.

"Heat Balance and Electrical Equipment in the Gennevilliers Station" by R. H. Andrews. *Power*, August 15, 1922. Wiring diagram and description of switch houses. Description of closed system method used for cooling air to generators. Station heat balance compared with those of other large stations such as Colfax and Delaware.

"The New Superpower Plant near Paris Approaching Completion." *Electrical World*, August 5, 1922. A review of the above article in English.

"Steam Power Plant at Comines" by J. Reyval. *Revue General de l'Electricité*, July 15 and 22, 1922. A description of the second largest steam power station in France.

"Caribou 165,000-Volt Development" by J. A. Koontz. *Electrical World*. September 23, 1922. A description of a 1010 foot head hydroelectric plant with 15,000 h. p. impulse wheels and transmission line of 165,000 volts.

"Innovations in New Brooklyn Power House". *Electrical World*. November 11, 1922. Description of the 400 000 kw. Hudson Avenue Station of the Brooklyn Edison Company.

"Design Features of Cahokra Station". *Electrical World*, December 31, 1922. Description of the large central station burning pulverized coal to supply St. Louis with electrical energy.

"The Pit River Power Developments" by Frank G. Baum. *Electrical World*, January 27, February 3, 1923. Details of a very large 220,000-volt hydroelectric development on the Pacific coast.

"Eight Systems with Output of 1,000,000,000 kw. in 1922." *Electrical World*, April 7, 1923. Reports of over 92 companies in the United States and Canada with outputs of over 100,000,000 kw-hr. in 1922.

"Full Automatic Hydroelectric Station" by E. B. Collins, May 19, 1923. 5000 kv-a. automatic generating station in inaccessible site tied in with other hydroelectric stations. Functioning under different conditions explained.

"The Mechells Power Station of the Birmingham Corporation" by W. Mobile Twelvetees. *Engineering* January 26, February 2, 16, 23, March 9, 23, 30, April 13, 1923. General description of the Mechells Power Station of the City of Birmingham, England.

"The Improvement of Power Factor" by Dr. Fisbert Kapp. *Engineering* November 24, December 1 and 8, 1922. Discussion of the economical trend of improvement, methods of securing improvement with special reference to the use of synchronous motors. Gives data as to changes made for service based on

power factor improvement by customers, by British Power Company.

"The Lancashire Electric Undertaking" *Engineering*, December 22, 1922. General description of extension of plant of the Lancashire Electric Power Co. at Radcliffe, England.

B—PRIME MOVERS AND GENERATOR DESIGN AND OPERATION

"Maintaining the Efficiency of Turbine Lubricating Oil" by C. H. Hapgood and F. R. C. Boyd. *General Electric Review*, September 1922. The improvements made in modern centrifugal purifiers and their application to power plant problems are discussed.

"Cooling of Turbo Generators" by A. R. Smith. December 1922, February 1923, May 1923, *General Electric Review*. The article discusses the various methods of cooling ventilating air when recirculated through turbo generators, the heat transfer, and the physical considerations and design of surface air coolers.

"Closed Air Circuit System of Ventilation" by John G. Monson. *General Electric Review*, December 1922. The author discusses the general principles of generator cooling by means of a closed air circuit.

"Modern Jet Condensers in Small Lighting Plants" by R. E. Hellmes. *General Electric Review*, January 1923. A variety of novel jet condenser installations are described.

"The 10,000 kv-a. Shawinigan Falls Waterwheel Generator" by J. Ralph Johnson. *General Electric Review*, May 1923. The article describes the design and construction of a very large modern water wheel generator.

"Hydraulic Turbine Governors" by W. R. Kepler. *Electric Journal*, February 1922. A general discussion of the subject is treated.

"Systematic Inspection Scheme for Preventing Breakdown" by Alex E. Bauhan. *Electrical World*, May 13, 1922. The article describes a very thorough plant of systematic inspection in a low head hydroelectric plant.

"Cracking in Condenser Tubes" H. Moore and S. Beckinsale. *Engineering*, March 17, 1922. The results of investigations of low temperature annealing applied to condenser tubes is given.

"The Size Factor in Steam Turbines". *Engineering*, March 31, 1922. A study of the factors affecting the size of rotor in steam turbines.

"Extinguishing Generator Fires with $C O_2$ " by J. B. Wheeler. *Electrical World*, July 22, 1922. Arrangement of fire-extinguishing equipment at the Ashley St. Plant of the Union Electric Light and Power Company is described and results of tests given.

C—BOILER PLANT DESIGN AND OPERATION

"The Control of Blower Motors" by Henry G. Issertell. *General Electric Review*, May 1922. The author has devoted his article to showing how to select the proper motor and form of control for various types of blowers.

"Preparations, Transportation and Combustion of Powdered Coal" by John Blizard, *Bulletin 217*, Bureau of Mines. A very complete manual on powdered coal.

"The Elasticity of Pipe Bends" by Sabin Crocker and S. S. Sanford. *A. S. M. E. Transactions*, December 7, 1922. This article covers a number of experiments on pipe bends conducted by the Detroit Edison Company.

"Boiler Room Performance and Practice at the Colfax Station of the Duquesne Light Company," by C. W. E. Clarke, *Mechanical Engineering*, May 1922. The operation and operating details of this superpower plant are quite fully described.

"400-lb. Pressure Adopted." *Electrical World*, September 16, 1922. A description of the boilers to be installed at the Waukegan, Ill. station of the Public Service Company of Northern Illinois.

"Fuel Economy in Steam Power Plants" J. B. C. Kershaw. *Beama*, October 1922. A series of articles covering very completely European practices in this line.

"Ash Handling for Central Stations" by John Hunter and

Alfred Cotton. *A. S. M. E. Transactions*, December 4, 1922. A very general descriptive article of the various methods employed in large and small central stations.

"Natural Gas as Fuel for Central Stations" E. A. Quinn. *Electrical World*, March 10, 1923. The author describes a new type of burner for gas as fuel.

"Present Day Boiler Room Operation" by I. E. Moulthrop and R. E. Dillon. *A. I. E. E. JOURNAL*, February 24, 1922. A description of how combustion efficiency and economical loading of boilers and turbines are attained in a large central station.

"A New System of Feed Water Deaeration". *Electrician*, January 19, 1923. Diagram and description of "closed feed" system whereby condensate from main turbine may be passed through condenser of house turbine, thus improving economy, make up water being deaerated in the process.

"A New Development in High-Pressure Steam Generation." *Power*, July 25, 1922. Description of a special high-pressure boiler and economizer developed by Thomas E. Murray and Power Specialty Company and installed at the Municipal Gas Company's plant at Albany, N. Y. Radical type superheater installed at rear of furnace. Data of tests given.

D—FUELS AND COMBUSTION STUDIES

"Generating Power from Waste" by H. S. Bastian. *Electrical World*, February 25, 1922. Description of the methods used in storing and burning "hogged fuel" or sawmill refuse at the plant of the Portland Railway, Light and Power Company.

"Fuel Economy and Production Expenses" by Allen M. Perry. *Electrical World*, July 15, 1922. Data given for electrical plants burning coal, oil, gas and "hogged fuel."

"Boiler Capacities Obtainable per Cubic Foot of Furnace Volume" T. B. Stillman. *Power*, Jan. 31, 1922. Results on burning oil under a boiler at 658 per cent rating.

"Pulverized Lignite or Boiler Fuel". *Engineering*, November 17, 1922. Data and results of tests of Australian Lignite Burned in Pulverized Form.

"Recovering Fuel from Ashes by Magnetic Separator". *Engineering*, January 5, 1923. Refers to a magnetic separator for removing unburnt fuel from ashes. Devised by Messrs. Fried Krupp and J. Germany.

"The Driving of Handling Machinery" H. Blyth. *Electrician*. December 29, 1922. Advantages of water drive for coal and ash handling equipment with special reference to water trough conveyors for ashes.

"Coal Handling and Electricity Supply" by George F. Ziminer. *Electrician* December 29, 1922. Methods used for handling coal at Blackburn Electric Station, England. Traveling crane unloads barges by grab bucket, or railroad cars by inverting them. General features of crane.

NICHOLAS STAHL, *Chairman*.

ELECTRICAL MACHINERY COMMITTEE

To the Board of Directors:

The activities of the Electrical Machinery Committee during the past year have been limited in scope and have been concerned almost entirely with the review of papers sent by the Chairman of the Meetings and Papers Committee for examination and report. Eighteen papers were thus submitted for review.

While the industry has made great strides in the development of electrical generating units of gigantic capacity, reaching 62,500 kv-a. in individual units, this work has not advanced to a stage which permits its outline and description for presentation to the members

of the Institute. This will be the task of the Committee during the coming year.

B. A. BEHREND, *Chairman.*

REPORT OF TELEGRAPHY AND TELEPHONY COMMITTEE

To the Board of Directors:

The work of the Telegraphy and Telephony Committee was handicapped early in the year by the sickness and death of Mr. R. E. Chetwood, who had been appointed its chairman. The Committee prepared the following statement to express the feelings of the members of the Committee with regard to the death of Mr. Chetwood:

"The Telegraphy and Telephony Committee of the American Institute of Electrical Engineers wish to express the feeling of great loss of the members of the Institute in the death of the Committee's late chairman, Mr. R. E. Chetwood. The communication art loses in him one of its outstanding figures, not only in technical ability, but also in personality."

This statement was read by President Jewett at the opening of one of the sessions on communication at the February Convention.

In accordance with the custom of the last few years, the report of our committee is a brief summary of the advances which have been made or which have come into prominence in the communication art during the past year.

MACHINE-SWITCHING TELEPHONE CENTRAL OFFICES

The year has been marked by a considerable increase in the number of machine-switching telephone central offices.

A paper was read at the midwinter convention by Messrs. Craft, Morehouse and Charlesworth, describing the so-called "panel" or power-driven type. Offices of this kind have been cut into service in New York, Philadelphia, Seattle, Providence and Buffalo. The step-by-step machine-switching system, which is of the direct-control type, has been installed in a number of the smaller cities. Further extensions of both panel and step-by-step machine switching systems are under way.

LONG DISTANCE TELEPHONE CABLES

The extremely important developments which have been carried out in long distance telephone cables are well described in the following papers:

(1) "Philadelphia-Pittsburgh Section of the New York-Chicago Cable," by J. J. Pilliod, in the A. I. E. E. JOURNAL for July, 1922.

(2) "Telephone Transmission over Long Cable Circuits," by A. B. Clark, in the A. I. E. E. JOURNAL for January, 1923.

(3) "Telephone Equipment for Long Cable Circuits," by C. S. Demarest, to be presented at the A. I. E. E. June 1923 Convention.

SUBMARINE CABLE TELEGRAPHY

Several of the Western Union Telegraph Company's transatlantic cables are now being operated directly between New York and London. In this service, special regenerative repeaters are employed which make use of phonic wheel motors controlled by electrically operated tuning forks. Other developments which were required in connection with this system include a new form of repeater and terminal equipment for the land line extensions.

The same company is having manufactured a trial length of an improved type of ocean cable developed by the Western Electric Company. Tests of this cable will be made in the near future and if they result successfully, future transatlantic cables are expected to be of that type.

It is reported that an a-c. telegraph system is being operated, superimposed on an ordinary d-c. channel, on a cable of $KR = 0.9$ without affecting the speed of the d-c. circuit. Details of this system are promised for publication later.

LONG DISTANCE RADIO TELEGRAPHY AND TELEPHONY

On January 14, 1923, a group of about 60 people gathered in London and listened for two hours to speeches transmitted by radio from America. This was a part of a series of tests being carried out on long distance radio telephony. A complete description of the methods employed and the results obtained will be found in a paper by Messrs. Arnold and Espenschied on "Transoceanic Radio Telephony" to be presented at the June, 1923, A. I. E. E. Convention. This work is being actively continued.

Since atmospheric disturbances or "static" constitute one of the principal limitations to long distance radio communication, a great deal of effort has been directed towards finding methods of reducing its effect. The most successful line of attack has been the employment of directive receiving systems. The greater the degree of selectivity, the smaller will be the amount of interference from static coming in directions other than that from which the signals are being received. In transoceanic radio communication, the natural conditions are fortunate in this respect, since European signals arrive from the northeast, while the preponderance of static is from the southwest. On the Pacific Coast, static comes mainly from the east and southeast, and is favorable to the reception of trans-Pacific signals. A paper presented before the Institute at the Midwinter 1923 Convention on "The Wave Antenna" by Messrs. Beveridge, Rice and Kellogg, describes and explains the most successful form of directive radio receiving system for long wave lengths which has been devised.

Considerable valuable work has been done by various investigators in determining the direction of static at different points on the earth's surface. This knowledge will be of great benefit in connection with the employ-

ment of directive receiving antennas along the lines mentioned above.

RADIO TELEPHONE BROADCASTING

The interest in radio telephone broadcasting has steadily developed, and considerable progress has been made, particularly in the telephonic quality of the material sent out by broadcasting stations.

The Department of Commerce, on March 20, 1923, called together a second National Radio Conference, in order that it might have the benefit of the advice of those qualified in the art, and interested in the industry, in the formulation of such rules and regulations particularly with regard to wave length assignments, as were consistent with the advancement of the art, and were possible under the existing laws. As a result of this conference, a much larger range of wave lengths has been made available for broadcasting, and a new scheme of assigning wave lengths has been set up, which should very much decrease interference between broadcasting stations.

INDUCTIVE COORDINATION OF COMMUNICATION AND POWER LINES

In the last two annual reports, reference has been made to the work undertaken in cooperation by the National Electric Light Association and the Bell Telephone System in setting up practises for the coordination of the lines of the utilities interested, so as to prevent interference to the communication service. The joint general committee of these two organizations has issued a third progress report, in which the principles previously agreed upon have been supplemented by a set of recommended practises. The committee has also appointed a subcommittee on development and research, to undertake a cooperative study to determine what practical measures, if any, may be developed and adopted, to lessen the effect of those characteristics of both power and communication systems which contribute to inductive interference.

The development of the art of communication at high frequencies has raised some interesting and novel questions regarding interference at these high frequencies.

STRENGTH OF POLE LINES

Of great interest in connection with the extremely important question of strength of pole lines is a paper on "Wind Shielding Between Conductors of Telegraph and Telephone Lines" by P. J. Howe, in the January, 1923, A. I. E. E. JOURNAL.

PRINTING TELEGRAPHY

In addition to increasing the number of its multiplex printing telegraph circuits, the Western Union Telegraph Company has put into service a number of "forked-series" circuits of this class. In the latter circuits, one or more of the multiplex channels are dropped at, or extended to other places from intermediate stations along the route of the main circuit. For

example, a New York-San Francisco multiplex circuit has one of its channels dropped at Los Angeles, thus giving the latter city direct and separate means of communication with New York and with San Francisco on a circuit previously used only for traffic from San Francisco to New York and vice versa.

Because of the constant increase in the number of securities listed by the New York Stock Exchange and the growth in the volume of sales made through that exchange, it has become desirable to operate at higher speed than in the past, certain groups of tickers which record stock transactions. This has been satisfactorily accomplished by substituting tape transmission for the directly connected keyboard transmitters formerly used. The tape is prepared for transmission by means of keyboard perforators which can be operated at high speed by skilled operators who are no longer limited in their manipulation of the keyboard by considerations of the varying line time required for the transmission of different characters.

RAILROAD TELEGRAPHY AND TELEPHONY

The importance of adequate and reliable communication facilities on the railroads is appreciated by those in charge of railroad operation, probably more than ever before. This has led to the adoption of greater mileage of telephone despatching and telephone message circuits, of greater mileage of trunk line facilities equipped with loading coils and telephone repeaters, of interest in telegraph printers for certain long distance telegraph business, of stronger open wire construction, and of proper installation of aerial and underground cable where conditions warrant it.

The use of radio on passenger trains, principally for receiving material from broadcasting stations for the entertainment of the passengers, has been experimented with by a number of railroads during the year. In one or two cases, railroads have made use of radio in emergency conditions, for locating trains, and for ascertaining the condition of the lines in connection with damage by severe storms.

MILITARY SIGNALING

During the year the Signal Corps have brought out for the air service of the Army three types of radio transmitters for aircraft use. The smallest is a telephone set used only between planes in formation flying, the maximum range being about five miles. The others are more powerful telephone and telegraph sets with rated telephone ranges between plane and ground of 30 and 250 miles respectively. All are designed on the master oscillator-power amplifier system, to assure constant frequency with changing antenna characteristics in flight. The receivers of all the sets are identical, consisting of single circuit tuners and "super-heterodyne" amplifiers of six stages.

Until this year, radio communication for infantry units smaller than a regiment had not been feasible. This year has seen the production, however, of a tele-

graph set for battalions employing a fixed loop of one turn with an area of less than 1 square meter for both transmission and reception over a distance of 4 miles and affording 10 working waves between 74 and 76 meters. The weight including storage batteries for 8 hours operation, is 78 lb. and is divided between two men for transportation in limited field movements. A break-in feature permits the receiving operator to break the transmitting operator at will and every operator in the net is cognizant of the readiness of all other operators in the net without the necessity for calling them. The development of this equipment serves a long felt need in a field where wire lines are ordinarily maintained in action only at tremendous sacrifice of personnel.

The Signal Corps has in operation a radio network extending over the country. This net consists of twelve primary stations, located at the administrative headquarters and other important points, supplemented by about sixty secondary stations, located at posts, camps and stations.

EDUCATION IN COMMUNICATION ENGINEERING

There has been a considerable development of interest in the technical school in communication engineering. This is due to the large demand for graduates of technical schools by telephone and telegraph operating and manufacturing companies, to the stimulating effect of the important part which communication played in the world war, and to the growth of radio telephone broadcasting.

Elective communication courses are generally offered in electrical engineering schools, and in some cases communication courses are required. Many of the schools, however, have not appreciated the value of properly arranged communication courses, in teaching the fundamentals of electromagnetic action which underlie not only communication engineering, but all electrical engineering.

Graduate work in communication engineering, and courses in physics especially adapted for communication students, are given in a number of the colleges. Signal Units of the Reserve Officers' Training Corps have been installed in eleven of the technical schools. Research work in electrical communication is being carried out in a number of technical schools. There is a considerable demand for students with extra training in mathematics and physics to enter research and development work in the larger communication companies.

The communication companies, because of the highly technical nature of the work required of their men, are spending considerable effort in setting up company schools, lecture courses, etc., for training their employees.

FINE WIRE TELEPHONE CABLE

Advances in the art are permitting the use of much smaller wires in cable, particularly for the shorter

subscribers' cables. Cables in all sizes from 1200 pair down, of 24 A. w. g. gage are coming into very extensive use.

JOINT CHICAGO AND NEW YORK A. I. E. E. MEETING

An interesting demonstration was given during the Midwinter Convention of the possibilities of present-day telephony, when simultaneous meetings were held in Chicago and New York, and the two audiences were made effectively one in being connected by telephone lines and loud speakers. Addresses, papers and discussions given in part at each place were heard by all, as well as though the complete audience had been at a single point.

The above report has been prepared from material contributed by the following members of the committee: G. A. Cellar, H. P. Charlesworth, H. W. Drake, L. F. Morehouse, C. W. Rice, J. K. Roosevelt, General Edgar Russell, A. B. Smith, and C. A. Wright.

OTTO B. BLACKWELL, *Chairman.*

REPORT OF THE EDUCATIONAL COMMITTEE

To the Board of Directors:

The past year has seen an exceptional gain in interest in the problems of engineering education on the part of the profession at large. Significant movements have been inaugurated both in the colleges and in outside circles looking toward better coordination between preparatory training and professional education on one hand, and between the latter and the industrial demand on the other. Specific changes in educational practise growing out of these movements have not yet appeared, but may be anticipated.

CHANGE IN CURRICULUM

The deans of fourteen engineering colleges in the middle west have held two conferences on changes in curriculum which have culminated in the following resolutions:

"In order to meet the constantly enlarging responsibilities of the engineering profession, we favor an advance in engineering education at this time that shall provide five years of collegiate training for those engineering students whose aim is to become qualified to take positions among the creative leaders in the profession, and that such advance shall be made in substantial accordance with the following plan:

1. Include in the four-year engineering curricula a substantial proportion of fundamental and humanistic subjects, omitting, if necessary, a sufficient amount of the more advanced technical work. It is desirable that, so far as possible the curricula in the different branches of engineering shall be sufficiently uniform to permit students to defer their final choice of a specialty at least to the end of the second year.

2. Add a fifth year of advanced work, mostly or

wholly technical, and specialized to such an extent as desired.

3. The first four years of work shall lead to a bachelor's degree and the fifth year to an advance degree in engineering."

Among other considerations urged in support of these changes is the necessity of upgrading many of the applicants for admission to state institutions from certificated high schools which do not give a sufficient mathematical preparation for standard engineering courses.

This subject of the proper length and scope of engineering courses is being vigorously debated. Three parties can be identified easily: First, those who believe in the efficacy of the present standard four-year courses and who hold that whatever additional time is available should be given to graduate studies and research in the engineering field; second, those who believe that engineering training should be strictly professional in its methods and scope and that it should be preceded by two, three, or four years of work in the liberal arts or general sciences; and third, the group whose views are embodied in the resolutions quoted above.

THE COOPERATIVE PLAN

There is a slow but steady growth in the application of the cooperative plan of alternate periods of instruction and employment. The prototype of such courses has been in operation at the University of Cincinnati since 1906. Recent evolution tends to produce variants of the original plan. At Massachusetts Institute of Technology cooperation is carried on only with specific industries engaged in manufacturing, electric railway operation and electric power supply, and with programs of practical experience organized on lines as definite as the curriculum of studies. At Worcester Polytechnic Institute students in electrical engineering are offered the option of engaging in practical work for a continuous period of fifteen months between the junior and senior years.

The pedagogic merits of the cooperative plan of coordinated instruction and experience are of great interest but the possibilities presented by this plan for placing education on a plane of approximate self-support for both students and institutions are worthy of especial consideration. Demand for admission to colleges is rising rapidly and tends to outrun existing plant and teaching facilities. It is a serious question whether a great enlargement of facilities can be financed through private endowment or public support. This question bears a particularly serious relation to engineering education because of its high overhead and operating costs.

THE SUPPLY OF GRADUATES AND THE PROFESSIONAL DEMAND

Attendance at engineering colleges passed the post-war peak in 1922 and has since declined appreciably.

The peak with respect to numbers graduating occurs this year. In the past fifteen years the electrical industries of America have nearly quadrupled in magnitude while the number of men graduating each year in electrical engineering has advanced only about one fourth. With the prospect of a decline from the present peak the question of the adequacy of the supply of young engineers begins to assume serious proportions. Owing to the youth of the profession accessions to the ranks of electrical engineers during the past fifteen or twenty years have been almost entirely cumulative. With the rate of loss from death, superannuation and diversion to other fields rising and with the industry ever advancing in magnitude and complexity a stationary rate of accessions is certain to leave a serious deficit in the relation of supply to demand.

MOVEMENTS FOR INVESTIGATION AND DEVELOPMENT

Within the past year the National Industrial Conference Board has established a Joint Conference Committee on Engineering Education with a like committee from the Society for the Promotion of Engineering Education. The scope of the activities projected by these joint committees is well expressed by the following excerpts from an official statement.

"It was emphasized as a primary consideration that American industry's efficient development and contribution to the national welfare is closely bound up with the character and efficiency of the professional engineers educated in the various engineering schools, and required in industry as technical experts and inventors, as managers and executives of industrial enterprises. Equally important is the development of competent men as instructors in the engineering schools.

For these reasons and also because engineering schools are, after all, a part of the industrial system, and must therefore function efficiently if the system as a whole is to be efficient, it was agreed that there must be a close and cooperative relationship between engineering schools and American industry in its various branches; and adequate methods must be developed under which each will help the other in the common cause of adequately training professional engineers.

The Committee is not concerned with details of college curricula, but with the broader aspects of the problem, such as the best way of fitting the graduate of the engineering schools into industry; whether and how best to give the student industrial training coincident with his academic studies; an adequate supply of high-grade instructors and a better understanding of their responsibilities by both industry and the engineering schools."

The Society for the Promotion of Engineering Education has further created from its own membership a Board of Investigation and Coordination whose objects are stated to be:

"1. To ascertain the facts in engineering education, such as concerns (a) teachers, their origin, training,

experience and effectiveness; (b) teaching facilities; (c) curricula; (d) students and graduates, their origin, training, experience and effectiveness.

2. To ascertain present and future requirements in the fields served by engineer graduates.

3. To present the facts and requirements for their bearing on the training of the engineer to the end that he may (a) develop himself and his profession; (b) realize and fulfill his obligation to society.

4. To maintain close contact with engineering schools enabling them to participate in the investigations; and reporting to them from time to time; the end that the developments may be continuous from the initial contact between the colleges and the agencies of the Board.

5. To secure the necessary funds for these purposes." It is proposed to place a salaried director, with adequate staff, at the head of this Board and to create a Board of Counsellors representing the several industrial fields to which engineering education is related.

A movement of such scope and aims is of profound interest to the Institute and its sister professional societies. It is important that there should not be too many agencies of investigation and promotion working in an uncoordinated manner. It is also important that due weight should be given to the views and interests of the engineering professions as well as those of the colleges and the industries.

The importance of gaining the cooperation of the major engineering societies has been recognized by the Society for the Promotion of Engineering Education in its appointment of a committee for this express purpose.

It is the sense of the Educational Committee that the Institute should indicate its readiness to participate actively in any broad movement concerned with the development of engineering education. In view of the establishment of the Joint Conference Committee referred to above and the active steps already taken toward setting up its program, it is the feeling of this Committee that the Institute should await some indication of the details and order of this program before initiating active measures on its own account and that the Institute should act as far as practicable in concert with its sister professional societies.

WM. E. WICKENDEN, *Chairman.*

REPORT OF COMMITTEE ON ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY

To the Board of Directors:

This committee has been somewhat more active

during the past year than for several years previously. The situation covering past and prospective activities was discussed at the beginning by correspondence with the various members of the committee. Four or five of the seven members have shown an active interest in the work. No regular committee meetings have been held as there was no special occasion therefore. It was intended to hold a meeting at the Pittsburgh Convention but only two of the committee members were in attendance.

The particular activity of the committee for the year was the preparation for and conduct of a session on Electric Furnaces which was held under its auspices at the Spring Convention. In addition efforts have been made through committee members to obtain papers of Institute caliber along electrochemical and electro-metallurgical lines and several such papers are now in course of preparation so that it is hoped the committee will be in position next year to request a session for papers devoted to such subjects.

It would appear that the proper function of this committee should be that of a technical liaison between the A. I. E. E. and the American Institute of Mining and Metallurgical Engineers and the American Electrochemical Society. We should observe the technical activities of those societies and report with the correct Electrical Engineering slant those matters in which A. I. E. E. members should be interested. Any technical subjects which are investigated jointly by one of these societies and the A. I. E. E. should be under the direction of this committee for the A. I. E. E.

At the present time it seems that the most serviceable line of action for this committee lies in stating from time to time the status of the art and advancements in the art with particular reference to the power supply and the electrical equipment applications and such features of the chemical and metallurgical processes as directly affect the power and equipment. It is hoped that the next session under the auspices of this committee will have papers on the general subject of Electrical Equipment and Power Requirements for Electro-chemical and Electro-Metallurgical Service.

Since the apparatus and applications thereof in which this committee's activities are associated are so diverse that the whole field could not be covered in a brief resumé and since there do not appear to be any outstanding advances which have not been more specifically within the sphere of some other technical committee to report, no attempt is being made at this time to report the progress of the art.

Electrical Loud Speakers

BY A. NYMAN

Associate, A. I. E. E.
Westinghouse Elec. and Mfg. Co.

Review of the Subject.—An electrical loud speaker is a device applied to radiophone reproduction of speech and music.

This paper brings out the mechanical and electrical essentials of this device and gives a short description of present-day forms and methods used in developing and testing new types.

A technical analysis of one successful form brings out the

various factors involved and the means used for achieving satisfactory results. These results are illustrated by appropriate test curves.

The paper is a record of results obtained through technical analysis of this apparatus and is intended to direct attention to the necessity of similar analysis continued and extended.

THE popularity of radiophone broadcasting has created a considerable demand for an electrical loud speaker. Electrical loud speakers have been used for a number of years for such purposes as train announcing. However, this type of loud speaker was developed primarily for speech reproduction and as long as it possessed a certain degree of clearness, was considered satisfactory.

The major part of radiophone broadcasting is music and the aesthetic value of music is its vital element. Therefore, music reproduction should be so close to the original as to maintain its aesthetic value.

It has been found that music reproduction requires the presence of notes ranging in frequency from 25 cycles per second to 5000 cycles per second. The quality of reproduction is affected to a large extent by the loudness of individual frequencies; hence, the necessity of bringing in each frequency at a value proportional to the original volume. It can readily be seen that the quality of the pick-up instrument or microphone, as well as the design of the transmitting and receiving systems is of utmost importance.

Apart from the pick-up and transmission, the following essential features pertain to the loud speaker alone:

1. Uniform intensity of sound at all frequencies from 25 cycles to 5000 cycles.
2. Absence of resonance points capable of responding at a frequency different from applied or giving an excessive volume of sound when their frequency is applied.
3. The ability to reproduce a combination of frequencies with a volume of each frequency proportional to the input.
4. Absence of distorting harmonics at any individual frequency applied.

Feature 1 is particularly important in reproducing every kind of sound; for example: A weak or missing range of frequency is noticeable even to an untrained ear. However, if it is near either end of total range, i.e., below 400 or above 3000, an untrained ear may sometimes fail to detect this defect. Similarly an individual missing frequency can be occasionally overlooked. A loud range distorts the quality to a considerable extent

and a loud individual note has a very unpleasant blasting effect.

Feature 2, if overlooked is particularly liable to give blasting or an unnatural ring of certain notes. The fundamental may be suppressed and a harmonic of an altogether different pitch come through, possibly considerably louder than the applied note.

Feature 3, dealing with combination of frequencies, is particularly noticeable in speech reproduction. Normal vowel sounds consist of a fundamental of rather small volume and harmonics often much larger than the fundamental. Unless the proportionality is maintained the sound of the voice changes giving the impression of a changed pitch; tenor voice may sound like bass; soprano like contralto, or vice versa. The higher harmonics again determine the individual characteristics of the voice. Thus, in order to recognize a person's voice, the higher harmonics up to the 20th or 30th must be included and kept at their proportional value. What is true of voice is true of most musical instruments. The pitch, or the individuality may appear changed unless a proportionality is maintained.

Feature 4: Certain materials have qualities which give them peculiar forms of vibration. Thus, the vibrations of brass are usually different from aluminum, wood or micarta. This is generally due to a number of harmonics, each modifying the original note. In a loud speaker the pleasing quality and the naturalness of reproduction are dependent to a very great extent on the choice of materials, particularly of the material carrying a large amount of energy of sound.

STRUCTURES OF LOUD SPEAKERS

A number of structures have been used successfully as loud speakers.

Fig. 1 shows a loud speaker operating on the same principle as an ordinary telephone receiver. It has a thin iron diaphragm held at a small distance from two magnetic pole pieces, which are energized by a permanent magnet and also by two coils, one on each pole piece. The volume that can be obtained from this type of loud speaker is somewhat limited on account of the close spacing between the diaphragm and the pole pieces. Moreover, certain notes are accentuated, due to the resonance of the diaphragm.

Fig. 2 shows a moving coil type of loud speaker. A

circular coil is located in a round air-gap, with an iron core in the center. This air-gap is traversed by a strong magnetic field, excited by an inner coil which carries direct current while the circular coil mentioned above carries sound-producing alternating current and is attached to the center of a diaphragm. Very satisfactory results can be obtained with this type of loud speaker.

FIG. 1

FIG. 2

FIG. 3

Fig. 3 shows what may be termed the enclosed armature type. A small iron armature is located in the center of a coil and suspended by two thin piano wires. The coil is surrounded by two U-shaped pole pieces, forming two air-gaps. A permanent magnet produces magnetic flux in these air-gaps. The current in the coil causes diametrically opposite pole pieces to be energized

simultaneously, which causes the armature to rock. This rocking is communicated through a thin connecting rod to the center of a diaphragm.

Fig. 4 shows the sound distribution for a loud speaker constructed on this principle. The curve is taken by a method described below. The loudness is fairly uniform over the range. The curve shows the frequency from 100 cycles to 10,000 cycles for abscissa and loudness for ordinate.

Fig. 5 shows the "relay type" loud speaker recently developed. Its construction is similar to that of a

FIG. 4

FIG. 5

polarized telegraph relay. A thin iron armature is located between four pole pieces, each carrying a coil. These pole pieces are magnetized by an L-shaped magnet and the coils are connected in such a manner that diametrically opposite pole pieces exert simultaneous attraction. The armature operates through a rod on a corrugated aluminum diaphragm.

Fig. 6 gives a representative curve of this loud speaker. The range is fairly wide, while no part of it is exaggerated in volume.

through clear and similar to the original piano note. Low notes, in particular, should be checked for the presence of the fundamental tone. Some designs of loud speakers while giving a loud note at these pitches are found to be completely devoid of the fundamental—the note is just the sum of all overtones.

Speech transmission over the same circuit gives a splendid test for quality and recognizability of reproduction. For proper speech reproduction, the volume should be adjusted to equal approximately the loudness of the original speech. Of course, in a loud speaker designed for a large audience, with a special view to great volume, the speech must sound normal at the volume desired. The same loud speaker would not necessarily give natural reproduction at a lower volume.

An additional test for actual music reproduction is essential. Thus a piano selection, a baritone solo, and a soprano solo are particularly good for detecting

TESTS OF LOUD SPEAKER

1. Measurement of volume 60 to 5000 cycles.....	Uniformity of volume, absence of resonance points and foreign sounds
2. Musical scales on piano.....	Accurate reproduction of quality on each note, particularly the low note.
3. Speech.....	Clearness of articulation. Individuality of voice.
4. Piano Selection.....	Clearness and naturalness on abrupt tones
5. Baritone and soprano singing	Clearness and naturalness of sustained notes.
6. Flute or violin.....	Reproduction of high notes.
7. Speech and Music.....	Naturalness of superimposed sounds.

any faults in quality. In addition a violin or a flute solo can be used to advantage to determine the ability of the loud speaker to reproduce the high notes naturally. The table below shows the list of tests and results that can be learned from each.

One more test is very desirable. That is a combination of music and speech. Each possesses individual characteristics and the ideal loud speaker would maintain them. Very often, however, the presence of music will distort the speech and vice versa. Of course, in this latter case we could not expect the loud speaker to reproduce correctly a number of musical instruments simultaneously, although the distorting effect may not be as noticeable as in the case of speech and music.

RESONATING SYSTEMS

Considered from a mechanical standpoint a loud speaker is invariably a complicated resonance system. Certain subdivisions of resonance, are, however, possible.

1. *Mechanism as a whole.* In most loud speakers, the diaphragm is the surface producing sound. The force of a magnetic field is in all types except the moving coil type counteracted by a strain in the diaphragm. In a loud speaker of the type shown in Fig. 1, that is, the

telephone receiver type, this action is automatic. The diaphragm pulls down until its tension is equal to the pull of magnetic field. In the type shown in Figs. 3, 4 and 5, the normal position of armature is such that the magnetic pull is zero. Actually, however, it is very difficult to keep the armature in this position. Gener-

FIG. 9

FIG. 10

ally there is a little pull one way or another, balanced by the strain in the diaphragm.

For a movement of the diaphragm, the magnetic field begins to exert a force helping this movement. If the magnetism is increased by using a stronger magnet, the force of the magnet may be made so large that it

pulls the diaphragm over. Normally, a balanced condition may be obtained where very little force is required to produce a certain movement. Fig. 9 illustrates this fact. The two curves show the variation of force on the diaphragm with movement of the diaphragm, and show that with the magnet the diaphragm requires distinctly smaller force for the same movement.

In this way, the strength of the magnet and the tension of the diaphragm determine the force for certain movements and, consequently, the resonant frequency of the whole mechanism. By adjusting the magnetism in a way to get a very close balance, this resonant frequency may be placed very low. As a rule, the damping at these low frequencies is high enough to conceal the resonance; however, the whole of the low

of the diaphragm with harmonics at 2900, 5000 and 6000 cycles and higher. The ratios are not exactly 1:2:3:4, but modified by the presence of horn and the nature of the diaphragm.

FIG. 12

FIG. 11

range will be found raised. This is demonstrated on Fig. 10, showing two curves for one loud speaker, one with a 0.015-in. gap and the other with a 0.010-in. gap. The latter had a close magnetic balance; hence, all notes and the low notes in particular are increased. These curves were taken on relay type loud speaker. It is evident that similar adjustment is possible on all types except the moving coil type; in the latter the resonance point is determined entirely by mechanical strain and the mass of moving parts.

2. *Diaphragm and Horn.* The nature of the diaphragm as a vibrating structure is such that it has a number of resonant notes. Fig. 11, taken on a very stiff small diaphragm, illustrates these resonance points. The lower resonant points can be attributed to the effect of the horn. 1500 cycles is the fundamental

FIG. 13

Fig. 12 shows the resonance in the diaphragm corrugated to reduce the effect of harmonics.

Fig. 13 shows the same kind of curve for a flat diaphragm without corrugation. The resonance points are now more pronounced.

Both these curves were taken without a horn and show the diaphragm resonance only.

The effect of the horn is not independent of the qualities of the diaphragm, because the horn constitutes a load on the diaphragm. If this load is large, it produces a damping effect, which eliminates the resonance of the diaphragm. However, the horn itself has certain resonance points. For example, they can be seen very clearly on a curve like Fig. 10 which was taken on a loud speaker similar to the one used in Fig. 12. If the load due to the horn is small between its resonance points and the resonance of the diaphragm should occur at any of these points, the vibration may be excessive with a resulting rattle and noise. The longer horn favors more uniform load at different frequencies.

The effect of the horn depends to a considerable

FIG. 14

extent on the power applied to the loud speaker. Fig. 14 shows the intensity of sound per unit voltage from a loud speaker at 20 volts and at 100 volts, each time with a resistance 10,000 ohms in series. At 100 volts the load due to the horn is evidently more uniform than at 20 volts. The intensity per unit voltage is on the average lower at 100 volts.

Speech and music are both modified considerably depending upon the length and shape of the horn, also on the volume of the sound. A horn longer than one quarter wave length of the lowest pitch available gives the best reproduction. However, in practise the length of the horn seldom exceeds three feet, approximately one-fourth of the wave length of 90 cycles, the fundamental of the horn. If the horn is shorter than one foot (270 cycles fundamental) the bass and baritone voices are likely to be distorted, since their fundamental,

which is below 270 cycles would be reduced. It has been found that a loud speaker with a magnetic balance and a horn about two feet long is capable of very good reproduction of even very low frequencies.

Careful study has been made of materials to be used

FIG. 15

FIG. 16

in diaphragm and in the horn in so far as it affects the quality of reproduction. Aluminum or micarta diaphragms apparently give the best results while a wood horn or horn made of some "dead" material like hard rubber, is least likely to introduce a strange quality.

III. *Armature.* The armature of a loud speaker of enclosed armature or relay type is a strip of steel very short and stiff, but nevertheless possessing a resonance point within the audible range. It has been found that frequencies above this resonance point are difficult to reproduce. Thus, Fig. 15, taken on a loud speaker with a very small stiff armature, shows a range on higher notes extending to 5000 cycles.

Another effect of resonance of armature is the introduction of foreign notes. An example is seen in the Fig. 16 showing a reduction of volume at 800 cycles. At this frequency it was observed that the note had a strange high pitched harmonic; however, damping the armature by a piece of rubber cleared this note and brought up the volume of its fundamental. The trouble was eventually overcome by using a much stiffer armature.

IV. *Strip.* The strip supporting the armature has a resonance note, but the forces acting in it are generally very small compared with the forces in the rest of the system. Hence the effect of the strip is negligible. The only exception is in attaching the strip to supports. It seems that any looseness at this point will result in a rattle.

V. *Connecting rod.* The connecting rod is subject to a complicated torsional and longitudinal strain. Unless this rod is sufficiently stiff, vibrations may be set up which introduce a foreign note at the lower frequencies and limit the sound at the higher frequencies.

CONCLUSION

In conclusion a brief summary will cover the outstanding points.

The function of loud speakers is considered as that of a device for converting electric current of frequencies, ranging from 25 cycles to 5000 cycles, into sound waves.

The essentials of this conversion are as follows:

1. Uniform volume at all frequencies.
2. Absence of strange sounds.
3. The ability to reproduce a combination of frequencies correctly.

Four fundamental types of loud speakers are discussed:

1. Receiver type.
2. Moving coil type.
3. Enclosed armature type.
4. Relay type.

Test methods are outlined for:

1. Measuring the volume of sound.
2. Testing the quality of reproduction.

The effect of various parts of a loud speaker on its operation are considered, viz:

1. The magnetic structure.
2. The diaphragm.
3. The horn.
4. The details.

The art of designing a loud speaker is extremely new. The empirical work for ascertaining the effect of various factors is only in its embryo stage.

Eventually, we may expect to design a horn or a vibrating structure with the same facility as an electric motor because a loud speaker is really an electric motor, though its load is less tangible than the load of most motors.

The design of a loud speaker must be based on a scientific analysis of this load and of its reaction on the motor. This involves considerable acoustic research work, mechanical research on vibrating structures and electrical work on the effects of vibrating parts in an electromagnetic structure.

Discussion

E. W. Kellog: Mr. Nyman has mentioned a series of tests of loud speakers which I think may well be classified into what we might call the engineering tests and the listening tests.

The engineering tests are made with pure sine wave current supplied to the instrument and are to determine, first, what is the sound output per watt input for all frequencies in the useful range; and second, whether the force which acts on the diaphragm bears a linear relation to the current in the winding.

If the sound output per watt input is different for different frequencies, wave form distortion will result, because certain of the overtones present will be exaggerated and others partially suppressed.

If the force-current relation is non linear, the instrument will cause a different type of wave form distortion, producing harmonics which were not in the original.

The test for linear relation between current and force may be carried out by supplying the instrument with a sine wave current strong enough to give the diaphragm a maximum deflection equal to the greatest it will attain in practice. A trained ear can tell whether the resulting tone is practically pure. The current supplied to the instrument should be filtered to insure absence of overtones. Otherwise the instrument will be blamed for faults which are in the source of current.

If the loud speaker produced no distortion of either of the kinds just described, the other tests—listening to speech and various kinds of vocal and instrumental music—would be superfluous. But the loud speakers do not meet the requirements mentioned, especially the requirement of uniform sensitiveness over the whole working range of frequency, and it therefore becomes necessary to judge how seriously the imperfections of the instrument affect the quality of speech and music. This means many listening tests with many listeners, and the balancing of one fault against another, with an integrated appraisal of the various instruments compared. The loud speaker will be sold on the basis of the listening tests but it will be developed and improved through the information gained by the engineering tests.

It is in the tests for relative sensitiveness at various frequencies that the principal difficulties are encountered. These are the tests whose results are shown by curves such as Figures 4, 6, and 10 to 16 of Mr. Nyman's paper.

In view of their importance and the fact that this method of testing loud speakers is being applied in a number of places, I should like to see an interchange of ideas and experiences, and if possible an agreement on test conditions and methods of presenting the results, which will make the results obtained in different laboratories directly comparable.

Without pretending to be especially in a position to lay down standardization rules in regard to tests of this kind, I think that thought on the subject may be promoted and accelerated by my attempting to do so, because it will show what difficulties

or possible sources of error have occurred to me and tentative ways of avoiding them. Others who have had more experience than I have, can perhaps rule out some of these precautions as unnecessary and will probably add others that I have overlooked.

In order to get the proposition into concrete form I am going to suggest a tentative set of test conditions, the general method of testing to be as described in Mr. Nyman's paper, but the following conditions imposed:

(1) The oscillator which provides the current for testing should be provided with a filter to eliminate overtones.

(2) The amplifier between the electrostatic transmitter and the galvanometer should be provided with a tuning, or else a filter so that only the fundamental frequency will affect the galvanometer.

(3) The test room to be at least 15 feet by 15 feet, 10 feet high, with its ceiling and three of its walls heavily damped and the remaining wall hard.

(4) The loud speaker to face the middle of the hard wall, 6 feet above the floor and 6 feet from the wall to the center of the bell of the horn.

(5) The electrostatic transmitter to be located in a hole in the wall, directly in front of the loud speaker, and the floor between the loud speaker and the transmitter to be padded with damping material.

(6) The sound pressures recorded to be divided by 2 to reduce the results to equivalent free space pressure.

(7) Results to be given in dynes per square centimeter sound pressure per volt-ampere supplied to the instrument, accompanied by a statement of the instrument impedance and the maximum peak value of voltage or current which it can handle without distortion.

(8) Departure from standard test conditions to be stated.

Let me now give my reasons for some of the provisions named:

First, the oscillator which provides the current for testing should be provided with a filter to eliminate overtones. Let us take the case of very low tones. You noticed in the curves given in Mr. Nyman's paper that the sensitiveness of practically all of the instruments tested was at least 10 times as great for tones above 500 cycles as for tones below 150 cycles. Suppose we supply the instrument with an electric current of 100 cycles, and then measure the sound output by means of the electrostatic transmitter with amplifiers as indicated in Fig. 8 of the paper. If there are any overtones present in the electric current, those overtones may be reproduced so strongly that they will count very much more in the galvanometer reading than the fundamental, whereas we are only interested in the fundamental. Even if the current supplied to the loud speaker is a pure sine wave, the instrument itself may generate overtones. This will occur if the current-force relation is non linear. The overtones thus generated may be more strongly radiated than the fundamental, and since the purpose of the test is to determine not simply how much noise is produced but how much sound of fundamental frequency is radiated, I have called for a filter or tuning between the electrostatic transmitter and the galvanometer. A vibration galvanometer is an alternative.

Next in regard to the size of the testroom: The arrangement I have suggested places the loud speaker fairly close to the electrostatic transmitter, and the other walls farther away. The instrument gives out sound in all directions, and even where we have done the best we can at damping, there will be reflections of a substantial fraction of the sound that strikes the side and back walls. The reflected waves will interfere, producing at certain wave lengths subtractions and at other wave lengths additions to the sound coming directly from the loud speaker. The intensity of the interfering waves will be much reduced by placing the walls that are producing these objectionable reflections well away from the loud speaker. This means using a fairly large room, as well as damping the walls.

Why use a hard wall and locate the electrostatic transmitter

in the middle of it, in a hole in the wall? I mentioned that hole in the wall construction because I am not sure that all the electrostatic transmitters that would be used are constructed so that the air pressure cannot equalize on the front and the back of the diaphragm for the longest waves. In most of them, the back is housed in pretty well, perhaps well enough for all practical purposes, so that there will not be pressure equalization. But guarding against any possibility of it, suppose we put the instrument in a hole in the wall that fits it tightly. In some testing arrangements I believe the electrostatic transmitter has been placed some distance from the wall. This means that the sound waves given out strike the wall behind the electrostatic transmitter and come back to produce interference effects. If we place the electrostatic transmitter close to the wall so that it is at a pressure loop and motion node for all wave lengths—then we will get a pressure doubling for all waves, provided the wall is perfectly reflecting.

Next is the question of the distance of the electrostatic transmitter from the loud speaker. I mentioned six feet because I think that represents something like the distance that listeners would sit from a loud speaker in a home. I would place the transmitter closer to the loud speaker than six feet, except for the fact that I have some reason to believe there is a pressure variation very close to the horn of a loud speaker which does not represent energy actually radiated. There is a circulation of air which may be described as simply surging back and forth. It is represented by a reaction on the diaphragm not of energy dissipation or energy radiation, but an inertia factor, and may be compared to the magnetic field around an antenna less than a quarter of a wave length from the antenna. You would not think of using such a field as a measure of the energy actually radiated by the antenna. You would go at least a wave length or two away. I should be very glad to hear from any one who can answer the question whether there is such an effect as I have mentioned. I tried to look it up but could not find any literature on the subject, except Rayleigh's formula for the reaction of air on a diaphragm ("Theory of Sound", Vol. II., page 165).

I also suggested that results be given in dynes per square centimeter sound pressure per volt-ampere supplied to the instrument, accompanied by a statement of the instrument impedance and the maximum peak value of voltage or current which it can handle without distortion. While the quality of the loud speaker is pretty much a question of *relative* amplitudes at different frequencies, if we could give the distance and have conditions equivalent to the radiation in free space, without any surrounding walls, and give them in terms of sound pressure per volt-ampere supplied the instrument, we should also have a measure of the sensitiveness of the instrument, which is desirable for purposes of comparison.

The last condition mentioned in my list is that departures from standard test conditions are to be stated—of course that might for some time to come mean stating all conditions, but I think it highly desirable that they be stated in detail.

A. E. Kennelly: The method of testing loud speakers which is presented to us in this interesting paper is a valuable one for getting rapid empirical results. It seems to me that much more definite and scientific information can be obtained through the medium of the motional impedance circle. But in any case, whether we use one method or another, we may consider that the ideal instrument is one which produces a linear relation between the pressure of the air at the transmitter diaphragm and the pressure in free air at a defined point in front of the loud-speaking receiver, that the ratio of the two would measure the efficiency of the system; and that it should be the same all over the acoustic range considered.

It is not reasonable to expect that any such relation can be obtained in the near future, and we can only hope to arrive at it by a succession of approximations.

An ordinary diaphragm has its resonant point or a series of

resonant points. The horn has another; the transmitter has another; the electrical apparatus involved connecting them, may have another or a series of others. So it is only by suitably combining a series of such resonances that we can hope to produce conditions that will produce an equalization over the whole working acoustic range as far as possible. There is so much to be done in this direction, that we cannot expect perfection in the near future.

I think we have all been struck with the enormous advances that have been made in the last few years in the direction of frequency measurements, of repeater circuits, and of Atlantic radio transmissions, that it is evident one year produces at this favored time as much development as might have been expected in a dozen years only a little while ago.

W. H. Martin: Mr. Nyman's four requirements for a good loud speaker can, I think, be adequately expressed by two requirements; first, that the efficiency be constant over the frequency range and, second, that the device used produces no frequencies except those imposed upon it.

In going over this paper, I notice that the so-called "relay type" structure shown in Fig. 5, is described as a new development. Comparing the structure of Fig. 5 with the so-called "balanced armature" type of Fig. 3, it appears to me that the relay type is really a small modification of the balanced armature type. Magnetically the two are practically the same. The relay type appears to have the disadvantage, moreover, of having a more complicated winding system.

In the matter of obtaining a loud speaker which will be distortionless for the frequency and volume range required for reproducing speech and music, it seems to me that the important problem is not so much that of devising a new magnetic structure for converting from electrical power to mechanical motion; it is rather that of properly communicating this mechanical motion to the air. Indications are that there is a larger field for improvements in the vibratory and acoustical parts of the structure than in the electro-mechanical parts.

It would help in reading this paper if the author would state what the units of loudness are in which the curves of the paper are plotted. By loudness we might interpret these units to mean sound power, sound pressure, or, as is often meant by loudness in acoustical work, sensation in the ear. Since the second and third are respectively proportional to the square root and logarithm of the first, it is essential to know what the units are in order to interpret these curves properly.

Referring to the measuring apparatus used, the paper does not indicate that the transmitter and amplifier were calibrated to determine whether or not they are as free from distortion as it is assumed. In regard to the method of testing referred to in the paper, I can say that experience with this method has shown that unless more adequate means are used than are described in this paper for eliminating harmonics from the currents sent through the loud speaker and those given out by the amplifier, the results are open to question, particularly at the lower end of the frequency range.

Paul G. Andres: Two causes contributing materially toward the delinquency of a loud speaker in the matter of faithful reproduction or quality of tone are magnetic and mechanical hysteresis.

Considering the first, the presence of iron in the voice current magnetic circuit causes the diaphragm or armature to respond somewhat differently from what it would were no iron used with the result that foreign harmonics are introduced which tend to distort the output.

Mechanical hysteresis or the mechanical lag of the various movable members contributes further distortion. Spoken words and musical sounds have wave fronts that differ decidedly from pure sine waves. They may be very steep or peaked and consequently distortion may easily be introduced due to the diaphragm, armature or other parts of the vibrating system all of

which possess a certain element of inertia or have natural vibration periods of their own not being able to follow the impressed voice currents as readily as they might a pure sine wave, particularly if that be of low frequency. Then too, internal losses in the movable members add to the deviation of the acoustical output from the electrical input.

It would appear as though only an aural comparison of the output with the input can be used in passing final judgement on quality, although a test independent of the opinion of individual observers to determine faithfulness of reproduction or an indication of the distorting factors mentioned would be most desirable if such a one could be evolved.

A. Nynam: I will take up first the discussion by Mr. Kellogg. The first point Mr. Kellogg brought out was a question of engineering tests by the uniformity of volume over the frequency range. Mr. Kellogg made the statement that when the volume is uniform over the whole range of frequencies, it will not be necessary to have the other tests. I can't agree with that statement. The last speaker, I think, brought the point out very clearly. It is a question of the wave form of a combination of different frequencies. An individual frequency might have a wave form that is fairly steep, but a combination of frequencies might have a wave form which is considerably steeper than that, and a test at a single individual frequency will not give an indication of the effect of combined frequencies. That is only one of the things that affect it. Then there are numberless possibilities of combinations of sounds, such as music and singing, say, or different instruments in the orchestra, each one having a combination of different frequencies, and this combination has to be reproduced with exactness.

I fail to see how any test of individual frequency can possibly disclose the operation of the loud speaker in a complicated mixture of frequencies. So from this point of view I believe it will be always essential to have the actual acoustic tests performed on the loud speaker before it can be approved.

The second point brought out by Mr. Kellogg, on the standardization of tests, is very good. This is exactly what ought to come about. As far as the method of tests is concerned, I can't agree with Mr. Kellogg exactly. On the matter of sine waves for the oscillator and a tone filter in the receiving system, he is correct. I believe these steps should be taken, and we have attempted in our work to produce a current as close to a sine wave as possible.

On the other hand, that does not eliminate the test without the tone filter, because the tone filter will indicate the reproduction of the note that you have applied, but that does not exclude the possibility of some other frequencies appearing and distorting the sound; and you couldn't indicate these other frequencies except by making a test without the tone filter.

As far as the arrangement of the room for testing the loud speaker is concerned, Mr. Kellogg's suggestions are good, but I have one exception to offer. Mr. Kellogg suggests placing the loud speaker at a certain distance from the horn in a room especially constructed for the purpose. That is all right, provided the loud speaker were used under those conditions in actual practise. In actual practise, the loud speaker may be placed in a resonant room or in a room highly damped. And in a resonant room, it isn't so much a question of how much sound you get in a certain direction but rather it is, how much energy of sound is produced by the loud speaker.

I believe the problem is really complicated and for final standardization both tests would be required; that is, a directional loudness measurement and an energy of loudness measurement.

Methods for measuring the total energy of sound have not been developed. The only thing I can suggest would be an arrangement similar to the measurement of energy of illumination; in other words, by taking a polar curve around the loud speaker, that will indicate the energy.

With very simple tests that I have conducted, moving the

pick-up in front of the horn, I have observed that on most of the frequencies we have to deal with, the pick-up of sound at any point of the horn, provided the horn is designed properly, is practically the same. It may vary 20 or 30 per cent. Of course, this variation is not appreciable.

Mr. Kellogg is right in saying that the condenser transmitter is not uni-directional. I have taken polar curves of condenser transmitters and have found that especially on the low frequencies the pick-up from the back and the sides may be as high as 50 per cent of the sound from the front. This makes it so much more important to use either the method suggested by Mr. Kellogg or placing the transmitter directly in front of the horn, where the sound from the forward direction is so much larger than any reflected sound can be.

On the point brought up by Mr. Kennelly with regard to motional impedances, as I see it the motional impedance test is an essential feature of an electrical analysis of a loud speaker. Of course, the tests described in this paper are empirical tests applied on a practical scale in the engineering development. They are not pure research work. Motional impedance should be carried out on the loud speakers and on combinations of loud speakers and horns, and I believe that will be one of the best methods for determining the characteristics of different types and the operation of the system as a whole.

Mr. Martin brought up the point of efficiency of loud speaker

determining its characteristic—I believe the answer to this is the same as to Mr. Kellogg's statement, that is that the efficiency at individual frequencies will not determine alone the operation of the loud speaker. You should take the efficiency of individual frequencies in combined tones; that is, where a mixture of frequencies is applied, and determine whether the individual frequencies will come out in the values proportional to the input.

Mr. Martin is correct in saying the difference between the relay type and the enclosed armature type is very small. The difference is simply practical. In our manufacturing experience, we have found that the relay type is cheaper to manufacture and is more adaptable to changes necessary for proper operation.

The curves that have been plotted do not refer to any particular unit of sound. All of these curves are only relative curves. We start with a certain voltage and we obtain a certain voltage. It is the comparison of the efficiency of loud speaker transmitter systems that we are after. This transmitter—the condenser transmitter—is the most perfect transmitter that has been found practical, and naturally the loud speaker, for practical purposes, should be adjusted to this most perfect transmitter. But all results are purely relative. The transmitters that we have been using have all been tested and their resonance frequencies are well outside the range of the curves that have been shown.

Artificial Transmission Lines With Distributed Constants

F. S. DELLENBAUGH, JR.

Member, A. I. E. E.

Secretary, Research Div. Electrical Eng. Dept., Mass. Inst. of Technology.

Review of the Subject.—Artificial transmission lines have been very valuable in developing the theory of transmission of power. This theory has been developed in great detail for steady state conditions, and it is now important to extend it to cover transient conditions. This can best be done upon artificial transmission lines but the usual lumpy type of line introduces parasitic reflections caused by the discrete units of inductance, and therefore are of very limited use for this purpose. Attempts have been made from time to time to produce artificial lines with distributed constants, but the results were either unsatisfactory or expensive and bulky.

A method, originally proposed by Pupin, has been developed by which small compact and cheap artificial transmission line coils can be designed and built to represent any desired configuration of circuit. These involve tinfoil wound in with the wire between the different layers, insulated from the winding by the usual form of condenser dielectric paper. One of the most difficult parts is to arrive at a coil with the proper constants. Formulas have been derived for doing this which will calculate the result given by the coil within the limits of manufacturing error, and which can be used in a straightforward manner similar to the design of other electrical apparatus. Either single or polyphase lines may be represented, and a single-phase line representing the average configuration of a 110,000-volt line approximately 1000 miles (1600 km.) long has been constructed and successfully used for test over a period of about one year. A three-phase line of similar characteristics, but 400 (640 km.) miles long, has also been constructed and is now being used in experimental investigations. The cost of such lines is low, being approximately 6 cents per mile per phase, excluding the cost of mounting.

There are certain limitations of equivalence, but these are in secondary effects which do not cause serious error. One feature contributing largely to the success of this type of line is the possibility of operating at low potentials with moderate amounts of power, and obtaining readings by means of vacuum tube, or Triode, repeaters, which operate without drawing enough power from the circuit to disturb the conditions being investigated. The lines as constructed will easily withstand 110 volts a-c. which is sufficient for most test purposes.

INTRODUCTION

THE theory of the transmission of electricity has been materially advanced through the use of artificial transmission lines in the laboratory. It is difficult to test full sized lines due to the large spaces they cover, simultaneous readings at various points involving complicated communications, while the expense of construction renders the elimination of errors imperative. As longer and longer lines are necessary their behavior must be predicted with correspondingly greater accuracy. In addition, modern large power networks introduce still further complications, and with many lines interconnected to many sources of power the behavior of the system is not only difficult but in many cases impossible of exact mathematical solution. The use of artificial lines which cost a very small fraction of the actual line may thus represent a direct and economical method of investigating the phenomena involved, and may in many cases save expense and errors in designing the actual system.

Artificial lines of various types have been in use for about thirty years, one of the first investigations being in connection with submarine signaling (Bibliography No. 1) and later Pupin (Bibliography No. 2) developed

artificial equivalents in connection with his work upon loaded telephone lines. At the present time these artificial equivalents are used extensively in telephone and telegraph work for balancing circuits, or as standards of transmission distance, while a large number are used for educational purposes in the laboratories of engineering schools. In a few cases power companies have built equivalents of a portion of their system for investigations of the power distribution. (Bibliography No. 3).

The usual construction involves the use of lumped constants, or in other words, a coil having the desired values of resistance and inductance is connected in the proper manner to one or more condensers of the correct value of capacity, the group being equivalent to a section of line of definite length. These units may be connected in either star or delta combinations, and are usually referred to as a T or π section, the arrangement being shown in Fig. 1. If the equivalent section of line is short the values of the total inductance, capacity and resistance per section in the actual line and its artificial equivalent may be made identical without introducing more than a negligible error. If the equivalent section is long, however, correction factors must be used. A very complete description of the design and use of such artificial lines will be found in the special

Presented at the Annual Convention of the A. I. E. E., Swampscott, Mass., June 26-29, 1923.

books upon the subject by Kennelly. (Bibliography 4 and 5).

While this type of construction is in many ways satisfactory and useful it has certain very definite limitations which prevent the experimental development of transmission theory along certain lines. At present the most important of these is the investigation of transient phenomena. The lumpy type of line loses its equivalence to the actual line when the flow of current is not a repeating function, since the constants behave as separate units towards the wave fronts set up in changing from one state of flow to another, resulting in very large reflections from the inductance lump and very large conduction by the capacity lump. If the inductance were entirely free from distributed capacity then a vertical wave front would be completely reflected. However, the inductance coil must always contain a certain amount of distributed capacity and therefore the reflection of a wave front will depend upon the ratio

FIG. 1—(A) LOOP-MILE π SECTION OF LUMPY ARTIFICIAL TRANSMISSION LINE

If the constants are properly chosen it may also represent a wire-mile.

(B) A SIMILAR SECTION OF THE T TYPE, THE CONSTANTS HAVING VALUES GIVING THE SAME NOMINAL LENGTH AS (A).

of the inductance to the distributed capacity that actually exists. Since this capacity is not designed but merely occurs as a result of winding wire in a coil, it is a more or less hap-hazard feature of the usual artificial line. The wave resulting from a transient impressed upon a lumpy line consists of a multiplicity of superimposed reflections which distort it very far from its correct form. (Bibliography No. 6). It is therefore necessary to make an artificial line in which the inductance and capacity are intimately associated at all points in a manner similar to that which actually exists in the real line.

DEVELOPMENT OF THE ARTIFICIAL LINE WITH DISTRIBUTED CONSTANTS

This type of line is referred to as a "smooth" line in distinction from the more usual lumpy line. From

time to time attempts have been made to produce such a smooth line for the study of transient or other conditions. The Taylor and Muirhead (Bibliography No. 1) artificial cable was smooth, but included only capacity and resistance, and therefore could not support a traveling wave. The method used was to slit a sheet of resistance metal in a staggered manner to give the proper resistance, the sheet being separated from an unslitted sheet of similar dimensions by a proper dielectric to give the desired capacity. In 1898 Pupin (Bibliography No. 2) made a smooth line by winding spools of insulated wire with tinfoil interspersed between the layers. This gave the desired characteristics, but did not have sufficient dielectric strength, and failed under the impressed voltage so frequently that it was abandoned. Later Union College (Bibliography No. 7) in collaboration with Steinmetz constructed a smooth line consisting of large glass cylinders lined with tinfoil and wound with a single layer of wire. This had high dielectric strength but was a bulky design as the single layer of wire gave relatively low inductance for the material used, while the thickness of the dielectric resulted in low capacity. It also suffered severely from breakage of the glass cylinders. The amount constructed was equivalent to about 130 miles (209 km.) of single-phase line, occupied 1300 cubic feet (37 cu. m.), and weighed about $3\frac{1}{2}$ tons (3200 kg.).

The Research Division of the Electrical Engineering Department of the Massachusetts Institute of Technology started an investigation of the possibilities of making a satisfactory smooth artificial line in the fall of 1920. The work has been done largely by graduate students and research assistants. Mr. L. H. Becker began the first attempts at making coils with distributed constants, and the first tests were carried out by Messrs. M. F. Gardner and E. J. Arnold, all of these being research assistants. The design of the single-phase line was carried out by the author, and the more extensive tests, which are to be described in another paper, were carried out by Messrs. Scott, Van Ness and Jackson, graduate students, under the supervision of Mr. S. M. Jones, research assistant. The design of the three-phase line was done as a graduate thesis by Messrs. P. T. Coffin and L. O. Buckner, and the test work upon this line is now under way by a group of graduate students.

The first lines of endeavor dealt with lattice-wound coils, the capacity being obtained by copper plating over the insulation, or embedding the coil in Wood's alloy. This gave unsatisfactory results due to large dielectric hysteresis and variations in the resulting capacity. After considerable experimenting it was decided to develop the Pupin type of coil. The final type of construction consists of a multilayer coil wound with bare, or enamel insulated, copper wire of rectangular or circular cross section. Between each layer of winding, and also on the inside and outside of the coil, is wound a layer of tinfoil, insulated from the

conductor by impregnated condenser paper. Each layer of tinfoil projects at one end so that all the layers may be soldered together. There must also be a break in each layer along the same radial line, so that the tinfoil does not make a short-circuited secondary for the main winding. This results in a coil having the capacity uniformly distributed with respect to the conductor. The leakage is also uniformly distributed, but there is a certain periodicity of constants due to the existence of mutual inductance between turns in each coil. This does not appear to interfere with its equivalence to an actual line, as shown from tests made upon the lines. One important facility contributing largely to the success of this construction is the availability of three electrode vacuum tube amplifiers for use in making tests. The operation of the usual type of metering equipment and oscillographs requires so much power that if they are directly connected to the line the resultant equivalent load is very large and distorts the line conditions seriously. Such equipment can only be connected to the end of the line which is attached to the power supply without introducing serious errors.

FIG. 2—CROSS-SECTION OF ROUND WIRE TYPE OF SMOOTH ARTIFICIAL LINE COIL

The arrangement with rectangular wire is the same, but usually somewhat longer compared to the diameter.

By means of the vacuum tube amplifier or repeater, however, oscillographs and other devices may be operated by the plate current of the vacuum tube and controlled by the charge on the grid. If the grid is properly polarized it draws negligible power from the system and therefore does not introduce any undesirable incidental loads. Thus tests may be made with small amounts of power and moderate voltages, the dielectric strength required being low, and as a result the line construction compact. With the high grade materials now available coils of this construction can be made to withstand a working potential of 100 volts per mil of condenser dielectric. This allows a safety factor of from two to three.

Owing to the interdependence of the various constants in the coil the design is somewhat complicated. A change in any one dimension affects all the other constants and cut-and-try methods are very laborious and wasteful. Therefore a method of design has been worked out which will give reasonably accurate results.

It introduces of necessity several design constants, which have to be more closely determined by a sample coil, but usually one or two samples will suffice to predict the results within five to ten per cent, which is as close as coils of this sort can be manufactured commercially. If greater accuracy is necessary the coils must be wound slightly oversize and then unwound until they fit the required constants. Since the capacity reduces directly with the first power, and the inductance approximately proportionately to the square of the turns unwound, it is always possible to unwind an oversize coil to a point where the desired ratios are obtained. The equivalent size of conductor represented by the artificial line is roughly proportional to the size of conductor actually used in winding the coil, and varies but very slightly for a small change in the number of turns. Thus unwinding the coils changes the equivalent spacing rapidly, the equivalent length of line slowly, and the equivalent conductor size remains practically constant.

THE USE OF LOOP-MILE AND WIRE-MILE EQUIVALENT CIRCUITS

As mentioned above the transmission line may be represented by T or π sections having the values of inductance, capacity, resistance and leakance existing in the actual line. In the same way these constants may be worked into the smooth type of artificial line. In this case, however, since the constants are distributed, the actual values of the constants are used, and no correction factors applied. No attempt has been made to introduce leakance into the design, since this is rather an indefinite constant, depending, in the actual line upon the condition of the insulators and the weather and in the artificial line upon the amount of moisture present and the type of dielectric. Since it is usually very low in aerial lines no serious error is introduced by this omission provided its resultant magnitude is comparable to that observed in practise.

One point which frequently leads to confusion is the use of either wire or loop-mile equivalents. The wire-mile equivalent is a circuit equivalent to one wire of the transmission line represented, and is of no use by itself, always requiring a return circuit of similar nature. The loop-mile equivalent is a circuit representing both sides of the transmission line, that is the line going out and the line returning, and represents the complete transmission system by itself. A loop-mile circuit may be made from one or more wire-mile circuits. In the case of the representation of a single-phase line either one is satisfactory, the terminal conditions being identical, and the loop-mile equivalent usually being simpler to construct. In the representation of a three-phase line three wire-mile equivalent circuits must be used. Fig. 3 will perhaps make this clearer. Case (a) represents an artificial π line section with two groups of inductance and capacity. This can be broken up into two wire-mile equivalents as shown in (b), the

circuit on either side of the line $m-n$ being a wire-mile equivalent. It will be noted that this requires the use of larger capacity for each circuit, since the individual condensers are connected in series. Case (c) is a loop-mile equivalent circuit having the same terminal characteristics as either of the others, but requiring only one inductance coil and the minimum size of capacity. Case (d) shows the arrangement of an equivalent circuit for a three-phase line with equilateral spacing. This neglects the capacities to ground. Case (d) can easily be converted to (e), the condensers being connected in star instead of delta. It will be seen that this latter case consists of three wire-mile equivalent circuits. In some cases the constants are spoken of as inductance or capacity to neutral, which is merely a different way of stating the wire-mile values.

FIG. 3

 (B) THE SAME CIRCUIT AS (A) BROKEN UP TO SHOW TWO WIRE-MILE EQUIVALENT SECTIONS COMBINED TO REPRESENT THE LINE
 (C) THE SAME SECTION LENGTH AS (B) WITH THE CONSTANTS LUMPED TO GIVE A LOOP-MILE SECTION
 (D) A THREE-PHASE TRANSMISSION LINE REPRESENTED BY LUMPED CONSTANTS
 (E) THE SAME CIRCUIT AS (D) WITH THE CAPACITIES CONNECTED IN STAR INSTEAD OF DELTA

(The values of the constants in all the different sections are marked to show the values giving the same nominal length of section for each type of circuit). It will be noted that this is the same as three of the wire-mile sections used in (b).

The same arrangements can be used in the smooth line artificial coils, except that the capacity is of course distributed. The hardest thing to get in the design is sufficient capacity, particularly with round wire. Therefore, where it is possible to do so the loop-mile equivalent is desirable from the standpoint of economy and compactness. It is also the only type that can be easily obtained with round wire, and for this reason the three-phase lines are constructed with flat strip. While the flat strip is a little more difficult to obtain, usually standard sizes can be used, and it introduces greater flexibility in the design, since the resistance can be changed by altering the thickness without seriously affecting the capacity, which is dependent upon the width of the copper strip and the thickness

of the dielectric. The three-phase design later described may of course be also used for single-phase design, since it is merely a method of arriving at the constants of the coil, and these may be chosen to represent any desired form of line within the possible limits of the artificial coils. It should also be borne in mind that any coil containing inductance, capacity and resistance will represent some kind of transmission line, but the relations of the constants may be such that the actual line represented is of extreme or grotesque configuration.

DESIGN OF SINGLE-PHASE LINE WITH ROUND WIRE COILS

Appendix I gives the derivation of the design formulas. The resultant useful formulas are as follows:

$$l = \frac{0.915 l_e^{3/4} (\delta + k r)^{3/8} y^{1/4} 10^3}{(H K)^{3/8} r^{1/8}} \quad (12)$$

$$\delta = \left\{ 0.003 \left[\log_{10} \frac{2S}{d} \right]^{1.6} \left[\frac{y r}{l_e} \right]^{0.4} \left[\frac{K}{H^{0.6}} \right] - k \right\} r \quad (14)$$

The procedure in the design is as follows:

- 1st. Choose values to substitute in (14):

$\log \frac{2S}{d}$ is determined from the line configuration.

y depends upon the insulation or setting of winding lead screw. Enamel insulation alone has less dielectric loss than fabric covered wire. With this type of insulation (y) is found to be about 1.3. Obviously it can never be less than unity.

l_e may be arbitrarily fixed as a long line is represented by several sections. If the line is short it is made equal to the length of line to be represented. More than ten miles per section with the round wire coils makes bulky units, but the cost per mile is not greatly affected. A larger equivalent length for fixed equivalent spacing and thickness of dielectric requires an increase in the size of wire used. Thus if the wire radius is found to be very small it is advisable to increase l_e or δ .

K depends upon the dielectric used. For the usual types of condenser paper and impregnation it varies from 2.5 to 3.0. A good average value for trial is 2.8.

H depends upon the shape of the coil. Its maximum value is 6.06×10^{-4} and therefore a value slightly less than this should be used and the coil shape arranged to approach the maximum as closely as possible.

k should be taken as 0.215 unless considerable bedding occurs, in which case it is decreased somewhat.

δ is usually chosen for dielectric strength, and modified if necessary to alter the characteristics of the coil. It should never be less than 0.002 inches (0.005 cm.) and where possible should consist of two sheets of paper to obtain greater uniformity.

2nd. The constants having been determined and a value of l_e chosen, find r from (14) by cut-and-try or graphical solution.

3rd. Find l from (12). (Formula (13) Appendix I may also be used.)

4th. Check resistance of coil against resistance of actual line of same length (l_e) from formula:

$$R_2 = \frac{l \rho \times 10^{-6}}{\pi r^2} \quad (\text{See Appendix I}) \quad (10)$$

The resistance will vary very nearly directly with the value r^2 as shown in Fig. 4, so correct to the proper

FIG. 4—CURVE SHOWING THE RELATIONS BETWEEN THE DIAMETER OF WIRE WOUND IN THE SMOOTH ARTIFICIAL LINE COIL AND THE EQUIVALENT DIAMETER OF TRANSMISSION LINE CONDUCTOR REPRESENTED

The upper curve is for a wire spacing of 18 ft. (5.5 m.) and the bottom curve is for a spacing of 6 ft. (1.83 m.). The equivalent length of section varies from 2 to 40 miles (3.2–64 km.), increasing with the diameter of wire in coil. The length of wire in the coil varies from 5000 to 50,000 cm. (164–1,640 ft.), also increasing with the diameter of wire. The design constants were taken as follows:

$$K = 2.5 \quad \nu = 1.5 \quad H = 0.6 \times 10^{-3} \quad \delta = 0.0025 \text{ in.}$$

size of wire if necessary and repeat the last three steps, δ being corrected from (14).

5th. The values of r , l and δ having been determined, next calculate the mean winding radius, turns per layer, number of layers, etc.

H is maximum when $b/c = 1$ and $c/a = 0.06$ to 0.8 (Bibl. No. 8). The coil dimensions can be easily obtained from the following relations:

$$a = \sqrt[3]{\frac{l c 2 (y r)^2}{\pi b (c/a)^2}} = 1.20 \sqrt[3]{l (y r)^2} \quad (37)$$

(if the optimum values of c/a and b/c are used.)

$$c = 0.662 a = Q p = Q (2r + 2\delta + f) \quad (38)$$

$$b = c = 2 s y r \quad r_1 = a - c/2 \quad r_2 = a + c/2$$

Bibl. No. 8)

Since H is not critical the nearest values giving Q , n and s whole numbers should be used.

Winding the Coil. A mandrel is made with its diameter equal to $2 r_1$. A roll of tinfoil should be procured about one inch wider than the dimension b , and the dielectric paper should be about 1/2 in. wider than b . It is convenient to have a hot iron to melt the wax on the overlapping edges of this paper and thus fasten it in place. The winding is started by first covering the mandrel with paper, and then placing one sheet of tinfoil in place. The tinfoil must be cut to leave a gap about 1/8 in. wide at the ends to prevent short-circuited turns. All these gaps should be on the same radial line so that the ends can all be soldered together without producing short circuits from layer to layer. The tinfoil is then covered with the proper thickness of dielectric paper, and the winding started, one layer being completed. Another layer of dielectric tinfoil and dielectric is put in place, and another layer of wire wound, this process being repeated until the proper number of layers are completed. The coil is finished off by a final layer of tinfoil, and well covered with heavy paper for protection. In placing the dielectric paper it is a good plan to have the overlapping ends either carefully cut to fit in the tinfoil gap, or distributed as evenly as possible around the circumference, to avoid building up a bump upon one side of the coil, which tends to lower the capacity. The tinfoil is placed so that one side projects beyond the dielectric paper. These projecting edges are now all soldered together and the lead wire soldered on. The whole coil is then impregnated, preferably in vacuum. Ceresin wax is desirable for this as it is more nearly moisture proof than paraffin. Tests upon sample coils should always be made after they have been impregnated in exactly the same manner as the finished coils, since the capacity is changed quite materially by this treatment, usually being increased about ten per cent. Moisture affects the capacity, leakance and dielectric hysteresis of the coil, therefore the coils should be mounted in a tight box and preferably calcium chloride or other moisture absorbing compound used to take up the small amount that penetrates the walls.

EXAMPLES OF SINGLE-PHASE ROUND WIRE COILS

The single-phase line of this type in the Massachusetts Institute of Technology laboratories was built as an approximate duplicate of an aerial line with 10 ft. (3 m.) spacing. This would correspond to about average practise upon a 110-kv. line. No limitation was set upon the equivalent conductor size providing it was within reasonable limits. The results of the first four sample coils are given in Table I. The coil constants were chosen to give representation of the line by loop-mile equivalents. The final specifications are given in Table II, and the design check for the average constants in Appendix III.

On coils No. 1, 2 and 3, y came out lower than expected which increased the inductance. The paper dielectric ran thicker than specified which tended to decrease the capacity, but at the same time the dielectric constant was higher than expected so the variation in capacity was minimized. The equivalent length of section and diameter of conductor check reasonably with the design, but the spacing is in error,

TABLE II
SINGLE-PHASE ROUND WIRE COILS
Loop Mile Equivalent
FINAL COIL SPECIFICATIONS

Wire size.....	No. 23 B & S enamel covered
Diameter of winding mandrel.....	1.8 inches. (4.57 cm.)
Total number of turns.....	792
Turns per layer.....	36
Number of layers.....	22
Thickness of dielectric, one sheet....	0.002 inches. (0.0051 cm.)
Thickness of tinfoil.....	0.003 inches. (0.0076 cm.)
Gap in tin foil.....	0.25 inches. (0.6 cm.)
Tolerance.....	$L/C = 640 \begin{cases} + 3\% \\ - 5\% \end{cases}$

due to the difference in inductance and capacity both being in the direction to increase spacing, except in the first coil. The specifications were given in terms of layers and turns per layer, which increased the length of wire in coil slightly, as the layer pitch was greater than expected.

Coil No. 4 was designed upon the data obtained from the first three, and fairly close results were obtained. Breakdown tests upon the dielectric showed erratic results. The voltage varied from 320 to 1000, 60-cycle a-c. root-mean-square value. Most of the 8 coils tested for breakdown withstood from 450 to 600 volts. Wind wire with highest practicable tension. Impregnate coil after winding. Solder all tinfoil together on one end and attach flexible lead. The first and last layers to consist of tinfoil and dielectric. Protect outside of coil with 0.005-in. (0.012 cm.) fish paper.

FINAL COIL DIMENSIONS

126 coils of this type were manufactured representing approximately 1000 miles of single-phase line. The average results are:
Weight of complete coil.....1.88 pounds (0.858 kg.)

Outside diameter.....	3.5 inches (8.9 cm.)
Inside diameter.....	1.75 inches (4.45 cm.)
Winding length.....	$1\frac{1}{16}$ inches (2.7 cm.)
Coil length over insulation.....	1.5 inches (3.81 cm.)
Coil length over tinfoil, total.....	2.0 inches (5.08 cm.)
Winding depth.....	$\frac{7}{8}$ inches (2.22 cm.)

DESIGN OF ARTIFICIAL LINE WITH RECTANGULAR WIRE COILS

The derivation of the design formulas is given in Appendix II. The resultant formulas used in the design are as follows:

Mechanical dimensions of coil:

$$a = 3.2 (z/L) (w R t/\rho)^2 10^{-10} \quad \text{(I)}$$
$$b = 2 r_1 = y w s \quad \text{(II)}$$
$$c = Q p = n p/s \quad \text{(III)}$$
$$r_1 = b/2 = y w s/2 \quad \text{(IV)}$$
$$r_2 = r_1 + c = r_1 + n p/s \quad \text{(V)}$$

Winding Dimensions of coil:

$$n = \frac{5 \rho L 10^8}{z w R t} \quad \text{(VI)}$$
$$Q = n/s \quad \text{(VII)}$$
$$P = (t + 2 \delta + f) \quad \text{(VIII)}$$
$$s = \frac{a \pm (a^2 - y w n p)^{1/2}}{y w} \quad \text{(IX)}$$

NOTE: (IX) is derived from (7) and (8).

1. The equivalent line values are calculated by the more accurate formulas given in Appendix V. If the approximate formulas in Appendix I are used slightly different results are obtained.

Dielectric thickness:

$$\delta = \frac{88 w K q L}{N c Z} \quad (X)$$

The procedure in the design requires the assumption of a definite value of thickness of copper strip, the width and dielectric thickness then being chosen to give the desired characteristics. The constants of the line to be represented may be determined from any desirable formulas, those given in Appendix I being satis-

FIG. 5—CHART SHOWING THE RELATIONS BETWEEN THE VARIOUS DIMENSIONS AND EQUIVALENTS OF ROUND WIRE SMOOTH LINE LOOP-MILE SECTIONS

Values are calculated for a fixed value of dielectric thickness of 0.0025 in. (0.00635 cm.) Since they are all interdependent they can all be plotted to the same coordinates. For example, 20,000 cm. of No. 22 B & S wire will result in a section having an equivalent length of 10 miles with equivalent spacing of ten feet, and the ratio $2S/d = 700$, thus the equivalent conductor diameter is 0.34 in. The curves are plotted for average values of design constants and therefore give approximate results only.

factory. The procedure in the design will then be as follows:²

- 1st Determine values of L , R and C desired from line configuration and length of section desired to represent.
- 2nd Assume values of design constants z , q , y , ρ and K .
- 3rd Assume several values of thickness of copper strip.
- 4th Solve for (w/n) from formula (X).
- 5th Solve for (wn) from formula (VI).
- 6th Determine values of (w) and (n) from last two steps.
- 7th Solve for value of (a) from formula (I).
- 8th Solve for value of (s) from formula (IX).
- 9th All other dimensions may then be determined by direct substitution in the desired formulas.

2. The design of this first line has been made under the limited assumption of equilateral spacing, and absence of the ground plane. The extension of the design to the more general case is discussed later on in the paper. The methods are the same, different constants being used.

It will be seen that the width of copper strip is determined from the design and that a definite value is necessary for any given thickness. It is usually desirable to try several sizes for the preliminary steps. As the formulas are based upon the fixed relation that the winding length is equal to the internal diameter, (see Appendix II) it is easy to form a mental picture of the size of the coil from the average winding radius (a) determined as in the 7th step above.

As it is impossible to avoid variations in design constants due to non-uniformity of materials and manufacturing methods, a sample coil should next be made up, from which the correct design constants can be determined for the exact conditions encountered and the final design arrived at by the same methods.

It should be remembered that it is possible to make a coil which satisfies the requirements of L , R and C but does not meet the requirement that the winding length is equal to the internal diameter. After building a sample some slight modifications may be found desirable to make it fit the imposed conditions more accurately so that the finished coil may ultimately have a winding length different from the inner diameter by a small amount.

EXAMPLES OF THREE-PHASE RECTANGULAR WIRE COILS

The line in the Mass. Inst. Tech. laboratories was designed to duplicate an average of present standard practise upon 110-kv. lines. The following charac-

FIG. 6—SEVERAL TYPES OF SMOOTH ARTIFICIAL LINE COILS

Upper left is lattice wound embedded in Wood's Alloy. Upper right is round wire single-phase 8 loop-mile section. Lower left is experimental three-phase coil, and lower right the final three-phase coil of 20 wire miles per section.

teristics were taken from data upon a number of existing lines:

Length of section.....	20 miles. (For convenience) (32 km.)
Voltage.....	110,000 volts
Spacing.....	120 in. (3.05 m.)
Conductor.....	No. 0000 B & S
Arrangement of conductors.....	Equilateral

From these data the constants per section are:

Resistance per wire (R).....	5.185 ohms
Inductance per wire (L).....	0.04183 henries
Capacity per wire (C).....	0.2855 microfarads

Three thicknesses of copper strip were tried and No. 28 B & S seemed to give the best design. Two coils were made up, supposedly duplicates, and the results obtained are shown in Table III.

From these values it appeared that either the dielectric constant or the constant (q) in the capacity formula had been assumed too small, and that the tension used in winding had stretched the wire, increasing its resistance.

Coil No. 3 was then made up with the same specifications except that thicker dielectric was used and the results, as shown in the tabulation, check quite well except that the resistance is still a little high. Since no attempt was being made to duplicate an exact line, but merely to obtain one that would represent average conditions, this was considered close enough and the final design was based upon this information. The actual equivalence is shown in Table III.

TABLE III
THREE-PHASE RECTANGULAR WIRE COILS
Wire Mile Equivalent

Calculated Values		Test Values				
		Coil No. 1	Coil No. 2	Error	Coil No. 3	Error
L	0.0418	0.0410	0.0420	2%	0.0425	1.7%
C	0.2855	0.3470	0.3270	21%	0.2850	0.0%
R	5.185	5.862	5.879	13%	5.946	14.5%

	Calculated Values	Test Values	Coil No. 3	Error
Length.....	20 miles (32 km.)	20.2 miles (32.4 km.)		1.0%
Spacing.....	120 in. (3.05 m.)	120 in. (3.05 m.)		0.0%
Size of conductor	212,000 c. m. (107 sq. mm.)	186,000 c. m. (94 sq. mm.)		12.3%

The fact that the length and spacing of coil No. 3 both check so closely is of course merely a coincidence with this particular coil.

The final coil specifications and measurements upon finished coils are given in Table IV. The calculations of the final coil are given in Appendix IV. It will be noted that the specifications are not exactly the same as the calculations, slight changes having been made to meet the commercial conditions. Thus the nearest standard size of fiber tubing for a hub had a diameter of 4.16 in. (10.6 cm.) making the value of r_1 actually 2.08 in. (5.3 cm.) instead of 1.88 in. (4.8 cm.) as designed. To compensate for the increase in diameter, the spacing of the turns was increased slightly as well, which resulted in the final coils being of substantially the same characteristics as expected.

Wire to be wound with uniform tension. Solder all projecting ends of tinfoil, and attach flexible lead. Impregnate coil after winding. The first and last layers to consist of tinfoil and dielectric. Protect the outside of coil with heavy fish paper.

FINAL COIL DIMENSIONS

60 coils of this type were manufactured, representing approximately 400 miles of three-phase line. The average results are:

Weight of complete coil,	
approximately.....	7.5 pounds, (3.4 kg.)
Outside diameter.....	Varies from 5.5 to 5.8 in. (14 to 15 cm.)

FIG. 7—THE 1000 MILE SINGLE-PHASE SMOOTH LINE ASSEMBLED IN BOXES. ONE BOX IS OPENED TO SHOW ARRANGEMENT OF COILS

Inside diameter.....	4.125 in. (10.5 cm.)
Over all length.....	Approximately 5.5 in. (14 cm)
Winding depth.....	Varies from 0.69 to 0.87 in. (1.75 to 2.2 cm.)

FINAL COIL CONSTANTS AND EQUIVALENT VALUES

	Per coil	Total average, per wire
Resistance.....	5.51 to 6.02 ohms	114.0 ohms
Inductance.....	0.041 to 0.043	0.84 henries
Capacity.....	0.251 to 0.312	5.25 microfarads
Equivalent length of line.	19.1 miles (30.5 km.)	382.75 miles (613 km.)
Equivalent spacing.....	144 inches (3.56 m.)	144 inches (3.56 m.)
Equivalent conductor diameter.....	0.426 in. (1.08 cm.)	0.426 in. (1.08 cm.)

Both sets of lines were manufactured by the General Radio Company of Cambridge, Mass. They are particularly fitted for the manufacture of this type of apparatus since it involves production methods very similar to those used in the manufacture of radio

apparatus. The author would like to take this occasion to express his appreciation of their assistance in developing these lines and in carrying out some of the experimental work.

A number of the coils were tested for breakdown potential between the wire and tinfoil. The voltage required was rather erratic due to variations in dimensions and quality, the single-phase coils breaking down under an impressed a-c. voltage of from 320 to 1000 volts, root-mean-square value. The three-phase coils, having thicker dielectric, withstood higher potentials, the lowest breakdown being found at 700 volts, and the majority of those tested running between 800 and 1200 volts. After about one year's service in more or less continual use, the single-phase line has only developed one case of trouble, one of the coils having high leakage which developed into a breakdown. Upon removing this coil no further trouble has been experienced. The voltages impressed were usually 110 volts a-c.

FIG. 8—THE ARRANGEMENT OF FOUR SECTIONS OF THE SMOOTH THREE PHASE LINE IN CONTAINING BOX

Coils are spaced so that mutual between them is negligible, but can be moved to obtain desired value if required. The cage in corner of box is for moisture absorbing compound.

or d-c., and higher values occurred in parts of the line during some of the tests.

The constants of the coils were measured in the development work by means of bridge measurements at 1000 cycles, for the inductance and capacity and leakage, the resistance being measured upon a d-c. bridge. After assembly into the final line the average constants were then determined by the free and grounded impedance method with a-c. potentiometer readings at 60 cycles. These latter readings of course give the values that should be used in computing the line, and very little difference in constants was found, being less than the individual error between different coils due to variations in manufacture.

The cost of coils is interesting. It will vary with the type of line used, the form of representation and the size of conductor. In general the larger the transmission line being represented, in terms of spacing and conductor size, the more expensive will be the artificial line coils. The single and three-phase lines being

described both cost almost exactly 60 cents per mile per phase for the coils without mounting. The single-phase coils are smaller but represent approximately eight miles of line. The three-phase coils are larger and more expensive, but represent about twenty miles of line each. The three-phase line of course requires three coils for each section and therefore is about three times as expensive to build as the single-phase line,

FIG. 9—THE 400 MILE THREE PHASE SMOOTH LINE, AS IT STANDS IN THE LABORATORY, IN USE FOR TRANSIENT INVESTIGATIONS

Spacing cribs are placed between boxes to eliminate mutual inductance vertically.

since single coils would be of about the same cost per mile. The labor cost depends to a large extent upon the number of layers per coil, since it is the placing of the tinfoil and paper that is the expensive operation.

TESTS UPON THE SINGLE-PHASE SMOOTH ARTIFICIAL LINE

An extensive study of the behavior of the line under d-c. transient conditions was made by graduate students as already mentioned. The d-c. transients were

FIG. 10—THE DIRECT CURRENT TRANSIENT AT THE HOME END OF 992 MILES OF THE SINGLE-PHASE ARTIFICIAL TRANSMISSION LINE, THE FAR END BEING OPEN

chosen as a preliminary step to the investigation of a-c. transients, since the former can be calculated with reasonable facility while the theory of the latter is still extremely embryonic. Fig. 10 shows the current transient upon 992 miles (1590 km.) of the line, the far end being open with no load and the current being taken at the near end. It will be seen that there is no evidence of partial reflections and that the line appears to behave in the same manner as the actual line it represents. Theoretical checks upon the transients

confirm this. Fig. 11 shows the current at the near end of the same length of line when the far end was short-circuited. In these curves the reflections occur at the proper intervals for the travel of the wave front over the whole line. The mathematical analysis of these oscillograms shows that they check the expected results with excellent fidelity. The details will be omitted here as another paper is to be devoted to the discussion of the test details, and these are merely shown as examples indicating the absence of lumpiness in this type of artificial line.

FIG. 11—THE DIRECT-CURRENT TRANSIENT AT THE HOME END OF 992 MILES OF THE SINGLE-PHASE ARTIFICIAL TRANSMISSION LINE, THE FAR END BEING SHORT-CIRCUITED

LIMITATION OF EQUIVALENCE OF THE SMOOTH TYPE OF LINE

There are certain limitations in representing an actual system by this type of artificial line. Some of these involve the characteristics of the materials used in the coil, while others deal with the possibilities of arrangement to represent unsymmetrical configurations, conditions of unbalance and the like.

Under the first classification the most noticeable is the effect of dielectric hysteresis, which is present in the artificial lines and is absent or negligible in the actual line. This means that the apparent leakance is a function of frequency, and must be minimized by maintaining the hysteresis loss as small as possible. Its effect upon the transient is to distort the wave front and cause it to deviate from the perpendicular. The effect is not large if good materials are used and should not cause serious error. There is also no control over the actual leakance, but its magnitude appears to be of the proper order. The leakance in the artificial coils is entirely distributed, while in the actual line it is lumped at the towers. This difference does not appear to cause any discrepancy since the effect of leakance in aerial lines is usually very small.

In the actual transmission line skin effect is present, while this effect is practically absent in the artificial line coils. It is of small magnitude compared to other factors, but may be of great importance in dealing with steep wave fronts and high-frequency transients. The dielectric hysteresis of the artificial line is of somewhat similar character, and therefore exact equivalence under high-frequency conditions would appear to depend, at least in part, upon the possibility of

obtaining equivalence of skin effect by dielectric hysteresis.

The ordinary lumpy type of artificial line has a definite periodicity of arrangement of discrete constants and therefore acts as a filter, with fixed values of cut-off frequency, the usual type being a low pass filter. It is important to have this cut-off value very different from any of the frequencies encountered in the test work in order to have correct representation. Strictly speaking an artificial line is only equivalent to the actual line for one frequency. If the cut-off frequency is remote from the operating frequencies, however, the discrepancies for the different frequencies are very slight. In dealing with transients, high frequencies occur in two ways. The period of reflection or oscillation of the transient may be of high frequency, and a steep wave front may be represented as a Fourier's Series containing a very large, or perhaps infinite number of frequencies. Thus it is extremely necessary that the characteristics of the line shall not alter as the frequency is increased, except in the same way that the characteristics of the actual line would alter. In the smooth type of artificial line there is a certain amount of periodicity due to a number of separate coils being used, and the mutual inductance between turns in each coil being lumped within the coil, there being no mutual between separate sections. On the other hand the capacity is entirely distributed with respect to the wire. This is to be the subject of further investigation. Probably if any cut-off value exists it is of very high frequency.

The three-phase line has been designed to represent an isolated line of equilateral spacing with currents and

FIG. 12—THE ARRANGEMENT OF CONDENSERS USED BY GRAY IN LUMPY ARTIFICIAL LINE TO REPRESENT THE EFFECT OF THE GROUND PLANE

voltages that either are balanced or add up to zero, so that there is no residual potential between neutral and ground. The effect of the ground plane has, for the time being, been neglected. These assumptions do not coincide with the actual case, where the ground plane must be considered, but were chosen as the basis upon which to build up the experimental and theoretical investigation. Mutual inductance between coils has also been omitted, the coils being mounted far enough apart so that the mutual between them is negligible. This again does not entirely coincide with practise

as mutual exists between the different circuits of a three-phase transmission line, but if the limitations of current and voltage stated above are adhered to, the mutual upon an equilaterally spaced line cancels out and does not affect the distribution.

There are several ways in which these added factors may be introduced. Gray (Bibl. No. 3) has made a careful study of the equivalence of artificial and actual lines, and constructed a lumpy type of artificial line to represent an actual transmission system. His theoretical treatment takes into account the effect of the ground plane upon the capacities between conductors, as well as mutual inductance between circuits and the effects of unbalance. The condenser circuit used for the equivalent artificial section is shown in Fig. 13. The three condensers in star represent the capacities of the lines to ground, and the three condensers in delta represent the capacities between wires. By the usual star-delta transformation formulas (Bibl. No. 4) it is possible to transform this combined circuit to either one star or one delta combination of capacities. The only difficulty is that in doing so the ground plane connection disappears, since the neutral

FIG. 13—VACUUM TUBE REPEATER CIRCUIT USED FOR OBTAINING OSCILLOGRAMS WITHOUT DRAWING POWER FROM THE ARTIFICIAL TRANSMISSION LINE

of the condensers must represent the neutral zone of the system of transmission conductors. If the distance between conductors is small with respect to the distance to ground, then all the capacities in Gray's system, Fig. 13, can be assumed symmetrical with small error. With the configuration of the usual transmission system this will result in less error than the probable accuracy of the test work and the variations in the coils themselves, unless each one is individually adjusted by unwinding as mentioned above. In this case the capacities of all the wires to ground can be replaced by one capacity connected from the neutral of the system of conductors to the equivalent ground plane. This has not been tried, but should represent any desired configuration with reasonable accuracy. It introduces, however, discrete units of capacity which give periodicity and to a certain extent destroy the smoothness of the artificial line. This may have an undesirable effect under transient conditions, but it is improbable that it would be of very great magnitude since the capacities to ground are small compared to those between conductors. If the spacing of the conductors

is not equilateral, unsymmetrical capacities are needed. Usually this would require a section consisting of two coils with one value of capacity and the third coil with a different value. This can be obtained readily with the type of smooth line described by working through two designs for the desired characteristics, using the rectangular wire type of coil, the flexibility of the design allowing changes in capacity without altering the equivalent length of section. Possibilities in this direction and the accuracy of equivalence of the three-phase line which has just been constructed are to be the subject of further investigation.

Mutual inductance between the artificial line coils in any one section will be required if a current or potential distribution exists which impresses a residual voltage between the neutral of the transmission system and ground. In the actual case this will result in a current flowing in the ground. Therefore, in order to calculate the value of this mutual inductance, it is necessary to know the distance of the return path through the ground from the electrical center of the system. This is variable due to the characteristics of the soil adjacent to the transmission line. Gray has assumed that the center of the return path of the ground current lies 20 feet (6.1 m.) below the surface and adds this distance to the height of the transmission system above ground in order to calculate the required mutual inductance. It is probable that this is correct for some cases and represents an average condition, although other cases might depart from it materially. Upon this basis the mutual introduced has a magnitude of about 20 per cent of the self inductance of the coils, and so can be readily taken care of. If the transmission line coils are assembled so that this value of mutual inductance exists it will then represent a different actual line from the one it would represent if no mutual inductance were present. This occurs on account of the fact that, although the mutual inductance cancels out for zero summation, or balanced currents and voltages, it nevertheless reduces the effective value of inductance in the coils, the net resultant self-inductance being equal to the total self inductance less the mutual inductance. Gray gives the formulas for computing the mutual and self inductance under any assumed conditions as:

$$L_s = 2 \left(\log_e \frac{2S'}{d_1} + 1/4 \right) \quad (39)$$

abhenries per cm. per wire

$$L_m = 2 (\log_e S'/S) \quad \text{abhenries per cm. per wire} \quad (40)$$

The net resultant self inductance of the given length of artificial line will then be $(L_s - L_m)$ per wire, and this value should check the value obtained from the formulas of Appendix I where no mutual is taken into account. If the mutual inductance for a 110-kv. line of No. 0000 B & S conductors spaced 120 in.

(3.05 m.) is considered, the distance S' being taken as 50 ft. (16.3 m.), then:

$$L_m/L_s = \frac{\text{Log}_e (600/120)}{\text{Log}_e (1200/0.46)} = 0.204$$

[Omitting the term $1/4$ in (39)]

Thus for this case the mutual inductance is about 20 per cent of the total self inductance. In the case of the smooth three-phase artificial line discussed it was designed to have a value of self inductance equivalent to the value of $L_s - L_m$ as found by these formulas. Therefore if the mutual inductance is introduced to correct it for equivalence under special conditions it will change the line which it represents. Since the capacity and resistance remain the same and the inductance is reduced, it will have the effect of reducing the equivalent length of section and the equivalent diameter of conductor about 10 per cent. As the total capacity per coil remains unchanged, its value per unit length of equivalent line is thus increased and this will decrease the $2S/d$ ratio about 20 per cent. Since the equivalent diameter of wire has been decreased a lesser amount the spacing will be slightly decreased. Thus in general the effect upon the equivalent actual line of introducing mutual between the artificial line coils is to decrease the length, conductor size and spacing by an amount smaller in proportion than the amount of mutual introduced, when expressed as a per cent of self inductance.

CONCLUSIONS

Artificial transmission lines can be successfully built with distributed constants, which will in the main duplicate the behavior of actual transmission lines, not only under steady state conditions but also under transient conditions. Certain properties of the materials used in the coils introduce effects in the artificial line which are not present in the actual line, and the change in dimensions causes some of the effects present in the actual line to be absent in the artificial line. However, as shown by the correspondence between the experimental work and the theory for relatively simple cases, the results of these divergences from exact equivalence are very small, since the discrepancies are of secondary nature, and a great deal of information can be obtained by the use of such artificial lines in studying transient and other conditions. Single-phase lines can be easily and accurately duplicated. Three-phase lines require more complexity of circuit, particularly where special configurations of line or special load conditions are to be represented, but the method of design and construction is sufficiently flexible to allow of this being accomplished. The accurate introduction of the ground plane effects and mutual inductance between wires requires further analysis and study and the possibilities of duplicating networks will be developed with further experimental work. Complete transmission systems can be represented by such coils, but in order to be fully useful the

effect of terminal apparatus must be introduced by artificial equivalents as well, and this is the subject of separate investigations at the present time. From the economical standpoint this type of transmission line is cheap, compact and rugged.

Appendix I

DERIVATION OF DESIGN FORMULAS FOR ROUND WIRE COILS

Inductance of Transmission Line. From the usual theory is derived the inductance formula:

$$L_1 = 4 \log_e (2S/d) + \mu/2 \text{ abhenries per cm.} \quad (1)$$

The error in omitting the term $\mu/2$ is very small. For the configuration usually used in high-tension power lines this error is less than 2 per cent, which is smaller than the error resulting from differences in materials and dimensions of the artificial coils and can thus be neglected. Omitting the term $\mu/2$ and substituting the proper conversion factors the formula becomes:

$$L_0 = 1.482 \left(\log_{10} \frac{2S}{d} \right) 10^{-3} \text{ henries per loop mile} \quad (2)$$

Capacity of Transmission Line. The capacity between wires is given by:

$$C_1 = \frac{1}{4 \cosh^{-1} (S/d)}, \text{ and approximately,}$$

$$C_1 = \frac{1}{4 \log_e (2S/d)} \quad (3)$$

The result being in statfarads per cm.

The errors in the approximate formula are very small for aerial lines where the ratio $2S/d$ is large. For the average configuration the error cannot be detected in ordinary slide rule calculations. Therefore the approximate form is used. By substituting the proper conversion factors, (3) becomes:

$$C_0 = \frac{19.41 \times 10^{-9}}{\log_{10} (2S/d)} \text{ farads per loop mile} \quad (4)$$

Resistance of Transmission Line. The resistance of the line is given directly by the formula:

$$R_1 = \frac{2l_s \times 5280 \sigma}{d_1^2 \times 10^6} \text{ Ohms. (Total for the length}$$

being considered). The value of σ is about 10.4 per cm. foot at 20 deg. cent. for copper. (5)

These three formulas determine the constants of the line it is desired to reproduce, the units being in the usual American system. The leakance is omitted as discussed in the body of the paper.

Inductance of the Artificial Line Coil. The formula of the Bureau of Standards (Bibl. No. 8) is simple to use and gives reasonably accurate results:

$$L_2 = [l'^3/D^2] H \times 10^{-3} \text{ millihenries} \quad (6)$$

The form factor H does not vary rapidly for small changes in coil dimensions, and so may be assumed constant. (This is the factor G in the Bureau of Standards nomenclature.)

Since D is a function of the wire radius it is convenient to express: $D = 2 y r$. From which:

$$L_2 = \frac{l^{5/3}}{(y r)^{2/3}} H \times 10^{-3} \text{ millihenries} \quad (7)$$

Capacity of Artificial Line Coil. The best formula for the calculation of capacity is open to question. If the successive turns of wire were not so closely adjacent probably a logarithmic form similar to that of transmission line to ground would be more accurate. But the electrostatic field is actually so different that it does not hold. If the wire beds in the tinfoil and dielectric some form of concentric cylinder capacity formula would apply. If there is no bedding and the electrostatic field is uniform, the capacity formula for flat plates could be modified to give close results. Probably the actual case is a combination of the various circumstances enumerated, but an empirical investigation showed that the flat plate formula gives the closest results. Thus:

$$C_2 = (K A / 36 \pi x) 10^{-5} \text{ microfarads for flat plates} \quad (8)$$

With round wire: $A = \pi r$ per cm. per side of wire. And $x = (\delta + k r)$

Where k is found by integration to be 0.215 if no bedding is present.

Substituting these expressions in (8):

$$C_2 = \frac{K r 10^{-5}}{36 (\delta + k r)} \text{ microfarads per cm. of wire per side of layer} \quad (9)$$

Resistance of Artificial Line Coil. From the dimensions of the coil the resistance must be:

$$R_2 = \frac{l \rho \times 10^{-8}}{\pi r^2} \text{ ohms} \quad (10)$$

The value of ρ will vary from 1.7 to 1.8 microhms per (cm.)³

Combination of Fundamental Formulas into Design Formulas. (2) and (4) multiplied by the equivalent length of the line in miles will give the total values of inductance and capacity. If the equivalent length in terms of these constants is solved for, there is obtained:

$$l_e = \sqrt{L_0 C_0 / 28.8} \times 10^6 \text{ miles} \quad (11)$$

Solving for the length of wire wound in the coil from (7), (9) and (11) there is obtained:

$$l = \frac{0.915 l_e^{3/4} (\delta + k r)^{3/8} y^{1/4} 10^3}{(H K)^{3/8} r^{1/8}} \quad (12)$$

Solving for l again from (2) and (7):

$$l = \left[\frac{2.36 \log_{10} (2 S / d) l_e (y r)^{2/3} 10^3}{H} \right]^{0.6} \quad (13)$$

Eliminating l from (12) and (13) and solving for δ :

$$\delta = \left\{ 0.003 \left[\log_{10} \frac{2 S}{d} \right]^{1.6} [y r / l_e]^{0.4} [K / H^{0.6}] - k \right\} r \quad (14)$$

Formula (14) determines the thickness of the dielectric that must be used in terms of known constants, or factors that can be assumed. It would be more convenient to have it in such form that the wire size would be determined as a function of δ since the dielectric is generally chosen from considerations of operating potential. Unfortunately the large number of fractional exponents make this difficult except by graphical methods. See Fig. 5.

NOTE UPON THE MINIMUM SIZE OF COIL REQUIRED

In equation (12) for a given case all the terms are constant, or nearly so, except those containing δ and r . Thus it can be written:

$$l = M \frac{(\delta + k r)^{3/8}}{r^{1/8}} \text{ Where } M \text{ is a constant including all other terms} \quad (15)$$

Thus if $(\delta + k r)^{3/8} / r^{1/8}$ is made a minimum, the length of wire required in the coil will be a minimum. Substituting 0.215 for k , differentiating this expression with respect to r , and equating the result to zero for minimum, this condition becomes: $\delta / r = 0.43$.

Equation (14) may be written: $\delta = (B - k) r$ Where B represents the first expression within the brackets.

$$\text{Thus} \quad B = (\delta / r) + k \quad (16)$$

And substituting the value of δ / r found from test for minimum:

$$B = 0.645 \quad (17)$$

From this relation it would be simple to find a definite value for r directly from the line configuration values required in (14). Unfortunately it usually results in a prohibitive value of δ . Substituting the value of B just determined in (14), the value of δ becomes:

$$\delta = 0.43 r \quad (18)$$

This implies the use of either extremely small wire or very heavy dielectric, both of which are objectionable for other reasons, and it would appear that the theoretical minimum length of wire cannot be taken advantage of in ordinary designs.

Appendix II

DERIVATION OF DESIGN FORMULAS FOR RECTANGULAR WIRE COILS

Inductance of Artificial Line Coil. Maxwell's fundamental inductance formula can be modified to fit in well with the design, and is therefore made use of, a correction factor (z) being included, the value to be determined from empirical data. The Bulletin of the

Bureau of Standards, Vol. VIII, p. 135 gives this formula as:

$$L = 4 \pi a n^2 \left(\log_e \frac{8a}{G} - 2 \right) 10^{-9} \text{ henries} \quad (19)$$

The errors involved are due to distortion of the current sheet and the shape of the coil. Comparison of this formula with one of the more accurate ones over a range of shapes likely to be used for this purpose gives an average correction of about plus 13 per cent. The formula as it will be used in the following derivation is thus written:

$$L = 1.134 z \cdot 4 \pi a n^2 \left(\log_e \frac{8a}{G} - 2 \right) 10^{-9} \text{ henries} \quad (20)$$

Capacity of Artificial Line Coil. Due to edge effect and bedding of the conductors a very accurate capacity formula is impossible. The one for two parallel flat plates is used:

$$C = (8.85 K A 10^{-8}) / (\delta) \text{ microfards}$$

If the total area of one side of the copper ribbon is assumed as one plate and the projected area upon the tinfoil as the other plate, then:

$$C = (2 \pi a w \times 2 n \times 0.0885 \times 10^{-8} K q) / (\delta) M F \quad (21)$$

The correction factor (q) is inserted to adjust for variations determined empirically.

Resistance of Artificial Line Coil. The resistance of the coil will of course be given by the expression:

$$R = (2 \pi a n \rho) / (w t) \text{ ohms} \quad (22)$$

Leakage of Artificial Line Coil. Predetermined attempts to design for leakage are omitted as discussed in body of paper.

* * * * *

Combination of Above Fundamental Formulas into Useful Design Formulas. Since $y = b/w s$ and $c = n p/s$. G may be expressed as

$$G = 0.2235 (y w s + n p/s) \quad (23)$$

Also it is evident that

$$a = r_1 + (n p/2 s) \quad (24)$$

Dividing (24) by (23) we obtain

$$a/G = \frac{2 r_1 s + n p}{0.447 (y w s^2 + n p)} \quad (25)$$

If this can be reduced to a numeric constant then the term $[\log_e a/G]$ in (20) acquires a fixed value and results in great simplification. This can be done if we make $b = 2 r_1$, as then $r_1 = y w s/2$ and substituting this value in (25)

$$a/G = \frac{y w s^2 + n p}{0.447 (y w s^2 + n p)} = 2.235 \quad (26)$$

Substituting (20) in (26) we then get

$$L = 1.262 z a n^2 10^{-8} \text{ henries} \quad (27)$$

It must always be remembered that this involves fixing the dimensions by the relation $b = 2 r_1$.

Now dividing (21) by (27) we obtain

$$C/L = \frac{88.2 w K q}{\delta n z} \quad (28)$$

And multiplying this by (4) gives

$$\frac{R C}{L} = \frac{5.538 a K \rho q 10^2}{\delta z t} \quad (29)$$

By rearranging (27) we can write

$$a n^2 = 7.93 (L/z) 10^7 \quad (30)$$

And from (28) and (29)

$$\delta = \frac{88.2 w K q L}{n z C} = \frac{5.538 a K \rho L q 10^2}{z R C t} \quad (31)$$

From which

$$a n = 0.1593 (w R t / \rho) \quad (31)$$

(a) and (n) may now be obtained by simultaneous solution of (30) and (31), giving

$$n = \frac{4.975 \rho L 10^8}{z w R t} \quad (32)$$

$$\text{And } a = 3.205 (z/L) (w R t / \rho)^2 10^{-10} \quad (33)$$

By means of these and one or two self evident combinations all dimensions of the coils may now be determined.

RECAPITULATION

(all dimensions in cm.)

Mechanical Dimensions of Coil

$$a = 3.2 (z/L) (w R t / \rho)^2 10^{-10} \quad (\text{I})$$

$$b = 2 r_1 = y w s \quad (\text{II})$$

$$c = Q p = n p/s \quad (\text{III})$$

$$r_1 = b/2 = y w s/2 \quad (\text{IV})$$

$$r_2 = r_1 + c = r_1 + n p/s \quad (\text{V})$$

Winding Dimensions of Coil

$$n = \frac{5 \rho L 10^8}{z w R t} \quad (\text{VI})$$

$$Q = n/s \quad (\text{VII})$$

$$p = (t + 2 \delta + f) \quad (\text{VIII})$$

$$s = \frac{a \pm (a^2 - y w n p)^{1/2}}{y w} \quad (\text{IX})$$

Note: (IX) is derived from (25) and (26).

Dielectric Thickness.

$$\delta = \frac{88 w K q L}{n z C} \quad (\text{X})$$

The numerical constants in (I), (VI) and (X) have been shortened to approximate figures as the accuracy is still greater than that possible in actual design due to variations in materials and methods of assembly.

Owing to the flexibility of the design in using flat strip it is possible to make various sizes of copper satisfy the same criteria of line constants by changing the dimensions of the coil. Therefore the formulas have been developed from the standpoint of using a given size of strip, since usually definite sizes are commercially available, and a few preliminary trials

will quickly determine the one probably most suitable, parallel designs being carried through partway as with most electrical machine design. There are so many considerations to be taken into account in completing the design, such as desired voltage, length of section, flexibility of connections, etc., that no general rule to cover every case can be made.

Appendix III

CALCULATION OF DESIGN OF SINGLE-PHASE ROUND WIRE COILS

(Loop mile equivalent section)

The line to be represented is 110 kv., spaced ten feet (3.05 m.) with a conductor diameter of 0.30 in. (0.763 cm.). Using these values and average values of the various constants gives

$S = 10 \text{ ft. (3.05 m.)}$	$y = 1.13$
$d = 0.3 \text{ in. (0.763 cm.)}$	$l_o = 8 \text{ miles (12.8 km.)}$
$2 S/d = 800$	$K = 2.8$
$\log_{10} 2 S/d = 2.9031$	$H = 6 \times 10^{-4}$
	$\delta = 0.0025 \text{ in. (0.00635 cm.)}$

The values required for equation (14) are as follows

$$[\log_{10} 2 S/d]^{1.6} = [2.9031]^{1.6} = 5.5$$
$$\left[\frac{y r}{l_o} \right]^{0.4} = [1.13 \times r/8]^{0.4} = 0.455 r^{0.4}$$
$$K/H^{0.6} = 2.8/(6 \times 10^{-4})^{0.6} = 239$$

Thus substituting in (14) we get

$$\delta = (0.003 \times 5.5 \times 0.455 r^{0.4} \times 239 - 0.215) r = 0.00635 \text{ cm. (by assumption)}$$

Next try the value of r for No. 23 B & S wire. This is about 0.03 cm. Substituting this above we get $\delta = 0.0068 \text{ cm.}$

Therefore the required insulation would be a little larger than that assumed. Referring to Fig. 5 it will be seen that a spacing of a little less than ten feet is to be expected with this combination. So make a new calculation with smaller spacing and the other constants the same, say $S = 9 \text{ feet (2.75 m.)}$, then

$$[\log_{10} 2 S/d]^{1.6} = [\log_{10} 720]^{1.6} = [2.858]^{1.6} = 5.35$$

Using the same value of r , and all previous constants the same

$$\delta = (0.003 \times 5.35 \times 0.112 \times 239 - 0.215) 0.03 = 0.00639 \text{ cm.}$$

This result gives a value of δ less than one per cent different from the desired value and so is satisfactory. The values for solution of (12) to determine l must now be derived:

$$l_o^{3/4} = (8)^{3/4} = 4.75$$
$$(\delta + k r)^{3/8} = (0.00639 + 0.215 \times 0.03)^{3/8} = 0.195$$
$$y^{3/4} = (1.13)^{3/4} = 1.03$$
$$(H K)^{3/8} = (6 \times 2.8 \times 10^{-4})^{3/8} = 0.0913$$
$$r^{3/8} = (0.03)^{3/8} = 0.644$$

Hence: $l = (0.915 \times 4.75 \times 0.195 \times 1.03 \times 10^8) / (0.0913 \times 0.644) = 14,800 \text{ cm.}$

This value can be checked from (13)

$$\log_{10} 2 S/d = 2.858$$
$$(y r)^{3/8} = (1.13 \times 0.03)^{3/8} = 0.1005$$

Thus: $l = (2.36 \times 2.858 \times 8 \times 1.005 \times 10^8) / (6 \times 10^{-4}) = 14,900 \text{ cm.}$

This checks the previous value, and l will be taken as 15,000 cm. The resistance of the actual line will be, from (5): take $\sigma = 10.4$, then, $R_1 = (2 \times 8 \times 5280 \times 10.4) / (0.3^2 \times 10^6) = 9.4 \text{ ohms.}$ The resistance of the artificial line coil per section will be: from (10): take $\rho = 1.75$, then, $R_2 = (15,000 \times 1.75 \times 10^{-6}) / (\pi 0.03^2) = 9.25 \text{ ohms.}$ Which checks closely with the desired values. The actual dimensions of the coils may now be obtained from (37) and (38):

$$a = 1.20 \sqrt[3]{15,000 (1.13 \times 0.03)^2} = 3.08 \text{ cm. (1.21 in.)}$$
$$c = 0.662 a = 2.04 \text{ cm. (0.80 in.)}$$
$$b = a = 3.08 \text{ cm. (1.21 in.)}$$

From a , $Q = a/p = 3.08 / (0.06 + 0.0128 + 0.0076) = 38.4$, so make layers 38

From b , $s = b/2 y r = 3.08 / (2 \times 1.13 \times 0.03) = 44.2$, so make turns per layer 44.

* * *

These results are not exactly the same as the final coil specifications. The final coils were given the last design adjustment after a trial of several samples in order to correct for the particular manufacturing variations encountered. The wire obtained for the actual coils also ran somewhat oversize which necessitated changes. The procedure to be followed after this step in the design would be to make up several samples and then obtain corrected values for the constants under the particular conditions, from which the final coil specifications can be drawn up.

Appendix IV

CALCULATION OF FINAL DESIGN OF 3-PHASE ARTIFICIAL LINE COILS

The values of the constants as determined from the trial coils have the following values:

$C = 0.2855 \mu\text{f.}$
$L = 0.0418 H.$
$R = 5.185 \text{ ohms.}$
$K = 2.8$
$q = 1.40$
$z = 1.14$
$t = \text{No. 28 B \& S tinned } 0.01304 \text{ in.}$
$y = 1.25$
$\rho = 1.8 \times 10^{-6}$
$\delta = 0.00634 \text{ in.}$
$f = 0.002 \text{ in.}$

From formula:

(X) $w/n = 0.365 \times 10^{-3}$

(VI) $w n = 192.0$

Thus $n = 725 \dots \dots$ Total number of turns

and $w = 0.264 \text{ cm.} = 0.104 \text{ in.}$

Width of strip

(I)	a	$= 5.56 \text{ cm.} = 2.19 \text{ in.}$	Average winding radius
(VIII)	p	$= 0.0705 \text{ cm.} = 0.0277 \text{ in.}$	Layer pitch
(IX)	s	$= 28.2 \dots \dots$	Turns per layer
	Make s	$= 29$	to avoid fractional layers
(VII)	Then Q	$= 25 \dots \dots$	Number of layers
(II)	b	$= 9.58 \text{ cm.} = 3.77 \text{ in.}$	Axial length of winding
(III)	c	$= 1.76 \text{ cm.} = 0.695 \text{ in.}$	Radial depth of winding
(IV)	r_1	$= 4.79 \text{ cm.} = 1.88 \text{ in.}$	Inside radius of coil
(V)	r_2	$= 6.55 \text{ cm.} = 2.58 \text{ in.}$	Outside radius of coil

Appendix V

Conversion formulas for determining the configuration of a transmission line represented by one or more artificial line coils.

$$l_e = 0.31 \sqrt{19.9 C^2 + 36 \times L C \times 10^4 - 1.38 C} \quad (34)$$

$$d_1 = 0.234 \sqrt{l_e/R} \quad (35)$$

$$\text{Log}_{10} s = 38.9 \times 10^{-3} [l_e/C] + \log_{10} d_1 - 0.301 \quad (36)$$

l_e to be taken in miles

d_1 " " " " inches

S " " " " inches

One mile $= 16.0 \times 10^4$ centimeters.

Effect of variations in coil constants upon equivalent line dimensions.

+ 10 per cent error in	{	R gives + 0 per cent error in l_e .
		L gives + 4.5 per cent error in l_e .
		C gives + 4.7 per cent error in l_e .
+ 10 per cent error in	{	R gives + 4.8 per cent error in d
		L gives + 2.4 per cent error in d
		C gives + 2.5 per cent error in d

		C gives a - 23 per cent error in S .

Appendix VI

THE USE OF VACUUM TUBES IN RECORDING TRANSIENTS

In general it is most convenient to record the transients upon the smooth transmission lines by means of oscillograms. For current readings the vibrator of the oscillograph may be inserted directly in the circuit without adding sufficient resistance to cause serious error. For voltage readings, however, the power required to operate the oscillograph represents a very

large equivalent load upon the transmission line due to the small scale upon which the work is performed. Therefore it can only be used directly when connected to the terminals of the source of power. The interesting cases usually involve the voltage at other points on the line, and for obtaining these use may be made of three-electrode vacuum tubes, or Triodes, of the usual type developed for communication work. Providing the grid is maintained negative, practically no current is drawn, and the change in the charge upon the grid may be caused to control sufficient current in the plate circuit to successfully operate the oscillograph.

Fig. 13 shows one of the circuits used for this purpose. It is necessary in dealing with transients to eliminate reactance in the repeater circuit to as great an extent as possible. For this reason it is not possible to use a transformer to couple the plate circuit to the oscillograph, and the impedances of the two circuits thus connected being of very different magnitudes, the combination is not very efficient. The resistance $R O$, Fig. 13, is used as a potentiometer connection, one terminal and a variable tap being connected to the oscillograph vibrator $Vib.$ through the battery E . The steady flow of current through the plate circuit due to the battery B is thus balanced out of the vibrator circuit, and the oscillograph will be operated by the variations in current produced by changes in the charge upon the grid. The voltmeter $V P$ measures the plate potential, and, if small batteries are used, must be left connected all the time if the apparatus is to be calibrated. Care must be taken that the resistance in this d-c. voltmeter does not contain inductance or distributed capacity of large enough amount to by-pass the transient to some extent. $R F$ is the usual filament control resistance, and should be of low value to give close adjustment. If the circuit is to be calibrated to give quantitative readings the filament temperature is very important in order to obtain duplication of results, and usually cannot be maintained sufficiently accurately with an ammeter. Therefore the resistance r and single dry cell D are introduced so that the filament current can be adjusted by means of the galvanometer G . The resistance r should have such a value that G will be on zero when the proper filament current is obtained. If only proper duplication of the wave without its quantitative value is required, then this refinement can be omitted.

The battery C , resistance $R G$ and voltmeter $V G$ are used to adjust the grid potential. M and N are the input terminals. If the resistance between M and N is extremely high, the return circuit of C through to the filament is blocked off and the battery will not be effective. Therefore it is sometimes necessary to connect about 1/2 megohm across $M-N$ to ensure proper control of the grid potential and to increase potential of battery C . This potential should be adjusted so that the current in the plate circuit lies midway on the straight portion of the triode characteristic curve when no potential is impressed.

upon $M-N$. Sometimes, if it is known that the transient voltage is to extend much further in one direction than the other, it is desirable to adjust to a different part of the curve in order to extend the range of the repeater without distortion. Three 5-watt power tubes in parallel connected at $V T$ were found to give sufficient current variation to operate the oscillograph successfully. About 5 volts plus or minus can be recorded without serious distortion. The repeater can be calibrated upon a d-c. circuit with fair accuracy, if care has been taken in eliminating reactance, and its faithfulness of reproduction can be observed by impressing an a-c. wave upon one vibrator direct and upon a second through the repeater, superimposing them upon the viewing device of the oscillograph. With correct adjustment the maximum deviation from duplication should not be greater than the width of the beam of light from the oscillograph mirror.

The operation of the repeater under transient conditions can also be checked either by photographing transient waves in a circuit where sufficient power can be drawn off to operate one vibrator direct without distorting the circuit. This can be visually observed if a switch is made up to alternately open and close a contact, causing transients in an experimental circuit, synchronously with the viewing device.

Other combinations can be used, but this seems to be the simplest to make up with the ordinary laboratory apparatus available. Distortion can be reduced by some form of push-pull circuit, and the use of a high inductive reactance and low capacity reactance as a transient block and pass system can be substituted for the potentiometer arrangement RO and E . But this is likely to introduce difficulties due to distributed capacity and similar attendant troubles.

LIST OF SYMBOLS USED IN FORMULAS

- A Surface area of one plate of condenser in sq. cm.
 C Capacity in microfarads per section per wire. (Or to neutral).
 C_1 Capacity between transmission wires in statfarads per cm.
 C_0 Capacity between transmission wires in farads per loop mile.
 C_2 Capacity of artificial line coil in microfarads.
 D Winding pitch per turn = $b/s = yw = 2yr$. Dimensions in cm.
 G 0.2235 ($c + b$).
 H Form factor for inductance formula, see Bib. No. 8.
 K Dielectric constant. 2.5 to 2.9.
 L Inductance in henries per section per wire. (Or to neutral).
 L_0 Inductance of transmission system in henries per loop mile.
 L_1 Inductance of transmission system in abhenries per cm. per pair of wires.
 L_2 Inductance of artificial line coil in millihenries.
 L_s Self inductance of one wire to ground return—abhenries per cm. per wire.

- L_m Mutual inductance between two wires having common return abhenries per cm. per wire.
 Q Total number of whole layers of winding.
 R Resistance in ohms per section per wire.
 R_1 Resistance of total length of actual line, ohms per loop mile.
 R_2 Resistance of artificial line coil in ohms.
 S Spacing of transmission line, in same units as d unless otherwise stated.
 S^1 Distance between transmission wire and common ground return, inches.
 a Average winding radius in cm.
 b Axial length of winding in cm.
 c Radial depth of winding in cm.
 d Diameter of actual transmission line conductor. In same units as S unless otherwise stated.
 d_1 Diameter of transmission line conductor in inches.
 f Thickness of tinfoil in cm.
 k A constant in capacity formula, usually equal to 0.215.
 l_e Equivalent length of transmission line in miles.
 l Length of wire wound on artificial line coil, in cm.
 n Total number of turns per coil.
 p Layer pitch or thickness of one layer, in cm.
 q Capacity correction factor, usually about 1.10 to 1.5.
 r Radius of round wire used in coils, cm.
 r_1 Inside radius of winding cm.
 r_2 Outside radius of winding in cm.
 s Turns per layer in winding.
 t Thickness of strip conductor in cm.
 w Width of strip conductor in cm.
 x Average distance between surface of round wire and tinfoil, cm.
 y b/ws , the ratio of total winding length to net possible winding length. 1.3 to 1.6.
 z Inductance correction factor. 1.14 to 1.21.
 δ Thickness of dielectric in cm.
 ρ Resistivity of conductor in microhms per cm.² 1.72 to 1.85 for copper.
 σ Resistivity of transmission conductor in ohms per circular mil foot. 10.4 to 11.
 μ Permeability of transmission line conductor.

Discussion

J. F. Peters: I would like to comment on the paper by Professor Dellenbaugh. The performance of a simple transmission line at normal frequency, where the supply is at one end and the load at the other, can be calculated very accurately and with a small amount of labor. When the load or supply is distributed at several points, or there are a number of branches, the matter becomes considerably more complicated and an artificial line may be desirable; it may offer the easiest method of solution. However, the solution of the performance of the transmission line is not the important problem. The important problem is the solution of the transmission line including the rotating machinery; that is, it should include the reactions of the generators and the synchronous condensers that are generally used on high-voltage transmission.

The reactions in the machines are rather complicated, which would point more toward the solutions by means of artificial set-ups. But the reactions are individual; that is, vary widely for different machines, and particularly vary widely between large and small machines. So that in making a set-up of an artificial line it is necessary to obtain approximately the reactions that will be obtained in the final machine. That being the case, it is necessary to use machines in this miniature or artificial transmission line that have appreciable dimensions.

With reference to abnormal voltage conditions the ones that we are particularly interested in are those in the nature of surges or traveling waves. When an abnormal voltage or surge of this nature strikes an artificial line made up of lumped constants such as those described by Professor Dellenbaugh, although he obtains uniformly distributed capacitance, the conductance is still lumped, and a surge reaching one unit of that artificial line will first penetrate a few turns. Thus the inductance per turn will be only the inductance of that turn. As the surge penetrates further into the coil, it encounters very much higher inductance per turn, because then the inductance is the inductance of those turns plus the mutual inductance of the whole coil. The performance of a surge on a coil of this kind would pass through a wide cycle of constants periodically. It is very interesting to note the absence of these secondary reflections in the oscillograms. However, the secondary reflections in this set-up would have a reflection of approximately one-fiftieth of the length of the whole line, and it is possible that the oscillograph would not record that. It seems to me that with the facilities of artificial lines to date, the results obtained can be used only to corroborate calculations.

O. R. Schurig: An increasing number of the electrical-engineering problems met by transmission-line and operating engineers call for experimental investigations on miniature (or artificial) circuits. The problems are of two kinds:

(1) High-frequency problems, arising in connection with lightning, switching, arcing grounds, etc. The high-frequency problems ordinarily involve measurements at only a few points of a system, the currents frequently are relatively small (*i. e.* far below normal-load values), and the phenomena are of a transient character calling for a sensitive, high-frequency oscillograph. Uniformly distributed line constants are essential.

(2) Normal-frequency problems in large system networks, such as the determination of currents, voltages and their relative phases, both in normal operation and during short circuits. The normal-frequency problems often involve a large number of measuring instruments (frequently thirty, or more, in polyphase circuits); the currents are of the order of normal-load magnitudes or greater. Both steady-state and transient-state observations are called for. Indicating instruments exclusively may be used in many cases, while oscillographs are required in others. Lumped-line constants are generally permissible, though sometimes uniformly distributed line constants are preferable.

A question at once arising is whether there is one type of mini-

ature system which will permit the solution of both kinds of problems, that is of both the high-frequency and the normal-frequency problems. Since the "lumpy" type of line is not applicable to the high-frequency problems, the question becomes, more specifically, whether the lines of the type described in the paper are practically applicable to both high-frequency and normal-frequency problems.

The practical success of a miniature system for the solution of normal-frequency network problems calls for the minimum of complications due to measuring instruments, in view of the large number of practically simultaneous observations desired. In the solution of high-frequency problems the practical objection to the use of special measuring instruments (such as those employing vacuum-tube amplifiers) is much diminished because, as a rule, only a few of the special instruments are required.

Hence it is of importance to know how large the rating of the miniature equipment must be made in order that standard instruments may be employed without serious error, for both steady-state and transient-state observations at normal frequencies. It is conceivable that an increased current rating of the miniature circuit would also permit simplifying the measurements of high-frequency transients. It is the object of the following discussion to establish the minimum current rating of the miniature system which will permit the use of standard measuring instruments for normal-frequency problems.

As the author properly points out, the errors due to instruments are of two kinds:

(1) That due to the impedance introduced by series-connected instrument elements, such as ammeter or wattmeter current coils;

(2) The error due to the current abstracted from the circuit by shunt-connected instrument elements, such as voltmeter or wattmeter potential circuits.

The error due to series-connected instruments will be seen from figures for typical ammeters and wattmeters. It will not be attempted to give impedance data for the large variety of instruments of different manufacture. The data given in Table I are representative values indicating the order of the magnitudes. It is to be understood that materially larger values of impedance than those given as well as smaller values, are met among the different types of instruments.

If, for example, 10-ampere and 5-ampere current ratings are chosen, typical values of voltage drop at maximum current are those of Table I. If the ammeter and the wattmeter current-element are connected in series, as for power-factor measurements the combined voltage drops, due to the instruments, are seen to be a negligible percentage of the generator voltage in a 100-volt miniature circuit. However, the drops exceed 5 per

TABLE I
Approximate impedance drops at maximum r. m. s. current
at 60 cycles per second

	For 5-ampere rating	For 10-ampere rating
Ammeter.....	0.50 volt	0.25 volt;
Wattmeter current coll.....	0.65 volt	0.30 volt
Ammeter and watt meter element in series combination		
Voltage drop.....	1.15 volt	0.55 volt
Per cent drop in a 100-volt miniature circuit.....	1.15 per cent	0.55 per cent
Per cent drop referred to 10 volts.....	11.5 per cent	5.5 per cent
Oscillograph*		
Voltage drop.....	0.3 volt	0.3 volt
Per cent drop in a 100-volt miniature circuit.....	0.3 per cent	0.3 per cent
Per cent drop referred to 10 volts.....	3 per cent	3 per cent

Note: The data given apply to one of the customary types of commercial oscillographs, for which the vibrators have 1.5 ohm resistance and a current rating of 0.2 ampere; shunts are used for current values in excess of 0.2 ampere.

cent for the 10-ampere rating, and 10 per cent for the 5-ampere rating, when expressed as a percentage of the line drop over a line having a voltage drop of 10 per cent of the generator terminal voltage. The reason for referring the per cent error, due to series-connected measuring instruments, to the *line drop*, rather than to the generator terminal voltage, is that in network problems the division of currents over parallel-connected lines depends largely on the relative impedances of the lines.

The above considerations call for a miniature-line current rating of the order of 10 amperes for a 100-volt circuit, or 5 amperes for a 200-volt circuit, so that the errors due to the series elements of typical portable ammeters and wattmeters may not approach or exceed 10 per cent. Smaller current ratings will lead to larger errors due to the series elements of the instruments for the circuit conditions under discussion, because, roughly speaking, the impedance drops of the series elements at rated currents increase inversely as the current ratings.

The second error mentioned was that due to the current abstracted by voltmeter or wattmeter potential coils. The figures for typical voltmeter and wattmeter potential coils are those of Table II. It is seen that the largest errors due to shunt elements are those of the oscillograph, which gives a 4 per cent error for a 5-ampere circuit rating. For a 200-volt system, the percentage values for current abstracted will be the same as those given in Table II, provided the 300-volt elements are employed.

TABLE II

Approximate current at 60 cycles per sec., at 100 volts

Voltmeter (150-volt element).....	0.050 amp.
Wattmeter potential coil (150-volt element).....	0.030 amp.
Wattmeter potential coil and voltmeter in parallel combination (150-volt elements)	
Total current.....	0.080 amp.
Per cent current referred to 5 amperes.....	1.6 per cent
Per cent current referred to 10 amperes.....	0.8 per cent
Oscillograph* (at full-scale deflection)	
Current.....	0.2 amp.
Per cent current referred to 5 amperes.....	4 per cent
Per cent current referred to 10 amperes.....	2 per cent

*See note applying to Table I

It may, therefore, be concluded that an a-c. miniature circuit-current rating of not less than 5 amperes and preferably 10 amperes is required to limit the errors, due to the customary portable instruments and oscillographs, to values safely below 10 per cent. In regard to instrument errors, the 200-volt circuit rating is preferable to the 100-volt rating. If, therefore, the type of miniature circuit having distributed circuit constants, such as that described in the paper, can be constructed for the increased current ratings mentioned, the number of different types of artificial circuit could be materially reduced.

The current ratings established apply, of course, to the lumpy type of miniature system, as well.

D. C. Jackson: From the standpoint of the practising engineer, the value of this struggle with artificial transmission lines and other artificial circuits is to aid in discovering the analysis which will enable one to preconceive the reactions that will occur on an actual line, rather than make the design of the line without a full and adequate comprehension of all the factors that will arise.

But there is another important feature, which was referred to in the President's address, that I want to emphasize, and that is the relation of these things to the educational process.

A good many years ago there was that roomfull of line that has been referred to this morning as the Steinmetz artificial line, and at that time Dr. Pender (who was one of my colleagues at the Massachusetts Institute of Technology) and I had some discussions over the best methods of teaching the subject of power transmission from the theoretical aspects, for the purpose of enabling our students to have a correct vision of the problems. We also about that same time fell into some considerable dis-

cussions of the problems of skin effect. The consequence was that there was started a series of experimental investigations of skin effect in various conductors which resulted in a number of papers. Perhaps a quarter of the references in the bibliography accompanying Mr. Dwight's paper are papers that arose as a consequence of that argument between Pender and myself, which was later also taken up and carried still farther by Dr. Kennelly when he became a colleague of ours.

At the same time Dr. Pender and I struggled with the problem of a transmission line which could be long, preferably as long as a quarter of a wave length with 60 cycles per second. Consequently, a replica of a line about 1000 miles long with conductors of two or three thousand circular mils and spacing for a couple of hundred thousand volts, was made up. It is quite an expensive affair but it does not occupy a roomful of space by any means. It was made up in that characteristic form that was shown in a paper some years back by Dr. Pender, of pancake coils placed in a toroidal arrangement so as to secure substantially distributed resistance and self-inductance without much mutual induction between coils.

That line was made up with large enough conductors so that it would carry sufficient current for enabling us to put oscillographs, ampere-meters and voltmeters in any part of the line we chose to without disturbing its performance and it works admirably for steady state conditions up to several hundred cycles, per second, but the capacity is lumpy and it does not represent distributed effect with transient conditions.

It is on that line that Professor Ricker, for instance, a good many years ago, as shown in a paper of his, found experimentally the difference in admittance for odd and even harmonics which exist between even and odd quarter wave lengths.

Later Dr. Bush took up this aspect of our work. He came to me one day and urged that our students will not be meeting the present situation in the art unless we can deal with transients experimentally in the laboratory on long lines. One of the outcomes is the artificial line equipment described in the papers by Professor's Bush and Dellenbaugh.

What I want to emphasize is this: that while the sort of work described by Dr. Bush and Professor Dellenbaugh in their papers, and referred to by Mr. Dwight in his paper is directly serviceable to the art, the fact is that that work which you find described in the papers of Bush and Dellenbaugh, and the papers that are referred to by Mr. Dwight that came from Kennelly, Laws, Pierce, and so on, was actually planned for educational purposes and was carried out for those purposes; that the philosophy of the thing is to bring the senior students and graduate students in the engineering school into contact with the most advanced philosophy of engineering structures that we have; and, if possible, carry them on into experimental and mathematical work which advances the state of knowledge to some degree as well as soundly founding them for creative work in the art.

That is not what the physicist would call fundamental research, but it is definite and effective engineering research, and when carried on by senior students and graduate students in laboratories that are associated with the under-graduate work, it affects the junior students by causing a tremendous stir of the heart and expansion of the ambition. If this ideal can be more fully adopted by the engineering schools of the United States and even greater sympathy for it be exhibited by the industries of the United States, it will during the next decade change the whole aspect of our engineering practise, because it will give us a more and more effective group of young engineers coming forth into the profession year by year.

The fact that the thing has been fruitful—it has been carried on for a dozen years at the Massachusetts Institute of Technology as a definite philosophy of engineering education and is carried on in other institutions also to a considerable degree;—that it has been fruitful is shown by the fact that in the bibliographies

of the papers presented today and in the discussions related to them you will find that a considerable number of the papers referred to have been produced as a consequence of this philosophy. For instance, papers by Lyons, Kennelly, Laws, Pierce, Affel and others come within the category. Professor Bush as a graduate student came in contact with the ideal and he has been very effectively carrying it on since he joined our staff, along with Professor Dellenbaugh, Professor Kennelly and a number of our other colleagues on the staff of the department from which these papers came.

I do not wish to divert attention from the important problems of engineering practice and the philosophy underlying engineering practice in this matter of long distance transmission of power, but it seems to me that it is worth while introducing here this educational aspect of these papers on account of its great interest to us as electrical engineers since, of the various branches of the engineering profession, probably electrical engineering is more soundly based on the fundamental physics and mathematics than any of the other branches.

Harold W. Buck: There are a few unorthodox considerations that I want to speak of in connection with this general question of power transmission particularly in connection with the papers under discussion. These papers are extremely interesting and exhibit wonderful mathematical and engineering skill but why do we have so many papers on this particular subject? It looks like a confession of weakness somewhere.

One of the speakers has referred to the fact that troubles on transmission systems increase as the square of the size of the network. I think that is quite true. Our very high-voltage systems of great length of today are beginning to bring up difficulties and complications which are really very serious. The papers are the result of this situation and are an attempt to analyze the phenomena and to predict what is going to happen under various conditions.

I think a good test of engineering progress is whether simplification is resulting. If we look around and into our power transmission problems at very high voltage at the present time and apply that test, it seems to me that the result is not satisfactory.

The transmission of power from a piston for instance to a rotating wheel through a connecting rod is a very simple proposition but when the connecting rod is lengthened out to such a distance that its inertia and elasticity become factors which cannot be controlled then some other method must be found.

A transmission line is merely a connecting rod and in the very high-voltage lines of great length the inertia and elasticity are becoming difficult factors to handle and the papers under discussion prove it.

Our big transmission systems at very high voltage are not getting more simple but more complex and I think we will have to admit whether we like it or not that many new troubles are developing in connection with them.

Take for instance a 200-mile line at 220,000 volts. We have here a charging current of the order of 50,000 kv-a. This requires for satisfactory control a synchronous condenser installation approximating in size the power house itself. We accept it from force of habit and tradition but it is a grotesque situation from the standpoint of real engineering. The switches are becoming of enormous size and cost and all controlling apparatus is increasing in complexity and cost. Worst of all instability is increasing. Satisfactory adjustments may be made for a given set of conditions but if a sudden change occurs as must frequently happen things are thrown badly out of balance.

All of these things we accept as a matter of course because we have gradually been led into them but it would be well to consider under all the circumstances whether we are not really approaching the limit of transmission of power by alternating current.

There is a great deal of loose talk in the papers nowadays of

transmission of power a thousand miles at a million volts and super-power bus bars running from New York to San Francisco. This is all, of course, absurd and if any such thing were attempted under the present state of the art I do not think there would be mathematicians enough in the country to figure out what had happened after it was all over.

This is all more or less heretical but it seems to me that engineers should pause occasionally in the evolution of engineering and see whether they are really headed in the right direction. After all, reduced to its lowest terms, transmission of power is merely the transfer of electrons from one point to another. If we consider all that is involved in a three-phase 220,000-volt transmission it seems almost obvious that we are carrying out this physical operation in a very clumsy way.

I have no suggestions to offer except to go slow. However, physicists are learning more and more about electrons, their characteristics and methods of controlling them. I cannot help feeling that before this great long distance super-power problem is worked out satisfactorily some radically new method of transferring electrons from one point to another will be worked out.

F. S. Dellenbaugh, Jr.: I would like to add just one thing, that we have since this paper was written built an artificial cable by this same method. The formulas employed and the constants are a little different but I don't think there is any necessity for describing that separately.

I want to offer one word of apology on the systems in measurement Dr. Kennelly said, "What a perfectly horrible lot of units you have!" I admit it. The difficulty lies in the fact that to make it practical, you must deal with transmission lines in the unit you are used to. You don't design 16,000 centimeters of transmission line—that doesn't mean much to you. You deal in miles, unfortunately, but still you do. And so we have miles in length, feet in spacing, and inches in diameter. The fundamental formulas deal with centimeters in C. G. S. or absolute units. So we must convert from the metric or absolute units of our fundamental formulas for the coils to ultimate dimensions, obtaining the line in miles, feet and inches; and as a result I have attempted to put in the duplicate units all the way through.

It is very interesting to note that the work of Mr. Boyajian on the penetration of transients fits in directly with this kind of work, even though he dealt with transformers and we are dealing with transmission lines. It is the same thing, and it fits particularly on the lumpy type of line. In the old type of lumpy line, if we applied a transient or surge, it would partially penetrate the inductance coils. If they were perfect inductances, with no distributed capacity, there would be no penetration and the surge, when it hit the inductance, would immediately be totally reflected, and therefore the lumpy type of line would be absolutely useless for transient investigation. Practically, the coils must have distributed capacity, and so a transient on a lumpy line does penetrate the coils and does give you curves which represent more or less roughly the same curves you get on smooth lines, but filled with a lot of ripples due to partial reflections. The result is that the behavior of the lumpy line under transient condition depends upon the distributed capacity of the coils, which is an entirely haphazard thing and is not taken into account in the design. If you wish to look at it in that way, all this distributed line has done is to design the distributed capacity of the coil so that it is what you want, and leave out the lumped capacities.

Both Mr. Boyajian and Mr. Peters mentioned skin effect, dielectric losses and their relations. Mr. Peters also mentioned that the penetration of the transient, even in the distributed constant lines, as it went through a single coil, had to go through an infinite number of varieties of inductance. That, of course, is perfectly true, and is one of the points that worried us when we built the lines. So our first line was built with 8-mile sections. We built about 1000 miles of it in order that the sections might

be small compared to the total length, and that the total length might be enough to record easily on the oscillograph.

We were very much pleased to find that what we might call the "lumped mutual" of the distributed line has no apparent effect on the oscillograms and that they check remarkably well with the theory. Therefore, we might say that the proof of the pudding is in the eating in this case, and that these minor reflections which occur due to the penetration through the coil are of such a small magnitude that they do not show and are not recorded. That is, we don't attempt to say that we have a line which is exactly the same as an actual transmission line, because the only thing that is exactly the same is another transmission line built the same way. Even then the insulators and ground conditions would be different. But we have built a line which behaves very nearly the same way, near enough so that if we get reasonable checks we know that our theory is on the right track.

If we take fundamental physical laws and arrive at results, then take a transmission line which is somewhere near an actual line and test it and arrive at certain experimental results, then if the experimental results and the theoretical results coincide with reasonable accuracy, we can say, "Well, our theory must be pretty good." The final test is to go out and try it on a real line.

We did that last spring and found that our artificial line was very much better than the real line, because it checked the theory much closer. That of course, is a necessary and expected result because the real line is complicated with a lot of factors that can be eliminated entirely in the artificial line.

For the general study of transients and the development of theory in connection with them, we feel the artificial lines are very good, but we admit entirely all of these questions of errors: The effect of dielectric hysteresis; the fact that you still have skin effect but not as much as you have in the actual line; and the fact that there is a certain amount of lumped mutual and a certain value of cut-off due to periodic structure. They must be there, but the evil of their being there is far less than with the lumpy type of artificial line.

Mr. Schurig mentioned the question of errors due to current carrying capacity and was kind enough to state that the distributed lines can be made larger. With the distributed lines made with round wire, there is only one possible coil that will represent a certain combination of circumstances, so that you cannot make those larger; but with the distributed lines having flat wire, you can make them of any size you please because there are an infinite number of coils that will represent any particular set of circumstances, and as a result you can make the flat wire lines to carry any current you please. It is merely a question of size and expense.

The cost of the 2 lines that we have built—one a thousand miles single-phase, the other 450 miles 3-phase—was 60 cents per

mile-per phase for both. This covers the manufacture of the coils by an outside concern, and included their profit, I think.

For our work, we have found it much more convenient to use vacuum-tubes and meters drawing small power because that is the way our laboratory works. After you once get a vacuum-tube repeater trained and used to you, and not nervous about the particular person running it, it behaves very well. Every person that takes it up has the same troubles over again. It is apparently impossible to eliminate them by instruction. After it once goes, it behaves very well.

For instance, we have made a number of transient investigations with a 6-volt storage battery for our supply of power. That gets you away from any question of leads through conduits affecting the first surge. We measure the voltage rise on the line at different points, and the current through the line at different points, with 5 or 6 volts impressed on the near end. You can go up, of course, as far as you please, up to the limit of dielectric strength.

With regard to the errors Mr. Schurig mentioned, I would like to point out one thing: The series connection gives practically negligible errors under most conditions, particularly with transient work. The shunt errors are more serious than he pointed out, if you are dealing with transients. That is, his results were calculated for load conditions and more or less for steady work. What would calculate as a very small shunt error under his method might result in a rather large error if you dealt with transients on a line open circuited, for instance. I do not believe you can get transients on an open-circuited line with any kind of volt-meter across it; that is, even a very high resistance will pull it down greatly. We have found it necessary to go to several megohms resistance across the line in order to use the repeater without error due to the shunt resistance.

I would like to say a word on the scale of the system. The scale can be made extremely small, providing you are willing to go into the difficulties of testing with it. It is a question of a balance between the testing technique and the amount of room you want to give up to the line. Our thousand mile single-phase line is mounted in a rather loose framework. We leave plenty of room around and it stands about 4 feet high; in fact, it is very nearly 4 feet on a side—not quite, but we will say a 4-foot cube will include 1000 miles of single-phase line. The 3-phase line is very much larger on account of the way we have mounted the coils. They have been mounted so that mutual inductance can be eliminated; that means a lot of waste room. I don't remember the exact dimensions of the boxes, but they are, roughly, 4 feet square and about 5 feet high and take up, I should say, about 25 per cent more room than the single-phase line in cubic feet. Both of these are used for small current and both of them could be designed in considerably smaller space if it was necessary.

A General Consideration of T- and Pi-Type Artificial Electric Lines

In Connection with a Proposed Compensated Pi-Line

BY H. NUKIYAMA

Associate, A. I. E. E.

Prof. of Elec. Eng., Tohoku Imperial University, Japan

and

K. OKABE

Lecturer at Tohoku Imperial University, Japan

Review of the Subject.—A theory of the general artificial electric line circuit, including the T- and π -lines as its special case, is here laid down. This theory is applied to the determination of a simple method for designing a compensated π -type artificial electric

line whose electrical characteristics can be more closely approximated to the actual uniform line than a common T-line or π -line, when required to work, not at a single frequency, but over a definite range of frequencies.

IT IS well known that T-type or π -type artificial electric lines may be made externally equivalent to a uniform line, but they represent different characteristics at other frequencies. When compared with a uniform line, the characteristics of the T-line and π -line are in opposition to each other if they are represented by a complex number. (Bib. 3.)

In the same way that we can construct an artificial line which has better frequency characteristics than the

FIG. 1—T-LINE SECTION

FIG. 2—PI-LINE SECTION

T-line or π -line, by combining these two lines properly, we may obtain a similar result by using such artificial lines as are shown in Fig. 3. This construction is intermediate between that of the T-line (Fig. 1) and π -line (Fig. 2), and this type of artificial line will here be called the "Compensated π -line."

I. THE THEORY OF THE COMPENSATED π -LINE

In Fig. 3, $Z_{c\pi}$, Z_π and Z_c represent impedance between A B, C D and D B respectively. Z_c will be

Presented at the Annual Convention of the A. I. E. E., Swampscott, Mass., June 25-29, 1923.

called the "Compensating impedance." $Y_{c\pi}$ represents the shunt admittance.

We will consider the compensated π -line which is to represent the uniform line (Fig. 4). In Fig. 4, Z_0 and θ_0 denote the surge impedance and the total hyperbolic

FIG. 3—COMPENSATED PI-LINE SECTION

angle (vector attenuation constant) respectively. We put

$$\beta = \frac{2 Z_c}{Z_{c\pi}} \quad \text{numeric } \angle \quad (1)$$

which represents the degree of compensation. In order to have the conditions such that the compensated

FIG. 4—CONJUGATE UNIFORM LINE

π -line and the uniform line have the same electrical behavior at the terminals A and B, we will consider the case when the receiving end is short-circuited. The currents at the receiving end B, and at the sending end A, are represented by I_B and I_A . In Fig. 3 we get

$$I_A = [1 + Y_{c\pi} (Z_\pi + Y_{c\pi} Z_c Z_\pi + 2 Z_c)] I_B \quad \text{amp. } \angle \quad (2)$$

In Fig. 4, we get (Bib. 1, 2)

$$I_A = I_B \cosh \theta \quad \text{amp. } \angle \quad (3)$$

According to the condition of equivalency, we have

$$\cosh \theta = 1 + Y_{c\pi} (Z_\pi + Y_{c\pi} Z_c Z_\pi + 2 Z_c) \quad \text{numeric } \angle \quad (4)$$

From the equation (1)

are obtained. By (4) and (5), we have

$$\cosh \theta = 1 + Y_{c\pi} Z_{c\pi} \left\{ 1 + \frac{(1-\beta)\beta}{2} Y_{c\pi} Z_{c\pi} \right\} \quad \text{numeric } \angle \quad (6)$$

FIG. 5— β -PLANE

FIG. 6—VALUE OF $Z_{c\pi}$ FOR DIFFERENT VALUES OF β

$$\left. \begin{aligned} Z_c &= \frac{\beta Z_{c\pi}}{2} \\ Z_\pi &= (1-\beta) Z_{c\pi} \end{aligned} \right\} \text{ohm } \angle$$

FIG. 7—VALUE OF $Y_{c\pi}$ FOR DIFFERENT VALUES OF β

(5) FIG. 8—COMPARISON OF THE SURGE IMPEDANCE OF ACTUAL AND COMPENSATED PI-TYPE ARTIFICIAL LINE

Next we will consider the case when the receiving end is freed. The voltage at the receiving end and the current at the sending end are represented by V_B and I_A . In Fig. 3 we obtain

$$I_A = (2 + Y_{c\pi} Z_{c\pi}) Y_{c\pi} V_B \quad \text{amperes } \angle \quad (7)$$

In Fig. 4 we have (Bib. 1, 2)

$$I_A = V_B / (Z_0 \sinh \theta) \quad \text{amperes } \angle \quad (8)$$

FIG. 9—COMPARISON OF THE LINEAR HYPERBOLIC ANGLE OF ACTUAL AND COMPENSATED PI-TYPE ARTIFICIAL LINE

From (5), (7) and (8)

$$\frac{\sinh \theta}{Z_0} = [2 + (1 - \beta) Y_{c\pi} Z_{c\pi}] Y_{c\pi} \quad \text{mho } \angle \quad (9)$$

is obtained by the condition of equivalency. Solving the values of $Z_{c\pi}$ and $Y_{c\pi}$ from (6) and (9) we get

$$Z_{c\pi} = \frac{2 (\sinh \theta / \theta) Z}{\{1 - \beta + \beta \cosh \theta + \sqrt{\beta^2 + 2\beta(1 - \beta) \cosh \theta + (1 - \beta)^2}\}} \quad \text{ohm } \angle \quad (10)$$

$$Y_{c\pi} = \left\{ \frac{\tanh (\theta / 2)}{\theta / 2} \right\} \frac{Y}{2(1 - \beta)} \{1 - 2\beta + \sqrt{\beta^2 + 2\beta(1 - \beta) \cosh \theta + (1 - \beta)^2}\} \quad \text{mho } \angle$$

where Z and Y represent the total impedance and the

total admittance of the conjugate uniform line. The following relations being well known

$$\left. \begin{aligned} \theta &= \sqrt{ZY} \text{ hyps. } \angle \\ Z_0 &= \sqrt{Z/Y} \text{ ohm } \angle \end{aligned} \right\} \quad (11)$$

we can design the compensated π -line by equation (10) assigning an arbitrary value to the compensating factor β . Solving (6) and (9) with respect to θ and Z_0 , we get,

$$\theta = 2 \sinh^{-1} \sqrt{\frac{Y_{c\pi} Z_{c\pi}}{2} \left(1 + \frac{(1 - \beta) \beta}{2} Y_{c\pi} Z_{c\pi} \right)} \quad \text{hyps. } \angle$$

$$Z_0 = \sqrt{\frac{Z_{c\pi}}{Y_{c\pi}}} \left\{ \frac{\sqrt{1 + 0.5(1 - \beta) \beta Y_{c\pi} Z_{c\pi}}}{1 + 0.5(1 - \beta) Y_{c\pi} Z_{c\pi}} \times \cosh (\theta / 2) \right\} \quad \text{ohm } \angle \quad (12)$$

So that the constants of the conjugate uniform line can be obtained from the constants of the compensated π -line, $Z_{c\pi}$, $Y_{c\pi}$ and β .

FIG. 10—VALUE OF $Z_{c\pi}$ FOR 60-CYCLE SECTION

II. THE RELATION BETWEEN THE CORRECTING FACTOR AND THE COMPENSATING FACTOR

We can understand easily by (10) that the series impedance and the shunt admittance of the compensated π -line are obtained by multiplying the correcting factors

$$K_1 = \frac{2 \sinh \theta / \theta}{\{1 - \beta + \beta \cosh \theta + \sqrt{\beta^2 + 2\beta(1 - \beta) \cosh \theta + (1 - \beta)^2}\} \text{numeric } \angle} \quad (13)$$

$$K_2 = \frac{\tanh(\theta/2) \div \{(1 - \beta)(\theta/2)\}}{1 - 2\beta + \sqrt{\beta^2 + 2\beta(1 - \beta) \cosh \theta + (1 - \beta)^2} \text{numeric } \angle}$$

into the series impedance and half the shunt admittance of the uniform line respectively. These correcting factors are not only functions of θ (functions of frequency accordingly), but are also functions of β .

In the case of absence of Z_c , i. e., $\beta = 0$, it is a pure

$$\left. \begin{aligned} K_{1(\beta=1)} &= \frac{\tanh(\theta/2)}{\theta/2} \text{numeric } \angle \\ K_{2(\beta=1)} &= \frac{\sinh \theta}{\theta} \text{numeric } \angle \end{aligned} \right\} \quad (15)$$

which are the well known correcting factors of a T -line.

As mentioned above, the compensated π -line is to be considered as the general type of artificial line, including both π -lines and T -lines. The complex values allowed for β are limited from the physical point of view. If negative resistance is not allowed, the following relation must obtain:

FIG. 11—VALUE OF $Y_{c\pi}$ FOR 60-KM. SECTION

π -line. We obtain the following correcting factors by putting $\beta = 0$ in (13),

$$\left. \begin{aligned} K_{1(\beta=0)} &= \frac{\sinh \theta}{\theta} \text{numeric } \angle \\ K_{2(\beta=0)} &= \frac{\tanh(\theta/2)}{\theta/2} \text{numeric } \angle \end{aligned} \right\} \quad (14)$$

which are the well-known correcting factors for the π -line. On the contrary, the pure T -line is obtained in the case $Z_r = 0$. We get the following correcting factors by putting $\beta = 1$ in (13).

$0 \leq \text{real part of } \beta Z_{c\pi} \leq \text{real part of } Z_{c\pi} \text{ ohm } \angle \quad (16)$
In the β -plane in Fig. 5, the domain of β may be determined by (13) and (16). As a special case, we consider β to be real. In this case the following relation holds:

$$-\pi/2 < \gamma < \pi/2 \text{ radian}$$

γ being the slope of $Z_{c\pi}$. Therefore from (16), we get

$$0 \leq \beta \leq 1 \text{ numeric}$$

So that the value of β must not be more than 1 nor less than zero on the real axis.

The general case when β is complex, is not so simple, but in a practical case it will be convenient to study the nature of the correcting factors by trial, choosing proper

values for β from a consideration of the physical construction of the artificial line.

III. HOW TO DESIGN THE COMPENSATED π -LINE

In the compensated π -line, resistances and inductances are connected in series for the impedance $Z_{c\pi}$ etc., and for the admittance $Y_{c\pi}$, condensers and resistances are connected in parallel, so that their frequency characteristics are the straight lines parallel to the imaginary axis. Not only so, but the imaginary parts are proportional to the frequencies. Hence, if we take such a value of β that the frequency characteristics of $Z_{c\pi}$ and $Y_{c\pi}$ are similar to those above mentioned, the compensated π -line whose nature is approximately similar to that of the uniform line, may be obtained.

As an example, the following aerial telephone line will be calculated.

Copper wire, B. w. g. No. 8, distance between the centers of wires, 40 cm.

km. section of the above line was calculated. The total series impedance and the total shunt admittance were obtained as follows:

$$Z = 30 [2.494 + j \omega \times 0.0022] \text{ ohms } \angle$$

$$Y = 30 [10^{-6} + j \omega \times 0.005285 \times 10^{-6}] \text{ mhos } \angle$$

FIG. 12—COMPENSATED π -LINE FOR 3-KM. SECTION OF STANDARD CABLE

FIG. 13—COMPARISON OF THE SURGE IMPEDANCE OF ACTUAL AND COMPENSATED π -TYPE STANDARD CABLE

Series resistance $r = 2.494$ ohms/km.
 Series self inductance $l = 0.0022$ henrys/km.
 Leakage conductance $g = 10^{-6}$ mhos/km.
 Shunt capacitance $c = 0.005285 \times 10^{-6}$ farads/km.
 The compensated π -line which corresponds to the 30

$Z_{c\pi}$ and $Y_{c\pi}$ are calculated for the various real values of β (0, 0.2, 0.4, 0.6 and 1) in the range of frequencies between 2000 and 20,000 in angular velocity. The results are shown in Figs. 6 and 7. In the various values of $Z_{c\pi}$ and $Y_{c\pi}$, we see that those which cor-

respond to $\beta = 0.4$, are satisfactory, because the characteristic is nearly vertical and the imaginary parts are proportional approximately to the frequency. Then two straight vertical lines, ab (Fig. 6) and cd (Fig. 7) are drawn as a proper approximation to the characteristics of $Z_{c\pi}$ and $Y_{c\pi}$. The constants of the compensated π -line were chosen so that the characteristics of $Z_{c\pi}$ and $Y_{c\pi}$ are ab and cd . Thus we have

$R_{c\pi} = 70 \text{ ohms}$
 $L_{c\pi} = 0.0645 \text{ henries}$

$R_c = 0.2 \times 70 \text{ ohms}$
 $L_c = 0.2 \times 0.0645 \text{ henries}$

for calculation, since it is not a composite line as is the case of the combined T - π -type.

Similar calculations were made for the same telephone line, increasing the length of section to 60 km. The results are given in Figs. 10 and 11. In this case, it is difficult to choose the value of β properly. If we cannot have $Z_{c\pi}$ and $Y_{c\pi}$ with the desired vertical characteristics etc. for the various values of β , the length of one section must be decreased.

As another example, it was found that the proper value of β should be 0.4, for the 3-km. section of the

FIG. 14—COMPARISON OF THE LINEAR HYPERBOLIC ANGLE OF ACTUAL AND COMPENSATED PI-TYPE STANDARD CABLE

$G_{c\pi} = 3.2 \times 10^{-6} \text{ mhos}$
 $C_{c\pi} = 0.157 \times 10^{-6} \text{ farads}$

$R_{\pi} = 0.6 \times 70 \text{ ohms}$
 $L_{\pi} = 0.6 \times 0.0645 \text{ henries}$

The surge impedance $Z_{0c\pi}$ and the linear hyperbolic angle $\alpha_{c\pi}$ were calculated by (12). The corresponding values of the uniform line were also calculated by (II). The results of the calculation are given in Table I, Figs. 8 and 9. As shown by the table and the figures, the surge impedances and the linear hyperbolic angles of both lines coincide with each other approximately. Hence we can say that this compensated π -line agrees satisfactorily in all electrical respects with the uniform line. Moreover this type is convenient

IV. COMPARISON WITH OTHER TYPES

If we choose the same sectional length, the compensated π -line is superior to the T -line (or π -line) of course, but the former is more complex than the latter in its construction. Therefore it is safe to compare it with the section of the T -line and π -line of half the length. In the above two representative cases, we found that the compensated π -line could be designed to be more

FIG. 16—SHORT-CIRCUIT IMPEDANCE OF 60-KM. ARTIFICIAL LINE

satisfactory than the T -line or π -line of half length. Moreover, in these particular cases, this type gave better results experimentally than the combined T - π -type. In this case, the total length of the compensated π -line was taken as 60 km. and the length of the section was taken as 30 km. For the combined T - π -line, the total length was taken as 60 km., but for the length of each section 15 km. was chosen.

The short-circuit impedance of the compensated π -line $Z_{sc\pi}$, the open-circuit impedance of the same $Z_{jc\pi}$, the short-circuit impedance of the conjugate

uniform line Z_f , and the open-circuit impedance of the same Z_f are given in Figs. 15 and 16. These are to be compared with Figs. 14 and 15 in a previous paper. (Bib. 3).

A Miniature A-C. Transmission System

For the Practical Solution of Network and Transmission-System Problems

BY O. R. SCHURIG

Member, A. I. E. E.

General Electric Company, Schenectady, N. Y.

Review of the Subject.—The use of so-called "artificial lines" — i. e. miniature models of electric circuits — for experimental laboratory studies of transmission-line phenomena is well known. The miniature models are commonly made so as to represent, in true proportion, the electrical constants of a real line. Thus there are artificial telephone lines, artificial submarine cables, artificial long-distance power-transmission lines, etc. A miniature line is a true model of a real line to the extent that the miniature circuit has, for any desired degree of approximation, the same electrical behavior as the full-size circuit. Such laboratory models frequently permit — far more conveniently than the full-size circuit — the study of actual circuit phenomena in a practical and efficient manner. When their limitations are properly understood, miniature circuits may be of great value to transmission-line and operating engineers.

Miniature electric circuits may for the present purpose be divided into two general classes:

(1) Miniature circuits intended for the study of problems on long lines, such as lines having continuously distributed circuit constants.

(2) Miniature circuits for the solution of problems involving complete system networks, inclusive of generating-station and substation apparatus.

The following paper deals with a three-phase miniature a-c. system of the network type. The circuit includes synchronous machines, transformers, adjustable resistors, reactors, and condensers, for complete representation of generating stations, substations, lines and loads. The circuit connections are variable, so that any system having not more than the available number of circuit elements may be represented for the correct experimental solution of low-frequency problems.

This miniature system has so far given about three years of service in the experimental analysis of transmission system behavior, for existing systems and for systems to be constructed. The problems solved have been within the realms of both the designing and the operating engineers, and have been applied to power systems in this country as well as abroad.

One of the by-products of the miniature system is the confirmation and extension of the theory of transmission-line phenomena. Several prominent engineers have expressed the belief, and made the prediction, that after a few years of proper use of the miniature system, the theory and calculation of the present transmission problems will have been so well established that experimental solutions will no longer be necessary.

In this paper are given (1) a brief discussion of some of the present problems calling for solutions by the miniature experimental method, (2) a full description of the miniature equipment, (3) an outline of the operating procedure in the solution of problems, and (4) an example illustrating the application of the miniature equipment.

INTRODUCTION

A TYPE of miniature electric circuit which has been found to be of great practical value is one designed primarily for the experimental solution of problems arising in transmission networks. One of the problems is the determination of current division in a system network, both under normal load and during short circuit. Furthermore, the proper use of relays often requires definite knowledge as to both magnitudes and relative phases of currents and voltages at numerous

points of a system under short-circuit conditions. The solution of these problems involves not only the line characteristics and the transmission network connections, but also the type and connections of transformers, the characteristics of synchronous apparatus and their location with respect to the transmission network. Likewise, the stability of rotating machinery, under changing loads or for different methods of system operation, is a highly important practical problem in connection with transmission system design and operation.

While a number of the problems of the type men-

tioned in the preceding paragraph can be and have been solved theoretically by calculation, experimental solutions are often desirable—not only as a means of verifying the calculations and thus establishing the practical value of, and the fullest confidence in, the theoretical solution, when the latter is possible,—but also as the only available practical procedure for problems not readily subject to theoretical solution.

The requirements of problems of the above type, suggest a laboratory miniature electric system embodying the following features:

Two or more generators capable of representing separate generating stations.

Two or more banks of transformers permitting a variety of connections in accordance with central-station practise.

Adjustable resistor, reactor and capacity units, for polyphase (three-phase) circuits.

A sufficient number of the line units to permit representation of interconnected networks (or at least of portions thereof).

Switching arrangements for facilitating the practical procedure of interconnecting the various elements of the miniature system in any manner desired.

Provision for inserting measuring instruments, actual relays, current transformers, etc. at any point of the system.

A sufficiently high rating of the miniature apparatus such as to render inappreciable the errors introduced by the connection of practical measuring apparatus to the system.

A miniature system designed to meet these requirements has been installed and experimented with in the General Engineering Laboratory at Schenectady. The conception of the plan is due to Mr. H. H. Dewey, and a considerable amount of preliminary work preparatory to the construction of the miniature system was done by Mr. W. W. Lewis. Acknowledgements are also due to Messrs. D. P. Savant and A. R. Miller for their work in connection with the design and installation of the miniature system. The miniature system was built in 1919 and has since then been applied to the solution of a variety of electric-circuit problems.

OBJECT

It is the object of this paper (1) to review and discuss the nature of some of the practical problems to which this miniature system is applicable, (2) to describe its essential parts, and (3) to illustrate by an example its application to practical problems.

General Discussion of Problems

Under this heading will be shown the practical nature, and the importance to transmission system design and operation, of some of the problems which called for the construction of the miniature transmission system. The results of the experiments made will not be pre-

sented here. In some cases these results were applicable to one central-station system only, in others they have been of a fundamental character and therefore applicable more generally. A number of problems of each kind considered below have been solved with the aid of the miniature system.

DETERMINATION OF CURRENT DIVISION DUE TO NORMAL LOADS

This problem, already referred to, is one of vital importance to the economical layout and efficient operation of a transmission system. For a purely radial system of transmission from generating station to substations, without interconnecting feeders between substations, calculations of current flow in the feeders are relatively simple. Experimental solution is then of no particular advantage. For complex networks, however, having numerous interconnecting tie lines, thus offering a multiplicity of paths of current flow from the generating stations (one or more), the calculations are quite lengthy and often impractical. The complications of calculations are due not only to the circuit connections but also to the use of reactors—frequently causing dissimilar impedance angles in the various conducting elements of a network—and to dissimilar power factors of the loads on the system. Consideration has been given to the possible merit of approximating the solution of load-current problems by a d-c. experimental circuit, with the result that this sort of approximation cannot in general be expected to give reliable results, on account of the last-mentioned factors.¹ The experimental solution thus calls for an a-c. miniature system. With the proper equipment it is possible to determine, by the closing or opening of a switch, in the laboratory, the effect of adding to or withdrawing from the system a feeder or a tie line.

To summarize: The predetermination of normal current flow in the branches of networks is frequently desirable for the best design of new transmission systems as well as for the practical study of system additions or changes. The experimental solution of these problems calls for a miniature a-c. system.

DETERMINATION OF CURRENTS DURING SINGLE-PHASE SHORT CIRCUITS, FOR THE PROTECTION OF CIRCUITS AND ASSOCIATED PROBLEMS

When all three phases of a three-phase system are simultaneously short-circuited, the sustained short-circuit currents are balanced three-phase currents in all the circuit elements affected by the short circuit, regardless of the number of generating stations, the transformer connections or the circuit connections. For all other types of short circuits, an unbalanced current flow results. Such short circuits are

Short circuit between two phases,

1. See discussions of the paper on "Experimental Determination of Short-circuit Currents in Electric-Power Networks," A. I. E. E. Midwinter Convention, New York, 1923.

One-phase-to-ground short circuit on grounded-neutral circuit,

Simultaneous ground short circuits occurring on two phases of a grounded-neutral circuit.

While there are a great many cases where consideration of three-phase short-circuit currents, as obtained by the short-circuit calculating table, is sufficient for the determination of relay settings, circuit-breaker ratings, electromagnetic stresses, etc., detailed studies of single-phase short circuits are often necessary, when it is considered that a large number of short circuits are of the single-phase variety.—According to L. C. Nicholson,² the short circuits due to lightning on an aerial system were observed to be proportioned as follows: 60 per cent two-wire short circuits, 10 per cent three-phase short circuits, and 30 per cent single-wire-to-ground flashovers.—During short circuits, causing an unbalanced current division among the phases, the voltages between the lines generally become distorted from their normal balanced condition (represented by an equilateral triangle of voltage vectors). This distortion may be very pronounced at the points at which relay operation is desired. The distortions of the voltage triangle are due to the tendency for the voltage between the points short-circuited to approach zero. If, for example, a short circuit occurs between phases *A* and *B* on a three-phase circuit, the phases of which are *A*, *B* and *C*, the voltage V_{AB} will approach zero at the point of short circuit, while the voltages V_{BC} and V_{CA} at the point of short circuit will tend to become equal, each being less than its normal magnitude before the short circuit. Moreover, the relative phases of currents and voltages throughout the system will be far different from those applying to normal load conditions or to three-phase short circuits. Calculation of power-directional relay torques (their magnitude and direction) for the types of short circuits under discussion is often extremely laborious in view of the above considerations. Miniature tests in the laboratory on a suitable a-c. miniature system enable practical data on the performance of power-directional relays to be obtained under short circuits simulating those in actual service. Furthermore, miniature studies of this kind permit the factors affecting voltage and current relations during short circuits and their bearings on relay performance to be analyzed. Consequently a miniature laboratory transmission system serves not only in the solution of protection problems for the selected systems tested in miniature, but should aid, above all, in the advancement of knowledge towards a fuller understanding of short-circuit phenomena.

OTHER SHORT-CIRCUIT PROBLEMS

If a station with *Y*-connected generators has one generator neutral grounded, the other neutrals being ungrounded, the current contributed by each of the ungrounded generators to a line-to-ground short cir-

cuit will differ from that obtained when all the generator neutrals are grounded. This problem lends itself to laboratory solution by a miniature transmission system. A similar problem is due to the use of multiple *Y*-connected transformers when only one transformer neutral is grounded.

For short-circuit current determinations the reactance values, under short-circuit conditions, of generators and transformers must be known, as well as the paths traversed by the short-circuit current components.

Other problems within this class are the determination of transient³ and sustained reactances, of an alternator when short-circuited between terminals or from one or more terminals to neutral in the various possible ways.

Since relay operation commonly takes place during the short-circuit transient, the rates of short-circuit current decrement are of importance in the adjustment and behavior of relays, and in circuit-breaker application. The difficulties of short-circuit current determination increase when several generating units of dissimilar rates of current decrement feed current into a short circuit. Their combined effects on the short-circuit current transient, on relay behavior throughout a system, and on circuit-breaker requirements may be studied experimentally in miniature. To vary the time-constants of alternator windings, inductances and resistances external to the miniature alternators may be employed. Fundamental data on this kind of problem may be gathered by miniature tests with the aid of oscillograph records of current and voltage, and may be confirmed, in some cases, by direct connection of relays to the miniature circuit.

PROBLEMS ON STABILITY OF SYNCHRONOUS AND INDUCTION MACHINES

Both synchronous machines and induction motors will perform their normal functions and run in a stable manner only if operated within certain limits of load and circuit conditions, but will become unstable⁴ under other operating conditions. One of the problems of growing importance, within this class, is that of the stability of operation of induction motors and synchronous motors at the receiver end of long high-voltage aerial transmission lines. For this kind of circuit the voltage, current and power conditions for stable motor operation may be materially different from those pertaining to motors operating on constant-voltage mains. Various problems of stability of both synchronous and induction machines lend themselves to solution by calculations, without tests, provided the machine

3. The "transient" reactance is the reactance determining the r. m. s. a-c. component of initial short-circuit current.

4. The word "unstable" is used here in the following sense: A synchronous motor becomes unstable when the relations of power supplied to the motor and power demanded by the motor are such as to cause it to drop out of synchronism and come to a dead stop; similarly, in induction-motor operation instability occurs at the breakdown point.

2. Discussion, A. I. E. E. TRANSACTIONS 1911, part 1, p. 359

characteristics and the circuit constants are known. Nevertheless, our understanding of instability problems of this type can hardly be said to have been advanced to the stage at which experimental solutions for the verification of calculations are no longer required.

The Miniature A-C. System with Adjustable Circuit Constants

The miniature system consists of the following equipment (see Fig. 1):

motor driving its d-c. machine as a generator. A three-kw., motor-driven exciter set is provided.

Transformers: six type *M*, air-cooled, single-phase, 2 kv-a. 110/220-440-volt transformers. They may be connected to form two three-phase banks, thus permitting the various customary transformer connections, including auto-transformer schemes.

Reactors: twenty-four reactors, single-phase, air-cooled, iron-core type with fixed air-gap. Each reactor has 15 taps brought to a terminal board. In this way, 128 reactance values are available, ranging from 0.2 to 30 ohms at 60 cycles. The sustained current-carrying capacity is 10 amperes. The reactance values are constant for current values up to 20 amperes. The effective resistance of these reactors is negligible for all but the smallest values of reactance.

Resistors: twenty-four single-phase resistors, of "German silver" wire, wound on asbestos tubes; resistance range from 0.2 to 30 ohms, in 74 steps. The reactance, at 60 cycles per sec., of these units is less than 2 per cent of their resistance, and hence negligible. Their sustained current-carrying capacity is 10 amperes.

Condensers: The condensers are of the oil-immersed, flat, paper type. Enough units of approximately 2 and 5 microfarads are available to permit three-phase representation of lines several hundred miles long. The condenser units are not adjustable. The capacity values desired for any problem are obtained by series and parallel connections of the fixed units available. In Fig. 1 the condensers are not shown. Provision is

FIG. 2—WIRING DIAGRAM AND PANEL LAYOUT FOR MINIATURE TRANSMISSION SYSTEM

Generators: two type *A H I*, 3-phase, 4-pole, 3.75 kv-a., 1800-rev. per min., 110-volt, 60-cycle alternators, each coupled to a 10-h. p., 1700-rev. per min., 230-volt, d-c. motor. These generators are arranged for delta and star connections, and are of the revolving-field type. Each alternator may be operated as a synchronous

made for connecting them to the back of the switchboard.

Switchboard: A slate switchboard for interconnecting generators, transformers and line units is shown in Fig. 1 (rear view). The permanent circuit connections are shown in Fig. 2. Jumpers with copper terminals to

data appear in column 2, Table III. The problem is one of the simplest which has been encountered and can, of course, be solved by calculation. Its value should, therefore, not be judged on the basis of complexity. On the other hand, its merit lies in the fact that full-size system tests could be made for comparison with the miniature tests. Furthermore, the procedure in a more complex test differs in no essential respects from that outlined in this case.

FIG. 3A—ONE-LINE CIRCUIT DIAGRAM FOR THREE-PHASE, 60-CYCLE NETWORK WITH BALANCED LOADS

FIG. 3B—THE SIMPLIFIED DIAGRAM OF CIRCUIT 3A AS EMPLOYED IN MINIATURE TESTS

One of the most essential steps in the procedure is the choice of suitable conversion factors to be applied to the full-size data. Each problem to be solved generally calls for different reduction factors. Separate factors apply, in any one case, to the values of current, voltage, power, and impedance. A number of items which determine the reduction factors are: current, voltage,

and kv-a. rating of full-size circuit; the range of the miniature-system circuit constants; the type of problem, that is, whether short-circuit problem or normal-current problem; the method of measurement to be employed, i. e. whether oscillograph or indicating-meter method; the accuracy of the results desired.

For the problem under consideration, the miniature series impedances representing the lines should be as large as possible, on account of accuracy, and the current values should likewise be sufficiently high to give reasonably precise readings on the available indicating ammeters and wattmeters of low series impedance. A current value between 5 and 10 amperes, say 6 amperes, is a convenient one for the average of the currents in the principal lines A, B₁, and C₁ (in Fig. 3B). Thus a total generator current I_G of approximately 18 amperes is obtained, representing a full-size-system total generator output of 10,400 kw., or 11,820 kv-a. at a power factor of 0.88 (see bottom of column 2, Table III.) If, then, 440 volts are used — this value being the rated voltage of the high-voltage miniature equipment — and a line-to-neutral, single-phase representation of the (balanced three-phase) system is made, the three-phase miniature

*The full-size-to-miniature reduction factors are as follow: For computing miniature system values, divide the full-size values by these quantities:
500 for power or kv-a.
18.1 for voltage
27.6 for current
0.655 for resistance, reactance, or impedance

system value of kv-a. equivalent to the full-size value of 11,820 kv-a. is:

$$\frac{3 \times 440 \times 18}{1000} = 23.7 \text{ kv-a.}$$

This gives a kv-a. reduction factor of $\frac{11,820}{23.7} = 498$, or approximately 500, which latter value will be used. From the figures already given, the voltage reduction

factor is $\frac{13,800}{440\sqrt{3}} = 18.1$. Consequently, the current

reduction factor is $\frac{500}{18.1} = 27.6$, and the impedance

reduction factor is $\frac{18.1}{27.6} = 0.655$; that is, the minia-

ture-system resistance and reactance values are numerically larger than those of the full-size system. With these ratios, the desired miniature-circuit values of Table III, column 3, were obtained. Capacity charging currents, being practically negligible for the purpose of these tests, were left out of consideration. The effect of measuring instruments on the circuit impedances will be illustrated for the case of line B_1 . From Table III, column 3, the desired miniature value of Z_{B1} is $1.56 + j 3.85$ ohms. A 10-ampere ammeter and a 10-ampere current-coil of a wattmeter (both of type P3) introduce additional series impedances of $0.044 + j 0.019$ ohms and $0.030 + j 0.014$ ohms, respectively, representing a total combined impedance of $0.074 + j 0.033$ ohms due to the instruments. For line B_1 the

resulting errors are then $\frac{0.074}{1.56} \times 100 = 5$ per cent

for the resistance component, $\frac{0.033}{3.85} \times 100 = 1$ per

cent for reactance component, and, likewise, 2 per cent for impedance magnitude. The impedance error is negligible. In other cases, the resistance and reactance box settings were reduced in accordance with the instrument impedances, if the latter were more appreciable.

The loads L_1, L_2, L_3 and L_4 were represented as constant impedances by adjustable resistance and reactance units. It is quite feasible, when desired, to employ one or both of the 3.75 kv-a. alternators as motors in place of constant-impedance loads, as already indicated.

In column 4 of Table III, are shown the miniature-system data employed in the tests. These values differ slightly from those of column 3, *i. e.* from the desired miniature values, on account of the steps of the variable resistors and reactors. The differences in question, however, do not exceed 6 per cent for the values which determine the accuracy of the results.

From the four load values and the circuit impedances given in Table III, the experimental miniature results and the corresponding full-size results shown in Table IV were obtained. The results comprise the currents throughout the network and the voltages at the sub-

station busses, for balanced generator voltages and balanced loads. A sufficient number of phase angles were determined, with the aid of indicating wattmeters, to establish definitely the phases of all currents throughout the system.

FIG. 4—VECTOR DIAGRAMS OF VOLTAGE DROPS OVER THE LINES OF FIG. 3b FOR TEST CONDITIONS OF TABLE IV
These voltages were obtained by multiplying test values of full-size currents by actual-system line impedances. Disagreement between vector voltage drops is due to test errors.

Vector calculations for the accuracy of the miniature results were made, as indicated in Fig. 4. The vector voltage drops over each of the three paths from bus *a* to bus *e* (see Fig. 3b) were obtained by complex algebra,

by multiplication of test current values (converted to full scale, from Table IV last column) with actual-system impedances (from Table III, column 2). The maximum per cent mutual disagreement between the voltage drops so found is 7.5 per cent, while their per cent deviation from the average of the voltage drops is of the order of 4 per cent or less. It may, therefore, be concluded that the errors of the current values are

miniature-test data are a good equivalent of the actual-system behavior. Moreover, the preceding comparisons established a relatively good accuracy of the actual-system tests.

Conclusion

The miniature a-c. electric power transmission system described permits the experimental solution, in the

of a similar order of magnitude. The errors include, of course, those due to current and impedance magnitudes and phases. In view of the small errors of voltage drops, the errors of the bus voltages obtained by miniature test should be so small as to be hardly noticeable.

Finally, a comparison between actual-system tests and miniature-system tests will be made. While the load-kw. and power-factor values for these tests were the same as those previously employed (Table III, column 2), the line reactors X_B' , X_B'' and X_C' were omitted, all other impedance data being those of Table III. In the miniature tests, the load values (in kilowatts) were adjusted, as before, to approach reasonably closely to the values obtained in the actual-system tests, according to the lower part of Table III. Comparative results of both tests, shown in Table V, indicate discrepancies of less than 5 per cent, with the exception of the values of power for line A, which differ by 10 per cent. In the consideration of these differences, the complications involved in the actual-system measurements—made at mutually remote points under varying loads, with switchboard instruments,—should be taken into account. It may, therefore, be concluded that the

laboratory, of operating and design problems for actual transmission systems. Generating stations, transformers, substations, the transmission network and loads for systems may be correctly represented in the laboratory. Conditions of normal operation as well as short-circuit conditions may be reproduced. High-frequency transients, such as traveling waves, cannot be experimented with on this type of miniature system, on account of its lumped circuit elements, but the low-frequency transients, such as those of alternating-current generators, are correctly shown in the miniature circuit. Adjustable circuit constants, and quickly variable circuit connections, are used to permit miniature representation of the majority of the customary circuit conditions and system connections.

It has been possible with the aid of this miniature system not only to solve practical problems for transmission and operating engineers, but also to confirm, in several instances, the theory underlying calculations of circuit phenomena. The experimental laboratory solution has been compared, and found to be in good agreement, with the results of tests made in the field on commercially operating circuits and with the results of calculations.

Discussion

G. M. Armbrust: Mr. Schurig describes a very practical method for the solution of the most important problems in the design and operation of a transmission system.

The tendency of design of transmission systems generally is toward radial distribution or some limited form of network. This sectionalizing has resulted from numerous and extensive operating troubles occurring on a solidly inter-connected network such as the 12,000-volt transmission system of the Commonwealth Edison Company of Chicago, to which I refer. However, the radial scheme of distribution is expensive as reserve line capacity is required for every unit of load. It is therefore desirable to have some means of quickly solving a number of problems to determine the most economical design within the limits of the capacity of apparatus and protective schemes.

These problems are numerous as every group of load units has different geographic relations and electrical constants. The rapid growth of load makes these problems continuous.

This also brings about another condition; the time required to obtain and install cable makes necessary many temporary arrangements which must operate for a considerable time before an ultimate scheme can be realized.

The miniature a-c. scheme provides means for the practical solution of such cases without too great an amount or complication of equipment. The solution of problems mentioned is perhaps of the greatest commercial value, but as Mr. Schurig points out the scheme permits the investigation of many other problems.

In applying the miniature to the cable transmission system mentioned, it is apparent that solutions can be obtained without the use of a great number of units. Most of the problems would be single phase where a larger number of units are available, while in those requiring three-phase solutions it would not be necessary to represent the system in detail; sections could be represented by single units.

In studying the scheme, I had hoped that the miniature system could be reduced to a smaller scale, perhaps comparable with the d-c. calculating table, but limitations of a-c. measuring instruments make this impractical.

I should like to hear Mr. Schurig's opinion on this, regarding the possible minimum scale of the equipment.

V. Bush: It will not be long in my opinion before every large power system will install a calculating table as a part of its engineering equipment. Because of the much greater information available these tables will probably gradually be constructed as a-c. duplications. In addition to the advantages of the a-c. form mentioned by Mr. Schurig, such tables will allow of the investigation of such matters as are involved in power factor, the proper location and size of correcting apparatus, etc.

An a-c. network may be a single-wire or three-wire representation. The former is of course less expensive and may be installed first, and later form part of a three-wire representation. Single-phase short circuits, unbalance, etc. may be studied on the complete artificial system; but care must be used in order to properly represent the inherent tendency of rotating machinery to balance phases. This is a similar matter to that of proper representation of sustained short-circuit conditions. The constants of the piece of apparatus which represents a generating station must be altered to simulate the field reaction.

Either lumped or distributed constants may be used in the representation. Where only a few types of lines are involved, the latter is probably not much more expensive than the former, and it allows also of some small study of transient effects.

The difficulty of measurements on the a-c. system, without disturbing conditions on adding the meter, may be avoided by the use of the vacuum tube repeater. We have found at the Massachusetts Institute of Technology that this does not involve any great difficulty in maintaining calibration. Current

or voltage at any point in the network may be readily measured in this manner without drawing appreciable current. Hence the a-c. representation may be made as small in size as desirable.

There is one point in the artificial system that warrants considerable attention. This is the representation of the generating stations where several are simultaneously connected to the network. It is necessary that the relative phase displacements of the voltages supplied to the corresponding points in the artificial network be adjusted upon each change of load to correspond exactly to the phase displacements that will occur automatically under similar conditions in the actual system. Generating stations may be represented by a voltage supplied from a coil adjustable in a circular field, such as in a polyphase regulator; and the phase adjustment may then be made by rotating the coil manually. Similar treatment is necessary for any large synchronous apparatus in the system. It is not necessary that the coil of the regulator have internal constants corresponding to those of the station represented, for the constants can be added externally and the "generated" voltage maintained manually inside of these. The phase adjustment at each artificial station is a matter depending upon governor regulation. When full data on this point are available it is apparently possible to set up correct rules for the adjustment of phase upon change of load.

The transformers may of course be represented by equivalent networks, and all constants reduced to those corresponding to one voltage chosen as base.

A considerable amount of study is necessary before all the points in the manipulation of an artificial network of this sort are worked out. Some such means of attack is, however, imperative in order to properly lay out and operate systems of the magnitude at present projected.

O. R. Schurig: The miniature power generating and transmission system described in the paper has its chief application, as already pointed out, in the solution of *system network* problems, such as the determination of (1) normal load distribution in the lines and in generators, (2) system voltage regulation for balanced or unbalanced loads, (3) transient and sustained short-circuit currents at any point of the system for any kind of short circuit, (4) the behavior of relays during short circuits, (5) current-limiting reactor magnitudes and their best location (6) behavior of synchronous generators and motors in complex systems with several generating stations under changing loads, and short circuits, (7) power factor correction, (8) stability of generating and receiving apparatus on long lines, etc.

Dr. Bush suggests, if I understand him correctly, a type of miniature system of even broader application, namely one capable of solving, in addition to the above type of network problems, a variety of problems on high-frequency transients, such as those involving traveling waves, peak voltages due to lightning, arcing grounds, and switching. If fully developed in a practical form, the type of artificial circuit suggested would clearly represent a universal miniature circuit construction. Some of the developments, still incomplete, which the proposed universal type of miniature system would require are the following:

(1) Development of miniature line units: Miniature units of the "smooth" type would be needed to represent each of the sizes of cables as well as units to represent electrically the various types of aerial line construction. A far greater variety of artificial line units than now available would be called for in the representation of an average transmission system. Furthermore, the development of equivalent miniature generator, motor and transformer units—to meet the small scale of the proposed miniature system—would be necessary, as indicated by Dr. Bush.

(2) Measuring instruments and methods: A miniature system should permit measurements of current, voltage and power to be made with considerable facility. Several years of experience with practical miniature network tests have indi-

eated the necessity of having connected in circuit from 20 to 30 measuring instruments, on an average, for substantially simultaneous readings by the observers. That is a considerable number of instruments, covering a large table, when the customary portable type of instrument is used. In the low-current type of "smooth" miniature system proposed by Dr. Bush, special measuring methods such as those involving vacuum-tube amplifiers are needed. Though considerable progress has been made by Dr. Bush and his associates in the development of such measuring methods, the vacuum-tube amplifier scheme in its present state is probably too delicate and complicated for practical measurements when quick results and a large number of measurements are wanted.

One factor of prime importance in power system network investigations is the measurement of *power*. Experience has shown a visual direct-reading power indicator (such as an ordinary portable wattmeter) to be most essential. For the "smooth" type of miniature circuit, we need a new direct-reading wattmeter of much reduced current and voltage consumption.

The above considerations lead to the following summary:

There is a definite field for each of the two types of miniature circuit under discussion:

The network type of miniature system including synchronous machines and lumped transmission line units, as described in the paper, has already established its practical usefulness for the solution of normal-load and short-circuit problems at fundamental frequency; a large bulk of the pressing problems, both of the routine and research type, in transmission networks may be solved in a practical manner; the current rating of the generator and line equipment should be not less than 5 or 10 amperes. Thus, the equipment necessary and the methods of testing are substantially the customary and well-established ones, including power measurements by portable indicating wattmeters. The use of the miniature equipment by central-station and transmission engineers involves no radical departure from full-size system operation. It is not desirable to further broaden the use of the network type of miniature system by substituting "smooth" circuit elements for the "lumpy" type in an attempt to make it applicable also to high-frequency transient problems. The change would introduce new and unsolved problems of design. If "smooth" type of circuit elements having a current rating of an order of magnitude lower than 5 or 10 amperes were used, the convenient direct-reading type of instruments would no longer be applicable for voltage and power measurements. The vacuum-tube type of instrument has, up to the present time, not reached a state of development in which it can be considered practical for quick results when a large number of substantially simultaneous observations are wanted.

The "smooth" type of miniature line, on the other hand, is called for in high-frequency transient investigations. The current rating of the equipment is preferably below 5 amperes, and a good many of the tests may be so conducted as to require but a small number of measuring instruments, which (in accordance with the practise developed by Dr. Bush¹ and Professor Dellenbaugh¹) are of the vacuum-tube amplifier type. The design of equipment and the manipulation of the tests call for a high degree of specialization—somewhat outside the field of central-station and transmission-line engineering but well within

the field of a University laboratory. A number of the large engineering schools now have technical engineering laboratories supported by the industry. Thus, the transmission engineer's problems calling for smooth-line tests in miniature may be assigned to the proper university laboratory for solution, as has already been done in the past. The new contact thus afforded between the industry and the university seems to be beneficial not only to professors and students; but also to the industry as well.

In reply to Mr. Armbrust's question referring to the possible minimum scale of the a-c. miniature-system equipment, I will say that the size depends on the use to which the miniature system is to be put: If to be used for current measurements only, a much smaller equipment will suffice than for a miniature system intended for power and voltage measurements as well. It is assumed, of course, that indicating instruments are to be employed, at least part of the time. For tests involving *power, voltage and current observations* at several points of a system, a 10-ampere continuous rating at 440 volts (20-ampere short-time rating) has been found to be about the minimum for the line units of resistance and reactance. The figures given are those for the miniature system at Schenectady, as described in the paper. A lower current rating will introduce appreciable errors due to the change of circuit conditions brought about by the insertion of the customary portable measuring instruments, as indicated by Mr. Armbrust.

The minimum practical scale of an a-c. equipment for *current observations only* has not been definitely determined, because there has been no call for such an equipment. It is not at all unlikely that the current rating may be reduced to a value of the order of 50 milliamperes, the measurements to be made with thermocouple a-c. ammeters, some types of which have a voltage drop well below the maximum permissible value set by miniature-line requirements. The design of inductance units for the low current values, such as 50 milliamperes, should not offer great difficulties. In this connection, it will be recalled that there are a number of load division and short-circuit problems which call for current measurements, but not for power and voltage measurements. However, it has been felt in the past that the restriction of the equipment to observations of current only, was not desirable in view of the greatly increased use obtained from a device giving power and voltage data in addition to current. It should be pointed out here that the size and cost of the equipment are not to be expected to be proportional to the current rating on account of the increased number of turns required for the inductance units of lower current rating.

Another matter bearing on the size of the miniature equipment is *the number of circuit units required*. At first thought it might appear that the requisite number of miniature units must closely approach the number of network branches of an entire transmission system. As a matter of fact, there are relatively simple circuit transformations, of a mathematical or geometrical sort, that may be applied to complicated networks to reduce the total number of elements in the mesh of circuits. Transformations of the kind that I have in mind have been worked out by Kennelly², Fortescue³, Evans⁴ and others. It is often surprising how much labor is saved by the simplest of transformations.

A Simplified Method of Analyzing Short-Circuit Problems

BY R. E. DOHERTY

Associate, A. I. E. E.
Consulting Engineering Dept.
General Electric Company, Schenectady, N. Y.

Review of the Subject.—This paper presents the theoretical basis for a theorem by which the practical analysis and visualization of short-circuit phenomena can be greatly simplified. The theorem follows from the approximation of neglecting resistance in the application of Kirchhoff's Law to closed circuits. Thus in any problem of short circuits in which the effect of resistance is negligible in the initial moment, and this includes many of them, the theorem applies. It is: If the resistance of a closed circuit is zero, then the algebraic sum of the magnetic linkages of the circuit must remain constant.

Illustrative examples are given, including the transformer, the single-phase and polyphase alternator, and the induction motor.

THE practical analysis and visualization of many short-circuit problems may be greatly simplified by the theorem of constant flux linkages. This theorem has been mentioned in an incidental way on two previous occasions,¹ but its importance appears to warrant further emphasis. Attention was drawn to its possible greater usefulness, by the mathematics and some of the conclusions in a recent Institute paper on *Electromagnetic Forces*.²

SCOPE

The purpose of this paper, therefore, is to present the theoretical basis for the theorem, and illustrate its use by a few practical examples.

It is based on Kirchhoff's law of voltages, and follows from the approximation of neglecting the resistance in the circuits. It is stated as follows: *If the resistance of a closed circuit is zero, then the algebraic sum of the magnetic linkages of the circuit must remain constant.*

The theorem thus applies in any case in which the effect of resistance can be neglected. This includes most practical problems, because the effect of resistance in determining the initial rush of current is usually negligible. Its effect in determining the transient, or decay of current is, of course, decisive; but usually the problem is to determine the initial current rush. That is, the result of first importance is the initial condition, immediately following sudden short circuit; and this is, of course, practically the condition which would exist if there were no transient—in other words, the condition which would exist if the resistance in the circuits were zero. The application to practical problems, therefore, is very broad.

THEORETICAL BASIS

In most short-circuit problems, Kirchhoff's two laws are dealt with. The second law states that the sum of all e. m. fs. around a closed circuit must equal zero. That is,

$$\sum e = 0 \quad (1)$$

Simple Case. It follows that in a simple circuit³ as shown in Fig. 1,

$$r i + \frac{d}{dt} (L i) = 0 \quad (2)$$

where

r = resistance (ohms)
 L = inductance (henries)
 i = current (amperes)

FIG. 1

Referring to equation (2), if

$$r = 0$$

then

$$\frac{d}{dt} (L i) = 0 \quad (3)$$

That is, the product $L i$ is constant. But what does the product $L i$ represent? The inductance L is equal to the "flux-turns," or "linkages" per ampere. That is,

$$L = \frac{\phi N}{i \times 10^8}$$

3. Neglecting capacitance which is practically never a significant factor in short-circuit problems.

Thus the product Li represents ϕN , which is the magnetic linkages of the circuit. Therefore, *the magnetic flux⁴ linked with a closed circuit of zero resistance cannot change.*

It will be shown that this is true not only for the simple circuit shown in Fig. 1, but in general, even for a circuit which is part of a network and which may, in addition, be in mutual inductive relation to other circuits. The only conditions are, that the circuit shall be closed and shall contain no resistance.

General Case. The validity of the theorem for the general case will now be established.

Consider the circuits shown in Fig. 2, which are assumed to be in relative motion.⁵

Applying equation (1) to the closed circuit A,

$$ir + \frac{d}{dt}(Li) + \frac{d}{dt}(M_1 i_1 + M_2 i_2 + M_3 i_3 + \dots) = 0 \quad (4)$$

or in general

$$ir + \frac{d}{dt}(Li + \sum M i_s) = 0 \quad (5)$$

where i_s = current in secondary or inductively related circuits. Neglecting resistance,

$$\frac{d}{dt}(Li + \sum M i_s) = 0 \quad (6)$$

FIG. 2

or

$$Li + \sum M i_s = \text{constant} \quad (7)$$

But the expression

$$Li + \sum M i_s$$

represents the magnetic linkages of the closed circuit

4. More accurately, the magnetic linkages. For instance, two lines linking half the turns would obviously represent one total linkage. Thus on account of partial linkages, it is not quite accurate to say the "magnetic flux" is constant, but only the flux representing complete linkages is constant.

5. And therefore both the M 's and L 's are variable: M 's variable by relative motion; L 's may be variable either by saturation or by proximity to moving iron of secondary circuits.

A. Hence, the theorem applies to a detached closed circuit as shown in Fig. 2, in mutual inductive relation to any number of secondary circuits.

It remains to be proved that it holds also for the perfectly general case, as illustrated in Fig. 3, in which, as in Fig. 2, the circuits are assumed to be in relative motion and in addition the closed circuit A is made up of branches of a network.

Thus consider *any* closed circuit, as A in Fig. 3.

(a) in relative motion to, and inductive relation with, any number of secondary circuits.

FIG. 3

(b) in multiple connection with other circuits.

Let

i_a, i_b, i_c , etc. be the currents in the several individual branches of the closed circuit.

L_a, L_b, L_c , etc. be respectively the inductances of these branches.

r_a, r_b, r_c , etc. be the corresponding resistances.

M_1, M_2, M_3 , etc. be the mutual inductances between the closed circuit and the secondary circuits.

i_1, i_2, i_3 , etc. be the currents in the secondary circuits.

All the quantities are considered as variables. The units are: i 's in amperes; r 's in ohms; L 's and M 's in henries. By Kirchhoff's Law

$$\sum e = 0$$

Thus, summing the voltages around the circuit A,

$$(i_a r_a + i_b r_b + i_c r_c + i_d r_d) + \frac{d}{dt}(L_a i_a + L_b i_b + L_c i_c + L_d i_d + M_g i_g + M_e i_e + M_f i_f + M_1 i_1 + M_2 i_2 + M_3 i_3 + \dots) = 0 \quad (8)$$

That is,

$$ir + \frac{d}{dt}(\sum L i + \sum M i_s) = 0 \quad (9)$$

Neglecting resistance this becomes

$$\frac{d}{dt}(\sum L i + \sum M i_s) = 0 \quad (10)$$

But, as before, the quantity in the parenthesis repre-

sents the number of magnetic linkages of the circuit. The equation states that the rate of change of the number of linkages is zero; hence the number is constant. Therefore the theorem is general.

Thus to repeat: *If the resistance of a closed circuit is zero, then the algebraic sum of the magnetic linkages of the circuit must remain constant.*

It is well at this point to interpret the physical meaning of this statement. Magnetic linkages are expressed numerically by the product of the magnetic flux and the number of turns with which the flux is linked,⁶ or, in general, by the product of the inductance L or M by the current. Therefore in a closed circuit without resistance if the inductance, either self or mutual, changes for *any* reason, or if the current changes in any mutually related circuit, then there must be a compensating change in current in the closed circuit to maintain constant its magnetic linkages. Do not misunderstand. The distribution of linkages among the different branches or component, series elements of the closed circuit need not remain the same, but the algebraic sum of all linkages must remain constant.

However, in special cases of symmetrical branches such as the star-connected polyphase machine, with sine wave flux distribution on open circuit, it can be shown⁷ that the flux linkages in *each branch* or phase remains constant when the terminals are short-circuited.

ILLUSTRATIVE EXAMPLES

Transformer. Consider a few simple illustrations to visualize what this means. In Fig. 4A, a transformer

FIG. 4

primary is connected to a battery, the secondary being open. Of the total flux ϕ , established by and linking with the primary, part of it ϕ_m links the secondary, and the remainder ϕ_{11} passes between the windings, [that is, as leakage flux. Now close switch s_2 (Fig. 4B),

6. Keeping in mind the statement previously made regarding partial linkages.

7. *Short-Circuit Current of Induction Motors and Generators*, Doherty and Williamson, TRANS. A. I. E. E., Vol. 40, p. 537.

and assume zero resistance in the secondary. Obviously no electrical change will follow. Open switch s_1 (Fig. 4C). What happens? We know that the secondary linkages

$$\phi_m N_2 = i_1 M$$

cannot change, and hence a secondary current i_2 must appear such as to satisfy the condition

$$i_2 L_2 = i_1 M = \text{constant} \quad (11)$$

It is interesting to follow this further. Suppose the secondary winding is now taken completely out of the transformer, that is, away from any iron as indicated in Fig. 5A. The theorem still applies. The inductance

FIG. 5

L_2' is very much less, perhaps 0.005 of its former value, L_2 . It does not matter. The linkages must remain constant. Hence the current i_2 must correspondingly increase so that

$$i_2 L_2 = i_2' L_2' \quad (12)$$

Thus the current would increase 200 fold. In other words, regardless of what else happens, the magnetic linkages cannot change as long as the circuit is closed and the resistance is zero.⁸

A step further: How much work would be required to pull the coil away from the iron core, assuming infinitely thin saw cuts in the core that would permit removal of the coil. This work must be equal to the increase in stored energy. The stored energy is

$$1/2 L_2 i_2^2 \text{ before}$$

and

$$1/2 L_2' i_2'^2 \text{ after}$$

Work is

$$W = 1/2 (L_2' i_2'^2 - L_2 i_2^2) \quad (13)$$

But by (12),

$$L_2 i_2 = L_2' i_2'$$

Solving for i_2' and substituting in (13),

$$W = 1/2 L_2 i_2^2 (L_2/L_2' - 1) \quad (14)$$

If L_2 is large compared with L_2' , as here, (14) becomes,

$$W \approx 1/2 L_2 i_2^2 (L_2/L_2')$$

That is, the work is approximately equal to the initial stored energy multiplied by the ratio

$$L_2/L_2' = 200$$

or

$$W = 200 (1/2 L_2 i_2^2)$$

8. If the circuit contains some resistance, as of course it must, the linkages must decrease at a rate just sufficient to generate the $i r$ drop.

the only difference being that now the current is alternating. That is, the relation between the current before and after short circuit is the same in either case, namely,

$$\frac{1}{1 - K^2}$$

Assume now that s_1 is closed at the instant $\omega t_1 = \pi/2$, that is, when the secondary encloses, or is linked with, maximum flux. The fact that the secondary linkages thus "caught" by the short circuit must

$$i_2 = -i_0 M/L_2 \frac{\sin \omega t - 1}{1 - K^2} \quad (30)$$

also for values of $t > t_1$.

It will be observed that (29) and (30) each involve a constant or "direct" component of current in addition to the "alternating" component. In (29), for instance, the direct component is

$$i_1' = -i_0 \frac{K^2}{1 - K^2} \quad (31)$$

FIG. 8

FIG. 9

FIG. 10

remain constant, gives interesting consequences. Consider these consequences first in the light of the equations, and then from the physical point of view. By equation (25), for

$$\omega t_1 = \pi/2$$

$$i_1 = i_0 \frac{\sin \omega t - K^2}{1 - K^2} \quad (29)$$

for values of $t > t_1$, since the equations obviously hold only for conditions after the short circuit. And by (26)

and the alternating component is

$$i_1'' = i_0 \frac{\sin \omega t}{1 - K^2} \quad (32)$$

In (30), the direct component is

$$i_2' = i_0 M/L_2 \frac{1}{1 - K^2} \quad (33)$$

and the alternating component is

$$i_2'' = -i_0 M/L_2 \frac{\sin \omega t}{1 - K^2} \quad (34)$$

Equations (29) and (30) are plotted in Fig. 8, showing graphically the relation between the alternating and direct components.

Now examine the physics of the problem. Consider the case in which the switch s_1 , Fig. 6, is closed when the secondary is linked with maximum flux, that is, when $\omega t = \pi/2$. This flux, or linkages rather, must remain constant. But obviously one-half cycle later, the flux in the primary is full value in the opposite direction, since the impressed voltage is maintained. That is, the primary is trying to force flux through the closed secondary, which must not only prevent this opposite flux from entering, but also must maintain constant the flux with which it is linked. This instant corresponds to the maximum current in Fig. 8. Since the reversed primary flux cannot enter the secondary, and the secondary flux cannot enter the primary, it follows that both fluxes must pass through the leakage paths between the windings. It thus requires twice¹¹ as much maximum current as the case in which the switch s_1 was closed when the secondary enclosed zero flux.

Thus the actual current in both the primary and the secondary comprises a direct and an alternating component of about equal maximum values. In the secondary the direct, or constant flux, with which it is linked, requires a direct current to maintain it, and an alternating current is required to prevent the alternating flux of the primary from linking the secondary. And similarly the primary requires a direct current to prevent the direct flux of the secondary from linking it (since the primary flux must at all times correspond to the impressed voltage), and also requires an alternating component to force the alternating flux through the leakage paths. Thus the total current in either of these windings comprises the two components as shown in Fig. 8.

The transformer problem thus illustrates in fundamental respects the facility of calculation and of visualization made possible by the "theorem of constant magnetic linkages." Other illustrations will now be given in a much briefer way.

Single-Phase Alternator. In Fig. 9, aa represents the armature winding, bb the field winding. Assume that the field winding is excited by the current i_0 ; that the field winding, having zero resistance, is short-circuited at the collector rings.¹² Thus as long as the permeance of the magnetic circuit is not changed, i_0 would continue to flow, by the condition that the field linkages must remain constant. But whatever happens, the field linkages cannot change. Remove the rotor from the machine. The field current will increase

11. Actually $(1 + K^2)$ times as great. K^2 is of the order of 0.99 in a transformer.

12. The exciter voltage, of course, supplies only the $i r$ drop, and therefore corresponds to the initial rate at which the flux would actually die down if the collector rings were short-circuited on the given machine. Without resistance, it would not die down.

because the inductance has decreased. Replace it, and the current is once more i_0 .

When running with open armature circuit, the number of field linkages is

$$\Omega_b = i_0 L_b \quad (35)$$

and the armature linkages,

$$\Omega_a = i_0 M \quad (36)$$

where,

$$M = M_0 \cos \omega t \quad (37)$$

M_0 = mutual inductance between armature and field windings in position $\alpha = 0$, Fig. 9.

ω = electrical angular velocity.

Assume that a short circuit occurs at the time t_1 . Then by (36) and (37) the number of armature linkages at this instant is,

$$\Omega_a = i_0 M_1 = i_0 M_0 \cos \omega t_1 \quad (38)$$

and the field linkages

$$\Omega_b = i_0 L_b \quad (39)$$

Thus, after short circuit, Ω_a and Ω_b must remain constant, and

$$\Omega_a = i_0 M_1 = i_a L_a + M i_b \quad (40)$$

and

$$\Omega_b = i_0 L_b = i_b L_b + M i_a \quad (41)$$

Substituting (37) and (38), and solving simultaneously,

$$i_a = -i_0 M_0 / L_a \frac{\cos \omega t - \cos \omega t_1}{1 - K^2 \cos^2 \omega t} \quad (42)$$

and

$$i_b = i_0 \frac{1 - K^2 \cos \omega t_1 \cos \omega t}{1 - K^2 \cos^2 \omega t} \quad (43)$$

where,

$$K = \sqrt{\frac{M_0^2}{L_a L_b}}$$

Equations (42) and (43) are plotted in Fig. 10 for $\omega t_1 = 0$.

How does the magnetic energy storage vary during rotation, and what is the torque? Neglecting saturation, the magnetic energy storage in the field is¹³

$$W_b = 1/2 \Omega_b i_b 10^{-8} \text{ joules} \quad (44)$$

and in the armature,

$$W_a = 1/2 \Omega_a i_a 10^{-8} \text{ joules} \quad (45)$$

But Ω_a and Ω_b are constant. Therefore the energy of each circuit varies directly with the current. The total energy is

$$W = W_a + W_b = 10^{-8}/2 (\Omega_a i_a + \Omega_b i_b) \quad (46)$$

Since the electrical power supply is cut off, the change in energy must be supplied mechanically. That is, the energy supplied to the magnetic field during rotation through the angle $d\alpha$ is equal to the mechanical work done: Torque $\times$ angle. Hence,

$$dW = T d\alpha$$

13. Stored energy = $W = 1/2 L i^2 10^{-8} = 1/2 (L i) i 10^{-8}$ joules. But, $L i = \Omega$ Hence, $W = 1/2 \Omega i \times 10^{-8}$ joules.

That is, the torque is

$$T = \frac{dW}{d\alpha} \quad (47)$$

where $\alpha = \omega t$.

Differentiating (46),

$$T = \frac{dW}{d\alpha} = 10^{-8}/2 \left(\Omega_a \frac{di_a}{d\alpha} + \Omega_b \frac{di_b}{d\alpha} \right) \quad (48)$$

Thus the electromagnetic torque during short circuit is determined by the slope of the current curves.

Polyphase Alternator. At any moment the *total* flux from each field pole is linked with the coils of some phase or phases. If, for example, one phase encloses zero flux, then all of the flux must be enclosed by the other phases. Hence regardless of the point of the cycle at which a polyphase short circuit occurs, the full flux from each pole is "caught" by the armature coils. Therefore, after the short circuit, there must be a series of armature poles, of full flux, disposed around the periphery, the center lines of these poles corresponding to the center lines of the field poles at the instant of short circuit—thus, somewhat as if the field poles of the rotor had at the instant of short circuit, stamped their replica upon the stator, and then moved on.

Now imagine the rotor to be removed from the stator. Since the flux of the armature, as well as the flux of the field, must persist, it follows that, although removed from each other, each of these members must retain its own set of poles as shown in Fig. 11. If this picture is kept in mind, there will be little difficulty in visualizing polyphase short circuits. These two separate sets of magnetic poles—the armature and the field—both of about equal flux per pole, must persist, regardless of what happens, so long as the circuits are closed, and the resistance is zero. Thus if the rotor is again put into place and rotated, these two sets of poles, one rotating, the other stationary, pass over each other, and the currents adjust themselves so as to maintain constant flux linkages. When the poles are in the same relative position as that when the short circuit occurred, the currents will be of the value existing the instant before short circuit, namely, zero in the armature, and no load exciting current in the field. One

FIG. 11

pole pitch, *i. e.*, one half cycle, later, when the poles are opposing each other, thus forcing double flux through the leakage paths, the currents are maximum. Thus in the alternator, as in the transformer, if the armature, or secondary, "catches" any flux when the short circuit occurs, there must be a direct component of current, and also the maximum value of the total current occurs one half cycle after the moment of short circuit. Fig. 12 is an oscillogram of a three-phase

FIG. 12—THREE-PHASE SHORT CIRCUIT OF A 10,000 KV-A., 6600-VOLT, 63-CYCLE GENERATOR

Upper curve—current in phase a.
Middle curve—field current.
Lower curve—armature volts.

short circuit of an alternator, showing the current of one phase, the field current and the line voltage. The large direct component of current which produces nearly complete offset of the armature current wave, shows that at the instant of short circuit the particular armature phase had "caught" nearly full flux.

Induction Motor or Generator. At the moment the terminals are short-circuited, the rotating magnetic field, which is linked with the closed secondary, has a definite position on the face of the stator. Like the case of the polyphase alternator, this field is linked with the coils of some phase or phases of the short-circuited stator winding, and must remain stationary, and at full value. But the flux linked with the rotor must also remain at full value and stationary *with respect to the rotor winding*. That is, it must continue to rotate in space. In other words, the two sets of poles exist, just as in the case of the alternator, and with the same results.¹⁴ Of course in the actual case, there is resistance in the circuits and the currents would die down to zero. But initially the phenomena of short circuit in an alternator and in an induction motor are practically identical.

As a further illustration of this method of analysis it can be shown that the initial current rush to an induction motor¹⁵ is the same when the line switch is closed upon the motor at standstill, as when the motor is running at synchronous speed.¹⁶ In either case, the number of flux linkages in the closed secondary, or

14. For further discussion of this, see "Short Circuit of Induction Motors and Generators" by Doherty and Williamson, TRANS. A. I. E. E., Vol. XL, 1921, p. 509.

15. If the motor is of sufficient size so that the resistance is practically negligible in the first moment after short circuit.

16. To the Author's knowledge, no tests have been made to confirm this, but it follows from the theorem.

rotor, circuits is zero, and must remain so after the line switch of the primary circuit is closed. The primary circuits are open and of course contain zero linkages before the switch is closed. But consider the closed circuits formed by the switch, namely those each of which is made up of a motor phase and the corresponding alternator phase in series. In each of these circuits, each electrically disconnected from the other, a definite value of flux existed, or was linked with the circuit, at the moment the switch was closed, the value of flux linkages in each circuit depending, of course, upon the alternator pole position at that moment. The value of flux thus caught in each circuit must remain constant. But since, assuming constant line voltage, the flux in the alternator phase must continue to vary, through fixed values, and thus (by assumption of no leakage) can not hold the constant component of flux which must continue to exist somewhere in the circuit, it follows that it must exist in the primary phases of the induction machine. In other words there must be a direct, or stationary magnetic field around the periphery of the induction motor, just as in the previous illustrations. Also since the voltage is held up at the terminals of the motor there must also be a rotating field. That is, there exists a stationary, and a rotating set of poles around the stator periphery; and none of this flux can link with the rotor. Therefore, at standstill, the secondary must contain direct current to prevent the stationary primary flux from entering; and must contain alternating current to prevent the rotating flux from entering. And these components of current must be of the same magnitude since the fields they oppose are of the same value. On the other hand, the primary winding must contain direct current to sustain the constant or stationary component of flux in the linkage paths, and an alternating component to sustain the rotating field—both of same magnitude. Thus the total current in either the primary or secondary windings must contain a direct and an alternating component of current of the same magnitude.

If the rotor is driven by external means at synchronous speed when the switch is closed, then, since neither the rotating nor the stationary field of the stator (both, the same as in the foregoing case) can enter the rotor, all conditions will be the same as before, excepting the rotation. Now the stationary field of the stator of course requires direct current in the stator windings, but it produces due to rotation of the rotor, alternating current in the closed rotor circuits; also the rotating field of the stator requires alternating currents in the stator windings, but being stationary with respect to the rotor, produces therein a direct current. And all currents are of about the same maximum values, and hence the same as at stand-still.

SUMMARY

Summarizing briefly the points brought out in the paper, it follows from Kirchhoff's Law of Voltage,

that if the resistance of a closed circuit is zero, then the algebraic sum of the magnetic linkages of the circuit must remain constant. Thus if the reluctance of the magnetic path linking the closed circuit is increased, the current in the circuit must increase, and vice versa, to maintain constant the magnetic linkages. Or if a separate magnetomotive force is impressed on the magnetic circuit linking the closed circuit, tending to change the linkages of the closed circuit, then the current in the latter must adjust itself to balance the new m. m. f. and thus maintain constant linkages. The application of the foregoing theorem to the problems of short circuits of electrical apparatus accomplishes two important results: In the first place it tremendously simplifies the mathematics and calculation of the short-circuit current and related problems; also it makes it possible to visualize easily the phenomena—which, of course, is always highly desirable in any analysis.

Discussion

W. V. Lyon: As an introduction to the study of transients in electric machinery, Mr. Doherty's paper should prove interesting, but I am sure that neither Mr. Doherty nor any other serious student of the subject would be satisfied with this approximate solution. There is no doubt that a more careful analysis which does not neglect the dissipated forces is more difficult, but rather than proving a deterrent this difficulty makes the problem more interesting.

In electric machinery the only voltages that need ordinarily be considered are due to resistance and to variable flux linkages. If the former are negligible in comparison with the latter, the voltage that appears at the terminals of any circuit equals the time rate of change of the total flux linkages. If the circuit is closed on itself, the terminal voltage is zero, and the time rate of change of the flux linkages is zero; that is, the total flux linkages remain constant. If, on the other hand, a constant direct voltage is applied to an idle circuit, the flux linkages increase directly with the time.

The accuracy with which this "theorem of flux linkages" will predict the results obtained in practice depends upon the relative magnitude of the resistance and the self and mutual inductances. In a transformer the principal component of the transient current diminishes at a rate determined by the ratio of the resistance and the difference between the self and mutual inductances. In a certain 1000-kv-a., 60-cycle transformer this ratio is 56. In this transformer the first rush of current on short circuit is 163 per cent of the steady short-circuit current. If the resistance had been neglected, the first rush would have been 200 per cent, as Mr. Doherty states. The error is nearly 25 per cent. There is also another transient component, which is however but 2 or 3 per cent as large as the one just mentioned. This component diminishes at a rate determined by the ratio of the resistance and sum of the self and mutual inductances. This ratio is ordinarily 5 or 10 per cent, and might safely be assumed to be zero.

In a 75-h. p. induction motor we have tested, the ratio of the resistance to the self inductance was about 2.5 for the stator and 4 for the rotor. The two components of the transient current, instead of being constant as would be the case if the resistance were negligible, diminish at a considerable velocity. The one of higher frequency diminishes at a rate of 74 hyperbolic radians per second, and the one of small frequency at a rate of 48 hyperbolic radians per second. In this motor the first rush of current in one phase would be to a maximum value of about 3300 amperes if the resistance were negligible. Actually the first

current rush has a maximum value of about 2200 amperes. In this case, neglecting the resistance leads to an error of 50 per cent, whereas if the resistance is taken into account, students have been able to compute the first current rush with an error of less than 10 per cent.

From these examples it would seem that resistance plays a larger part in determining the first current rush than we might be led to believe from a cursory study of the subject.

A. Boyajian: I think Mr. Doherty's paper is a valuable contribution to the electrical literature in that it gives a physical interpretation to the short-circuit transient, a subject which has been dealt with almost exclusively mathematically in the past, starting with differential equations and finding a complete solution that will satisfy them. It is brought out in this paper in an extremely interesting and visual manner that the short-circuit transient of flux and current is produced by the flux which is trapped in the short-circuited coil. The fundamental principle that no flux can enter or leave a short-circuited coil of zero resistance is used masterfully in analyzing the short-circuit transient of a number of electrical apparatuses.

Of course, ordinarily, short-circuited coils have a certain amount of resistance, by virtue of which flux can gradually penetrate into them or leave them, and the transient decays in a short time to a negligible value in accordance with the attenuation constant of the circuit, as is well known. But Mr. Doherty, I think, is to be commended for maintaining the presentation of the principle simply by ignoring the calculation of the rate of decay, inasmuch as the mathematics of these transients are

quite old, but the physical interpretation of the phenomenon new to many.

R. E. Doherty: Professor Lynn considers the principle proposed in this paper as, at best, a poor approximation. What the paper presents is the proof of a useful theorem—at least the author has found it to be useful. Like any other theorem, if it is applied where it is not applicable, unreasonable results follow.

If any one is interested in seeing how the theorem may be *applied* for practical results in the case of induction motors, such as Prof. Lynn mentions, I would refer him to the method outlined in a previous A. I. E. E. paper.¹

Now I am in complete accord with Prof. Lyon as to the desirability of rigorous attack of any problem of this sort; but in practical engineering I have found that I can stick to rigor up to the point where it leads to hopeless complication. Then I have to do something else—because an answer must be obtained.

The value which I feel is in this method of attacking short-circuit problems lies in the fact that it is possible to visualize what is going on, and in a large number of cases, to get actual quantitative calculations in a very simple manner. In those cases in which it is not possible to make quantitative calculations, one at least can obtain accurately the initial condition, that following the instant or the moment of the short-circuit; and if one who is working on such problems has some notion of what the effect of resistance is, he can from that, estimate close enough for practical purposes the rate of decay of the current.

Proximity Effect in Wires and Thin Tubes

BY H. B. DWIGHT

Member, A. I. E. E.

Canadian Westinghouse, Ltd., Hamilton, Ont.

Review of the Subject.—Formulas are given, with examples, for the following new problems in proximity effect resistance ratio: Thin Tube and Infinitesimal Wire; Two Thin Tubes in Return Circuit; Two Thin Tubes in Parallel; Insulated Cable Sheaths in Single-Phase Circuit; Cable Sheaths in Three-Phase Circuit, Flat Spacing; Finite Wire and Infinitesimal Wire; Two Wires in

Parallel; Three-Phase Circuit, Triangular Spacing; Three-Phase Circuit, Flat Spacing.

Reduction formulas for Bessel functions, suitable for skin effect problems, are tabulated, and a table of values of the first five orders, for use in drawing curves, is given.

THE calculation of the alternating-current resistance ratio due to skin effect or proximity effect, has been worked out for a number of shapes and combinations of conductors. The case of an isolated wire was solved by Clerk Maxwell in 1873, (Reference 1). This solution is usually expressed in terms of Bessel functions of the first kind. In 1886, Lord Rayleigh gave the calculation for skin effect in an infinite plane conductor, (Reference 2), and in 1909 Dr. A. Russell published a calculation for a concentric main, that is, a return wire inside of a tube (Reference 3).

The effect on the resistance, caused by current distortion in conductors in armature slots, was treated by A. B. Field, 1905, (Reference 4), R. E. Gilman, 1920, (Reference 5) and W. V. Lyon, 1922, (Reference 6).

In 1915, A. E. Kennelly, F. A. Laws and P. H. Pierce published some very precisely measured curves of various shapes and combinations of conductors taken up to 5000 cycles, (Reference 7). These were very valuable, for in 1915 the only calculation which was in a form to be applied to a finite conductor and checked by test was the calculation for an isolated wire, which they checked exactly. Several of the other test

FIG. 1—THIN TUBE AND INFINITESIMAL WIRE

curves have since been checked by calculations, and the curves have been of undoubted help to those deriving the new formulas. Similar test curves up to 100,000 cycles were published in 1916 by A. E. Kennelly and H. A. Affel, (Reference 8).

The proximity effect resistance ratio in a return circuit of two thin straps close together was published by the writer in 1916, (Reference 9).

In 1918, (Reference 10), calculations were published by the writer for skin effect in an isolated tube, and in

*Presented at the Annual Convention of the A. I. E. E.,
Swampscott, Mass., June 25-29, 1923.*

an isolated thin strap, the latter at low frequency. (See also Reference 11 in which the exact skin effect ratio of a tube is given in terms of Bessel functions of the first and second kinds). In the 1918 paper, the "principle of similitude" was enunciated by the writer, that for a certain shape of cross section of circuit the resistance ratio is constant for a given value of f/R , thus correlating tests made at radio frequencies with those made for electric furnace work, etc. A proof of this principle was published by J. Slepian (Reference 12).

FIG. 2—TWO THIN TUBES IN RETURN CIRCUIT

The proximity effect in a return circuit of two wires was calculated for low frequencies in 1920 by H. L. Curtis (Reference 13). A complete solution was published by J. R. Carson in 1921, (Reference 14), and an alternative solution is given in this paper, (Formula VII).

The skin effect of a cable with steel armor wires and sea water return was calculated by J. R. Carson and J. J. Gilbert in 1921, (Reference 15).

The proximity effect of two thin tubes at low frequencies was given by the writer in 1922 (Reference 16). This result is checked and extended to high frequencies in this paper.

In 1922 a valuable mathematical paper on skin effect was published by Chas. Manneback (Reference 17), in which he describes a new method of attacking a skin effect problem. As with other new methods of solving skin effect problems mentioned in the above summary, this method is first used to obtain the standard formula for an isolated wire. The method is then applied to the case of the proximity effect of a finite wire and an infinitesimal wire, and an expression for the current density at any point of the section of the finite wire is obtained. No expression for the resistance ratio R'/R was obtained, and at first sight, the integration of the resistance losses over the section of the finite wire

would appear to involve very complicated integrals in Bessel functions. The method the writer has adopted to overcome this apparent limitation of Manneback's method is to make use of a device involving Poynting's Theorem, given by J. R. Carson in Reference 14, equation (18).

The writer has used the above general method to obtain new formulas for ten cases of proximity effect resistance ratio (see Part II). The formulas are good for high frequencies as well as low. Except in the case of a return circuit of two wires, and the low-frequency range of two thin tubes, the problems are new and the values of the resistance ratio were previously not obtainable. The problems are of practical value in electric furnace work, underground cable work and radio work, as indicated in the examples. See also the examples in Reference 16.

I. THIN TUBE AND INFINITESIMAL WIRE

Let $XM P$ be an extremely thin tube of radius a and thickness t , and let Y be a very small return conductor. The calculation applies to the case in which the ratio of the thickness of the tube to its diameter is very small, and so the change in current density from the inner to the outer surface is inappreciable compared with the changes in current density in different parts of the tube due to the proximity of the return conductor. The return current is assumed concentrated at the point Y .

Let the current density at M be $i_{(\theta)}$. Then the resistance drop at M is $i_{(\theta)} \sigma$ where σ is the specific resistance of the conductor, absolute units being used. Similarly, if i_0 is the current density at X , the resistance drop at X is $i_0 \sigma$.

The difference between the inductance drops at X and M due to flux caused by the current I_1 in the return conductor Y is given by the well-known inductance formula and is

$$j \omega 2 I_1 \log h \frac{D}{B} \text{ volts per cm.}$$

Let the current density at P be $i_{(\varphi)}$ and the element of area of section at P be $a t d \varphi$. The difference between the inductance drops at X and M due to flux caused by the current $i_{(\varphi)} a t d \varphi$ at P is

$$j \omega 2 \left(\log h \frac{d}{b} \right) i_{(\varphi)} a t d \varphi$$

This may be integrated around the tube and the difference between the inductance drops at X and M due to current in the tube is

$$j \omega 2 \int_{\varphi=0}^{\varphi=2\pi} \left(\log h \frac{d}{b} \right) i_{(\varphi)} a t d \varphi$$

Adding the resistance and inductance drops

$$i_{(\theta)} = i_0 + j \frac{2 \omega}{\sigma} I_1 \log h \frac{D}{B} + j \frac{2 \omega}{\sigma} \int_{\varphi=0}^{\varphi=2\pi} \left(\log h \frac{d}{b} \right) i_{(\varphi)} a t d \varphi \quad (1)$$

This is the same as Manneback's equation (5) Reference 17.

$$\text{Let } l^2 = \frac{\omega 2 \pi a t}{\sigma} \text{ as in equation (9)}$$

Reference 16.

$$\text{Then } j \frac{2 \omega}{\sigma} = j \frac{l^2}{\pi a t}$$

$$B = X Y = s - a$$

$$d^2 = M P^2 = a^2 + a^2 - 2 a^2 \cos (\theta - \varphi)$$

$$b^2 = X P^2 = a^2 + a^2 - 2 a^2 \cos \varphi$$

$$D^2 = Y M^2 = s^2 + a^2 - 2 a s \cos \theta$$

The series expansions given by H. L. Curtis, Note 1, Reference 13, where their derivation may be found, must now be used.

$$\log h d/a = - \{ \cos (\varphi - \theta) + 1/2 \cos 2 (\varphi - \theta) + \dots + 1/n \cos n (\varphi - \theta) + \dots \} \quad (2)$$

$$\log h b/a = - \{ \cos \varphi + 1/2 \cos 2 \varphi + \dots + 1/n \cos n \varphi + \dots \} \quad (3)$$

$$\log h D/s = - \left\{ a/s \cos \theta + \frac{a^2}{2 s^2} \cos 2 \theta + \dots + \frac{a^n}{n s^n} \cos n \theta + \dots \right\} \quad (4)$$

First, let the effect of the return current be neglected, and put $i_{(\varphi)} = i_0$

$$i_{(\theta)} = i_0 + \frac{j l^2}{\pi a t} \int_{\varphi=0}^{\varphi=2\pi} (\log h d/a - \log h b/a) i_0 a t d \varphi$$

Using the series expansions, all the terms of the integrals are zero, and $i_{(\theta)} = i_0$ when the effect of the return current is neglected. This result, of course, is known from the conditions of the problem.

Now, for the present, neglect the effect of i_0 and find a value of $i_{(\theta)}$ which will balance the effect of the return conductor.

$$i_{(\theta)} = \frac{j l^2}{\pi a t} I_1 \left(\log h D/s + \log h \frac{s}{s-a} \right) + \frac{j l^2}{\pi a t} \int_{\varphi=0}^{\varphi=2\pi} (\log h d/b) i_{(\varphi)} a t d \varphi$$

$$\text{The } n\text{th term of } \log h D/s \text{ is } - \frac{a^n}{n s^n} \cos n \theta$$

Find a solution $i_{n(\theta)}$ of the equation

$$i_{n(\theta)} = - \frac{j l^2}{\pi a t} I_1 / n \frac{a^n}{s^n} \cos n \theta + \frac{j l^2}{\pi a t} \int_{\varphi=0}^{\varphi=2\pi} (\log h d/b) i_{n(\varphi)} a t d \varphi \quad (5)$$

$$\text{Let } i_{n(\theta)}^{(1)} = - \frac{j l^2}{n} \frac{I_1}{\pi a t} \frac{a^n}{s^n} \cos n \theta \quad (6)$$

$$i_{n(\theta)}^{(2)} = i_{n(\theta)}^{(1)} + \frac{j l^2}{\pi a t} \int_{\varphi=0}^{\varphi=2\pi} (\log h d/a - \log h b/a) i_{n(\varphi)}^{(1)} a t d \varphi \quad (7)$$

$$i_{n(\theta)}^{(2)} = i_{n(\theta)}^{(1)} + \left(\frac{j l^2}{\pi a t} \right)^2 I_1 / n \frac{a^n}{s^n}$$

$$\int_{\varphi=0}^{\varphi=2\pi} \cos n \varphi \left[\sum_{k=1}^{\infty} \frac{\cos k(\varphi - \theta)}{k} - \sum_{k=1}^{\infty} \frac{\cos k \varphi}{k} \right] a t d \varphi$$

Now $\cos A \cos B = 1/2 \cos(A+B) + 1/2 \cos(A-B)$
The integrals of all the terms are zero except when $k = n$.

$$i_{n(\theta)}^{(2)} = i_{n(\theta)}^{(1)} + \left(\frac{j l^2}{\pi a t} \right)^2 I_1 / n \frac{a^n}{s^n}$$

$$\int_{\varphi=0}^{\varphi=2\pi} \left[\frac{\cos n \theta}{2n} - \frac{1}{2n} \right] a t d \varphi$$

$$i_{n(\theta)}^{(2)} = i_{n(\theta)}^{(1)} + \left(\frac{j l^2}{\pi a t} \right)^2 I_1 / n \frac{a^n}{s^n} \left(\frac{\pi \cos n \theta}{n} - \pi / n \right) a t$$

$$i_{n(\theta)}^{(2)} = i_{n(\theta)}^{(1)} - \frac{j l^2}{n} i_{n(\theta)}^{(1)}$$

$$- \left(\frac{j l^2}{n} \right)^2 \frac{I_1}{\pi a t} \frac{a^n}{s^n} \quad (8)$$

$$\text{Put } i_{n(\theta)}^{(3)} = i_{n(\theta)}^{(1)} + \frac{j l^2}{\pi a t} \int_{\varphi=0}^{\varphi=2\pi} (\log h d/a - \log b/a) i_{n(\varphi)}^{(2)} a t d \varphi$$

$$= i_{n(\theta)}^{(2)} - \frac{j l^2}{n} \frac{j l^2}{\pi a t} \int_{\varphi=0}^{\varphi=2\pi} (\log h d/a - \log b/a) i_{n(\varphi)}^{(1)} a t d \varphi$$

$$- \left(\frac{j l^2}{n} \right)^2 \frac{j l^2}{\pi a t} \int_{\varphi=0}^{\varphi=2\pi} (\log h d/a - \log b/a) \frac{I_1}{\pi a t} \frac{a^n}{s^n} a t d \varphi$$

from (7). The last integral is zero.

$$i_{n(\theta)}^{(3)} = i_{n(\theta)}^{(2)} + \left(\frac{j l^2}{n} \right)^2 i_{n(\theta)}^{(1)}$$

$$+ \left(\frac{j l^2}{n} \right)^3 \frac{I_1}{\pi a t} \frac{a^n}{s^n} \text{ as in} \quad (8)$$

$$= i_{n(\theta)}^{(1)} \left[1 - \frac{j l^2}{n} + \left(\frac{j l^2}{n} \right)^2 \right]$$

$$- \left(\frac{j l^2}{n} \right)^2 \frac{I_1}{\pi a t} \frac{a^n}{s^n} \left[1 - \frac{j l^2}{n} \right] \quad (9)$$

Similarly,

$$i_{n(\theta)}^{(4)} = i_{n(\theta)}^{(3)} - \left(\frac{j l^2}{n} \right)^3 i_{n(\theta)}^{(1)}$$

$$- \left(\frac{j l^2}{n} \right)^4 \frac{I_1}{\pi a t} \frac{a^n}{s^n}$$

$$= i_{n(\theta)}^{(1)} \left[1 - \frac{j l^2}{n} + \left(\frac{j l^2}{n} \right)^2 - \left(\frac{j l^2}{n} \right)^3 \right]$$

$$- \left(\frac{j l^2}{n} \right)^2 \frac{I_1}{\pi a t} \frac{a^n}{s^n} \left[1 - \frac{j l^2}{n} + \left(\frac{j l^2}{n} \right)^2 \right] \quad (10)$$

If this process is continued indefinitely, the value of $i_{n(\theta)}$ is given by convergent infinite series, provided the values of l and n are such as to make the series convergent. Since n is equal to 1 or greater, the series give the value of $i_{n(\theta)}$ for l less than 1. The sum of the infinite series is

$$\frac{1}{1 + \frac{j l^2}{n}}$$

$$\text{Thus } i_{n(\theta)} = - \frac{I_1}{\pi a t} \frac{a^n}{n s^n} \frac{j l^2}{1 + \frac{j l^2}{n}} \cos n \theta$$

$$- \frac{I_1}{\pi a t} \frac{j l^2}{n} \frac{a^n}{n s^n} \frac{j l^2}{1 + \frac{j l^2}{n}} \quad (11)$$

and the value of $i_{(\theta)}$ which will balance the effect of the return conductor is

$$i_{(\theta)} = \frac{j l^2 I_1}{\pi a t} \sum_{n=1}^{\infty} \frac{a^n}{n s^n}$$

$$- \frac{j l^2 I_1}{\pi a t} \sum_{n=1}^{\infty} \frac{a^n}{n s^n} \frac{j l^2}{(n + j l^2)}$$

$$- \frac{I_1}{\pi a t} \sum_{n=1}^{\infty} \frac{a^n}{n s^n} \frac{j l^2}{1 + \frac{j l^2}{n}} \cos n \theta$$

$$i_{(\theta)} = \frac{j l^2 I_1}{\pi a t} \sum_{n=1}^{\infty} \frac{a^n}{n s^n} \frac{1}{1 + \frac{j l^2}{n}} (1 - \cos n \theta) \quad (12)$$

To this must be added the quantity i_0 to obtain the total value of $i_{(\theta)}$

$$i_{(\theta)} = i_0 + \frac{I_1}{2 \pi a t} \sum_{n=1}^{\infty} \frac{a^n}{s^n} \frac{2 j l^2}{(n + j l^2)} (1 - \cos n \theta)$$

The total current = $I = -I_1 = \int_{\theta=0}^{\theta=2\pi} i(\theta) a t d\theta$

$$I = 2\pi a t i_0 - I \sum_{n=1}^{\infty} a^n/s^n \frac{2j l^2}{(n+j l^2)} \quad (13)$$

$$i(\theta) = \frac{I}{2\pi a t} \left[1 + \sum_{n=1}^{\infty} a^n/s^n \frac{2j l^2}{(n+j l^2)} \cos n\theta \right] \quad (14)$$

This value of $i(\theta)$ should now be checked by writing $i(\varphi)$ in accordance with it and substituting in the original equation (1).

i_0 is given by (13) and $i(\varphi)$ by (14), changing θ to φ .

$$\log h D/B = \sum_{n=1}^{\infty} \frac{a^n}{n s^n} (1 - \cos n\theta)$$

$$\log h d/b = \sum_{k=1}^{\infty} \left[\frac{\cos k\varphi}{k} - \frac{\cos k(\varphi - \theta)}{k} \right]$$

Substituting all these in (1) and carrying out the integration, we obtain equation (14).

This furnishes a check on equation (14) and further shows that it applies for all frequencies, that is, for all values of l . While the expression was derived by means of series which were convergent for l less than 1, the expression (14) itself is a convergent series for all values of l , that is, for all frequencies, so long as a/s is less than 1, and it has been shown to satisfy the fundamental equations of the problem, irrespective of the value of l .

It is now desired to find an expression for R'/R .

$$R = \frac{\sigma}{2\pi a t}$$

$$R' = 1/I^2 \int_{\theta=0}^{\theta=2\pi} i(\theta) a t d\theta \hat{i}(\theta) a t d\theta \frac{\sigma}{a t d\theta}$$

where $\hat{i}(\theta)$ is the conjugate of $i(\theta)$, that is, it is the same except that j is replaced by $-j$. The integration of the product of the two series is very similar to that used in deriving (8), all the terms being zero except when the coefficients taken from the two series are alike.

$$R'/R = \frac{2\pi a t}{I^2} \frac{I^2 a t}{(2\pi a t)^2} \left[2\pi + \sum_{n=1}^{\infty} \frac{\pi a^{2n}}{s^{2n}} \frac{2j l^2}{(n+j l^2)} \frac{(-2j l^2)}{(n-j l^2)} \right]$$

$$R'/R = 1 + \sum_{n=1}^{\infty} \frac{a^{2n}}{s^{2n}} \frac{2 l^4}{(l^4 + n^2)}$$

as in Formula I, Part II.

II. TWO THIN TUBES IN RETURN CIRCUIT

For the case of two thin tubes, equation (3') of Manneback's paper was not used. Instead, an element of current, $i(\gamma)$ at $d\gamma$ was assumed at P_1 , the current density $i(\gamma)$ being considered to be constant at first. The following expansions from H. L. Curtis' paper, Reference 13, are required:

$$\log h B/q = - \sum_{n=1}^{\infty} \frac{a^n}{n q^n} \cos n\beta \quad (15)$$

$$\log h D/q = - \sum_{n=1}^{\infty} \frac{a^n}{n q^n} \cos n(\beta - \theta) \quad (16)$$

$$\log h q/s = - \sum_{n=1}^{\infty} \frac{a^n}{n s^n} \cos n\gamma \quad (17)$$

$$\frac{\cos n\beta}{q^n} = 1/s^n \left[1 + \sum_{k=1}^{\infty} \frac{/n+k-1/}{/n-1/k/} \frac{a^k}{s^k} \cos k\gamma \right] \quad (18)$$

$$\frac{\sin n\beta}{q^n} = 1/s^n \sum_{k=1}^{\infty} \frac{/n+k-1/}{/n-1/k/} \frac{a^k}{s^k} \sin k\gamma \quad (19)$$

The same process for finding $i(\theta)$ is now gone through as for a thin tube and an infinitesimal wire, and when $i(\gamma)$ is constant the same result is obtained, namely eq. (14). This is to be expected, for a round tube or wire with uniform current density has the same external effect as if the current were concentrated at its center.

Now assume that there is the same current density in tube B as has just been calculated for tube A , and the resulting current density in tube A can be found. This again can be assumed for tube B . The process gives a symmetrical sequence of expressions, as given in Formula II, Part II. The expression for R'/R is obtained by direct integration, as previously described.

III. TWO THIN TUBES IN PARALLEL

This case is calculated in the same way as the preceding, except that I is used instead of $-I$ for the second conductor, with the result given in Formula III.

IV. INSULATED CABLE SHEATHS IN SINGLE-PHASE CIRCUIT

The assumptions for this problem are given under Formula IV, Part II. The calculation is similar to that of Formula I, the total current in the sheath being zero.

V. CABLE SHEATHS IN THREE-PHASE CIRCUIT, FLAT SPACING

The current is I in cable A ,

$$\begin{aligned} I e^{j\frac{2\pi}{3}} &= I \left(\cos \frac{2\pi}{3} + j \sin \frac{2\pi}{3} \right) \\ &= I \left(-1/2 + j \frac{\sqrt{3}}{2} \right) \text{ in cable } B, \text{ and} \\ I e^{j\frac{4\pi}{3}} &= I \left(\cos \frac{4\pi}{3} + j \sin \frac{4\pi}{3} \right) \\ &= I \left(-1/2 - j \frac{\sqrt{3}}{2} \right) \text{ in cable } C. \end{aligned}$$

VI. FINITE WIRE AND INFINITESIMAL WIRE

The formula for $i_{(r,\theta)}$ is derived in Mr. Manneback's paper, equations (14) and (19). It is

$$\begin{aligned} i_{(r,\theta)} &= \frac{I}{\pi a^2} \frac{j \alpha a}{2} \frac{J_0(j \alpha r)}{J_1(j \alpha a)} \\ &+ \frac{I_1}{\pi a^2} j \alpha a \sum_{n=1}^{\infty} \frac{a^n / s^n}{J_{n-1}(j \alpha a)} \frac{J_n(j \alpha r)}{J_n(j \alpha a)} \cos n \theta \quad (20) \end{aligned}$$

$$\text{where } \alpha^2 = \frac{j 4 \pi \omega}{\sigma} \quad (21)$$

In order to derive an expression for R'/R , the writer replaced $i_{(r,\theta)}$ by $E/\sigma - e_{(r,\theta)}/\sigma$ (see note 5 of Manneback's paper) where E is the voltage induced by flux cutting the axis of the wire.

By eq. (10) of J. R. Carson's paper, Reference 14,

$$j \mu \omega H_\theta = \frac{\partial}{\partial r} e_{(r,\theta)} \quad (22)$$

where μ is the permeability, assumed = 1 for this problem, and H_θ is the tangential component of the magnetic force.

At the surface,

$$\begin{aligned} H_{(a,\theta)} &= \alpha / \omega \frac{I \sigma}{\pi a^2} \left[-\frac{j \alpha a}{2} \frac{J_0'(j \alpha a)}{J_1(j \alpha a)} \right. \\ &+ \left. j \alpha a \sum_{n=1}^{\infty} \frac{a_n}{s_n} \frac{J_n'(j \alpha a)}{J_{n-1}(j \alpha a)} \cos n \theta \right] \quad (23) \end{aligned}$$

By eq. (18) of Carson's paper, the true energy transferred to or from one cm. of wire through its surface, according to Poynting's theory, is

$$\hat{I} I R' = \text{real part of } \frac{a}{4 \pi} \int_{\theta=0}^{\theta=2\pi} \hat{e}_{(a,\theta)} H_{(a,\theta)} d \theta \quad (24)$$

Since this involves only values at the surface of the wire, the integration is not complicated.

$$\begin{aligned} e_{(a,\theta)} &= E - \frac{I \sigma}{\pi a^2} \left[\frac{j \alpha a}{2} \frac{J_0(j \alpha a)}{J_1(j \alpha a)} \right. \\ &- \left. j \alpha a \sum_{n=1}^{\infty} \frac{a^n / s^n}{J_{n-1}(j \alpha a)} \frac{J_n(j \alpha a)}{J_n(j \alpha a)} \cos n \theta \right] \quad (25) \end{aligned}$$

The term involving E in $\hat{I} I R'$ is the real part of

$$\frac{a}{4 \pi} \int_{\theta=0}^{\theta=2\pi} \hat{E} H_{(a,\theta)} d \theta$$

By Carson's paper, (17),

$$4 \pi I = \int_{\theta=0}^{\theta=2\pi} H_{(a,\theta)} a d \theta \quad (26)$$

E is a voltage caused by flux generated in the axis by the current I in the finite wire and by the current $-I$ in the return wire. Current densities of the form $A \cos n \theta$ do not produce any voltage in the axis, nor any total current, when integrated around the circle. E is therefore in quadrature with I , and there is no real part of $\hat{E} I$, nor of

$$\int_{\theta=0}^{\theta=2\pi} \hat{E} H_{(a,\theta)} d \theta$$

We have therefore, as before, the integral from 0 to 2π of the product of two Fourier series (23) and (25). The terms will be zero except where the coefficients of θ taken from the two series are alike.

$$\text{Put } j \alpha a = b j \sqrt{j} \quad (27)$$

$$\text{where } b^2 = \frac{4 \pi a^2 \omega}{\sigma} \quad (28)$$

so that b is a real quantity. Omit the imaginary parts of the terms of the product and formula VI is obtained.

VII. TWO WIRES IN RETURN CIRCUIT

The procedure is the same as for two thin tubes in return circuit, and the same expansions are required. In the course of the calculation it is required to find the current density $i_{(r,\theta)}$ due to current density in the return wire

$$i_{(u,\gamma)} = c_k J_k(j \alpha u) \cos k \gamma$$

The result, after integrating over the surface of the return wire, that is, from $\gamma = 0$ to 2π and from $u = 0$ to a , is

$$\begin{aligned} i_{(r,\theta)} &= \sum_{n=1}^{\infty} c_k \frac{a^{n+k} / s^{n+k}}{J_{n-1}(j \alpha a)} \frac{J_n(j \alpha r)}{J_n(j \alpha a)} \cos n \theta \\ &\frac{n+k-1}{n-1/k} J_{k+1}(j \alpha a) \quad (29) \end{aligned}$$

This is only a partial expression used in the course of the calculation. The total value of $i_{(r,\theta)}$ is

$$\frac{I}{\pi a^2} \left[A_0 J_0(j \alpha r) + \sum_{n=1}^{\infty} N_n J_n(j \alpha r) \cos n \theta \right] \quad (30)$$

As previously stated, Formula VII is an alternative solution, the problem having been solved in J. R. Carson's paper, Reference 14.

VIII. TWO WIRES IN PARALLEL

Since in two wires in parallel, the current crowds to the furthestmost part of each wire, it is to be expected that their effect on each other will be less than if the current in one were concentrated at the center. So, also, in a return circuit the currents crowd toward each other and the effect is correspondingly greater. This is illustrated by the three values of R'/R given in the example. A similar result was found in connection with thin tubes, Formulas I, II and III.

IX. THREE-PHASE CIRCUIT, TRIANGULAR SPACING

In this problem, the time phase angles for three-phase currents given in connection with Formula V, cable sheath in three-phase circuit, must be used, and in addition the direction angle $\pi/6$ must be added to, or subtracted from, the angles θ , γ etc. With triangular spacing, the three wires and their currents are symmetrical, and each current can be obtained from the one preceding it in the order A , B , C , by multiplying

by $e^{j\frac{2\pi}{3}}$

X. THREE-PHASE CIRCUIT, FLAT SPACING

In this problem, as in V, the direction angle is π , used with the middle conductor.

XI. BESSEL FUNCTION REDUCTION FORMULAS

The first three or four orders of Bessel Functions of the required value of b are usually required. They can be worked out with less work than the remainder of the problem generally requires.

XII. TABLE OF BESSEL FUNCTIONS

This table gives the values of Bessel Functions of the first five orders, and their first derivatives, for argument $xj\sqrt{j}$, where x is any whole number from 1 to 10. These values are useful for drawing curves of proximity effect. Interpolated values cannot be obtained from this table, but must be separately derived by means of the reduction formulas given in XI, from the values of $\text{ber } x$ etc. given in Reference 11.

Part II

FORMULAS FOR PROXIMITY EFFECT RESISTANCE RATIO

I. ○ THIN TUBE AND INFINITESIMAL WIRE

$$l^2 = \frac{2\pi a t \omega}{\sigma}$$

a = radius of tube in cm.

t = thickness of tube in cm. (t is assumed very small compared with a).

s = axial spacing

ω = $2\pi f$

f = frequency in cycles per second

σ = specific resistivity in absolute units.

$$R'/R = 1 + \sum_{n=1}^{n=\infty} a^{2n}/s^{2n} \frac{2l^4}{(l^4 + n^2)}$$

$$\text{For infinite frequency, } R'/R = \frac{s^2 + a^2}{s^2 - a^2}$$

The above formula applies when the two conductors form a return circuit, and also when they carry equal currents in parallel, and are remote from other conductors. Example, $s/a = 4$, $l = 1$, $R'/R = 1.0641$.

II. ○ ○ TWO THIN TUBES IN RETURN CIRCUIT

$$A_n = \frac{2a^n}{s^n} \frac{(l^4 + j l^2 n)}{(l^4 + n^2)}$$

$$B_n = \frac{1}{2} A_n \sum_{k=1}^{k=\infty} \frac{a^k}{s^k} A_k \frac{/n + k - 1}{/n - 1 /k}$$

$$C_n = \frac{1}{2} A_n \sum_{k=1}^{k=\infty} \frac{a^k}{s^k} B_k \frac{/n + k - 1}{/n - 1 /k}$$

$$D_n = \frac{1}{2} A_n \sum_{k=1}^{k=\infty} \frac{a^k}{s^k} C_k \frac{/n + k - 1}{/n - 1 /k}$$

etc.

$$N_1 = A_1 + B_1 + C_1 + \dots$$

$$N_2 = A_2 + B_2 + C_2 + \dots$$

$$N_n = A_n + B_n + C_n + \dots$$

$$R'/R = 1 + 1/2 |N_1|^2 + 1/2 |N_2|^2 + \dots + 1/2 |N_n|^2 + \dots$$

$|N_n|^2$ is the square of the absolute value of N_n . $/0 = 1$.

Example, $s/a = 4$, $l = 1$, $R'/R = 1.0685$. The same value was obtained by the low frequency calculation given by the writer in Reference 16.

III. ○—○ TWO THIN TUBES IN PARALLEL

Let $A_1, B_1, \dots, A_n, B_n, C_n$ etc. have the same values as for two thin tubes in return circuit.

$$M_1 = A_1 - B_1 + C_1 - D_1 + \dots$$

$$M_2 = A_2 - B_2 + C_2 - D_2 + \dots$$

$$M_n = A_n - B_n + C_n - D_n + \dots$$

$$R'/R = 1 + 1/2 |M_1|^2 + 1/2 |M_2|^2 + \dots + 1/2 |M_n|^2 + \dots$$

$$\text{Example, } s/a = 4, l = 1, R'/R = 1.0600$$

IV. ○ . INSULATED CABLE SHEATHS IN SINGLE-PHASE CIRCUIT

Sheath replaced by a copper sheath of the same resistance, and mean radius and of thickness t , and considered as a thin tube. It is insulated from other sheaths except at one point.

Cable inside sheath replaced by a solid wire of the same resistance, and of radius a , and whose current density is considered uniform.

Return cable and its sheath represented by an infinitesimal wire.

$$l^2 = \frac{2 \pi c t \omega}{\sigma}$$

c = radius of sheath

Resis. loss in sheath

Resis. loss in cable at zero freq.

$$= \frac{a^2}{c t} \sum_{n=1}^{\infty} c^{2n}/s^{2n} \frac{l^4}{(l^4 + n^2)}$$

If the sheaths are connected at both ends, the currents and losses are approximately calculated by usual reactance formulas.

V. INSULATED CABLE SHEATHS IN THREE-PHASE CIRCUIT, FLAT SPACING

⊙ . . . OUTSIDE CONDUCTOR

Two cables and their sheaths represented by infinitesimal wires. Axial Spacing = s .

Resis. loss in sheath

Resis. loss in cable at zero freq.

$$= \frac{a^2}{c t} \sum_{n=1}^{\infty} (1 - 1/2^n + 1/2^{2n}) c^{2n}/s^{2n} \frac{l^4}{(l^4 + n^2)}$$

⊙ . . . Middle Conductor

Resis. loss in sheath

Resis. loss in cable at zero freq.

$$= \frac{a^2}{c t} \sum_{n=1}^{\infty} (2 - \cos n \pi) c^{2n}/s^{2n} \frac{l^4}{(l^4 + n^2)}$$

Example. 2,000,000 c.m. single-conductor cables, 60 cycle.

$c = 2.97$ cm., $t = 0.030$ cm., $s = 10.7$ cm.

$c/s = 0.278$ $\sigma = 2100$ at 75 deg. cent.

$l^2 = 0.1005$

Resis. loss in sheath

Resis. loss in cable at zero freq.

= 2.8 per cent for single-phase circuit.

= 2.1 per cent for three-phase circuit,

flat spacing, outside conductor

= 8.4 per cent for three-phase

circuit, flat spacing, middle conductor.

VI. FINITE WIRE AND INFINITESIMAL WIRE

All Bessel functions have argument $b j \sqrt{j}$

$$= j \sqrt{j} \sqrt{\frac{4 \pi a^2 \omega}{\sigma}}$$

$$u_0 + j v_0 = \text{ber } b + j \text{bei } b = J_0(b j \sqrt{j})$$

$$u_0' = \frac{d u_0}{d b} = \text{ber}' b$$

$$u_n + j v_n = J_n(b j \sqrt{j})$$

$$u_n' = \frac{d u_n}{d b} \text{ etc.}$$

$$R'/R_0 = 1 + \frac{2(u_0'^2 + v_0'^2)}{(u_0 v_0' - u_0' v_0)} \sum_{n=1}^{\infty} a^{2n}/s^{2n}$$

$$\frac{(u_n v_n' - u_n' v_n)}{(u_{n-1}^2 + v_{n-1}^2)}$$

The above formula applies when the two conductors form a return circuit, and also when they carry equal currents in parallel, and are remote from other conductors. R_0 = resistance of isolated conductor. As is well known,

$$R_0/R_{dc} = \frac{b}{2} \frac{(u_0 v_0' - u_0' v_0)}{(u_0'^2 + v_0'^2)}$$

This quantity is tabulated in Scientific Paper No. 169 of the Bureau of Standards, by E. B. Rosa and F. W. Grover, page 226. (Reference 18.)

VII. TWO WIRES IN RETURN CIRCUIT

All Bessel functions have argument $b j \sqrt{j}$

$$= j \sqrt{j} \sqrt{\frac{4 \pi a^2 \omega}{\sigma}}$$

$$j \sqrt{j} = \frac{-1}{\sqrt{2}} + \frac{j}{\sqrt{2}}$$

$$/0 = 1$$

$$A_0 = \frac{b j \sqrt{j}}{2 J_1}$$

$$A_1 = -a/s \frac{b j \sqrt{j}}{J_0}$$

$$A_2 = -a^2/s^2 \frac{b j \sqrt{j}}{J_1}$$

.....

$$A_n = -a^n/s^n \frac{b j \sqrt{j}}{J_{n-1}}$$

$n \neq 0$

$$B_n = \sum_{k=1}^{\infty} -A_k \frac{a^{n+k}}{s^{n+k}} \frac{/n+k-1}{/n-1/k} \frac{J_{k+1}}{J_{n-1}}$$

$$C_n = \sum_{k=1}^{\infty} -B_k \frac{a^{n+k}}{s^{n+k}} \frac{/n+k-1}{/n-1/k} \frac{J_{k+1}}{J_{n-1}}$$

$$N_1 = A_1 + B_1 + C_1 + \dots$$

$$N_n = A_n + B_n + C_n + \dots$$

etc.

$$R'/R_0 = 1 + \frac{1}{2 |A_0|^2 (u_0 v_0' - u_0' v_0)} \sum_{n=1}^{\infty} |N_n|^2 (u_n v_n' - u_n' v_n)$$

$$R_0/R_{dc} = \frac{2}{b} |A_0|^2 (u_0 v_0' - u_0' v_0)$$

These formulas apply very closely to cables as well as wires.

VIII. ●—● TWO WIRES IN PARALLEL

Let $A_0, A_1, B_1 \dots A_n, B_n, C_n$ etc. have the same values as for two wires in return circuit.

$$M_1 = A_1 - B_1 + C_1 - D_1 + \dots$$

$$M_2 = A_2 - B_2 + C_2 - D_2 + \dots$$

$$M_n = A_n - B_n + C_n - D_n + \dots$$

$$R'/R_0 = 1 + \frac{1}{2 |A_0|^2 (u_0 v_0' - u_0' v_0)} \sum_{n=1}^{\infty} |M_n|^2 (u_n v_n' - u_n' v_n)$$

Example. $s/a = 4, b = 10$

$$R'/R_0 = 1.101 \text{ for two wires in parallel.}$$

$$= 1.114 \text{ for finite wire and infinitesimal wire.}$$

$$= 1.129 \text{ for two wires in return circuit.}$$

The third value agrees with that given by J. R. Carson, Reference 14, Fig. 7.

IX ●●● THREE-PHASE CIRCUIT, TRIANGULAR SPACING

$$A_0 = \frac{b j \sqrt{j}}{2 J_1} = \frac{b}{2 J_1} \left(\frac{-1}{\sqrt{2}} + \frac{j}{\sqrt{2}} \right)$$

$$A_n = a^n/s^n \frac{b j \sqrt{j}}{J_{n-1}} \left(\cos \frac{2\pi}{3} + j \sin \frac{2\pi}{3} \right) n \neq 0$$

$$F_n = a^n/s^n \frac{b j \sqrt{j}}{J_{n-1}} \left(\cos \frac{4\pi}{3} + j \sin \frac{4\pi}{3} \right)$$

$$B_n = \sum_{k=1}^{\infty} a^{n+k}/s^{n+k} J_{k+1}/J_{n-1} \frac{/n+k-1}{/n-1/k}$$

$$\left(A_k \cos \frac{k\pi}{3} + F_k \right) \left(\cos \frac{2\pi}{3} + j \sin \frac{2\pi}{3} \right)$$

$$G_n = \sum_{k=1}^{\infty} a^{n+k}/s^{n+k} J_{k+1}/J_{n-1} \frac{/n+k-1}{/n-1/k}$$

$$\left(A_k + F_k \cos \frac{k\pi}{3} \right) \left(\cos \frac{4\pi}{3} + j \sin \frac{4\pi}{3} \right)$$

$$C_n = \sum_{k=1}^{\infty} a^{n+k}/s^{n+k} J_{k+1}/J_{n-1} \frac{/n+k-1}{/n-1/k}$$

$$\left(B_k \cos \frac{k\pi}{3} + G_k \right) \left(\cos \frac{2\pi}{3} + j \sin \frac{2\pi}{3} \right)$$

$$H_n = \sum_{k=1}^{\infty} a^{n+k}/s^{n+k} J_{k+1}/J_{n-1} \frac{/n+k-1}{/n-1/k}$$

$$\left(B_k + G_k \cos \frac{k\pi}{3} \right) \left(\cos \frac{4\pi}{3} + j \sin \frac{4\pi}{3} \right)$$

etc.

$$M_n = A_n + B_n + C_n + \dots$$

$$N_n = F_n + G_n + H_n + \dots$$

$$R'/R_0 = 1 + \frac{1}{2 \hat{A}_0 A_0 (u_0 v_0' - u_0' v_0)} \sum_{n=1}^{\infty} \left\{ \hat{M}_n M_n + \hat{N}_n N_n + (\hat{M}_n N_n + M_n \hat{N}_n) \cos \frac{n\pi}{3} \right\} (u_n v_n' - u_n' v_n)$$

$\hat{A}_0$ is the conjugate of A_0 , that is, the imaginary part of $\hat{A}_0$ is (-1) times the imaginary part of A_0 . Example. 500,000 c.m. three-conductor cable, 60 cycle, $s/a = 2.5, b = 1.4, R'/R_0 = 1.055$.

X ●●● THREE-PHASE CIRCUIT, FLAT SPACING

$$A_0 = \frac{b j \sqrt{j}}{2 J_1} = \frac{b}{2 J_1} \left(\frac{-1}{\sqrt{2}} + \frac{j}{\sqrt{2}} \right)$$

In the following, $n \neq 0$

$$A_{an} = A_{bn} \left[\cos \frac{2\pi}{3} + j \sin \frac{2\pi}{3} + 1/2^n \left(\cos \frac{4\pi}{3} + j \sin \frac{4\pi}{3} \right) \right]$$

$$A_{bn} = \frac{b j \sqrt{j}}{J_{n-1}} a^n/s^n = b/J_{n-1} a^n/s^n \left(\frac{-1}{\sqrt{2}} + \frac{j}{\sqrt{2}} \right)$$

$$A_{cn} = A_{bn} \left(\cos \frac{4\pi}{3} + j \sin \frac{4\pi}{3} \right)$$

$$A_{dn} = A_{bn} \left(1/2^n + \cos \frac{2\pi}{3} + j \sin \frac{2\pi}{3} \right)$$

$$B_{an} = \sum_{k=1}^{\infty} J_{k+1}/J_{n-1} \frac{/n+k-1}{/n-1/k} \left[(A_{bk} + A_{ck} \cos k\pi) a^{n+k}/s^{n+k} + A_{dk} \frac{a^{n+k}}{(2s)^{n+k}} \right]$$

$$B_{bn} = \sum_{k=1}^{\infty} J_{k+1}/J_{n-1} \frac{/n+k-1}{/n-1/k} A_{ak} a^{n+k}/s^{n+k}$$

$$B_{cn} = \sum_{k=1}^{\infty} J_{k+1}/J_{n-1} \frac{/n+k-1}{/n-1/k} A_{dk} a^{n+k}/s^{n+k}$$

$$B_{dn} = \sum_{k=1}^{\infty} J_{k+1}/J_{n-1} \frac{/n+k-1}{/n-1/k} \left[A_{ak} \frac{a^{n+k}}{(2s)^{n+k}} + (A_{bk} \cos k\pi + A_{ck}) a^{n+k}/s^{n+k} \right]$$

C_{an} , C_{bn} etc. are obtained from the same formulas as B_{an} , B_{bn} , etc., respectively, except that A is changed to B , and similarly for D_{an} , D_{bn} , etc., change B to C . This process can be continued indefinitely.

Outside Conductors.

Let $L_n = A_{an} + B_{an} + C_{an} + \dots$

R'/R_0 of outside wires = 1

$$+ \frac{1}{2|A_0|^2 (u_0 v_0' - u_0' v_0)} \sum_{n=1}^{n=\infty} |L_n|^2 (u_n v_n' - u_n' v_n)$$

Middle Conductor.

$M_n = A_{bn} + B_{bn} + C_{bn} + \dots$

$N_n = A_{cn} + B_{cn} + C_{cn} + \dots$

R'/R_0 of middle conductor

$$= 1 + \frac{1}{2|A_0|^2 (u_0 v_0' - u_0' v_0)} \sum_{n=1}^{n=\infty} \left\{ \hat{M}_n M_n \right.$$

$$\left. + \hat{N}_n N_n + (\hat{M}_n N_n + M_n \hat{N}_n) \cos n\pi \right\} (u_n v_n' - u_n' v_n)$$

Putting the B 's and C 's = 0 is equivalent to assuming two of the conductors to be infinitesimal. Formulas VIII, IX and X apply very closely to cables as well as wires. Example: 2,000,000-c.m. single-conductor cables, flat spacing 60 cycle. Neglect the lead sheaths. $s/a = 5$, $b = 2.7$ for 75 deg. cent., $R'/R_0 = 1.03$ for each outside cable, and 1.13 for the middle cable. Each of these figures is multiplied by 1.22 = R_0/R_{dc} in order to obtain R'/R_{dc} .

XI. BESSEL FUNCTION REDUCTION FORMULAS

Special

$$u_0 = \text{ber } x$$

$$v_0 = \text{bei } x$$

$$u_1 = + \frac{1}{\sqrt{2}} (u_0' - v_0')$$

$$v_1 = + \frac{1}{\sqrt{2}} (u_0' + v_0')$$

$$u_2 = - \frac{\sqrt{2}}{x} (u_1 - v_1) - u_0 = \frac{2 v_0'}{x} - u_0$$

$$v_2 = - \frac{\sqrt{2}}{x} (u_1 + v_1) - v_0 = - \frac{2 u_0'}{x} - v_0$$

$$u_2' = - \frac{1}{\sqrt{2}} (u_1 + v_1) - \frac{2 u_2}{x} = - u_0' - \frac{2 u_2}{x}$$

$$v_2' = + \frac{1}{\sqrt{2}} (u_1 - v_1) - \frac{2 v_2}{x} = - v_0' - \frac{2 v_2}{x}$$

General

$$u_{n+1} = - \frac{n \sqrt{2}}{x} (u_n - v_n) - u_{n-1} \quad n \neq 0$$

$$v_{n+1} = - \frac{n \sqrt{2}}{x} (u_n + v_n) - v_{n-1} \quad n \neq 0$$

$$u_n' = - \frac{1}{\sqrt{2}} (u_{n-1} + v_{n-1}) - \frac{n u_n}{x} \quad n \neq 0$$

$$v_n' = + \frac{1}{\sqrt{2}} (u_{n-1} - v_{n-1}) - \frac{n v_n}{x} \quad n \neq 0$$

Use these formulas with the table of $u_0 = \text{ber } x$, $u_0' = \text{ber}' x$ etc. in Reference 11.

These formulas are also suitable for Bessel functions of the second kind by changing u to l and v to m . Thus $\text{ker } x = l_0$ and $\text{kei } x = m_0$, etc.

TABLE I

BESSEL FUNCTIONS, $u_n + j v_n = J_n(x j \sqrt{j})$, $u_n' = \frac{d}{dx} u_n$

Floating Neutral n-Phase Systems

BY LEONARD A. DOGETT

Member, A. I. E. E.

Prof. of Engineering, U. S. Naval Academy, Annapolis, Md.

Review of the Subject.—Although this paper treats of the general case of floating neutral polyphase systems, one of its prime objects is to find the very simplest method of solving three-phase unbalanced star circuits. The method presented below is considered much simpler than the one in which the star circuit is replaced by an equivalent delta circuit; also simpler than the method of replacing one unbalanced circuit by two balanced circuits, one being subjected to direct phase rotation and the other to opposite phase rotation. Although these methods are fairly useful for the three-phase case, they become very unwieldy for a number of phases greater than three. Not only is this method more simple than any so far proposed, but it is a direct method, based on a straight forward application of Kirchhoff's Laws. A final and very important advantage of the method is that all the results are perfectly general, applying

equally as well to a single-phase system as to any polyphase star system.

INTRODUCTION

WHEN an a-c. receiving circuit is operated without grounding the neutral, the potential of the neutral in respect to the supply lines may take on a very wide range of values depending on the constants of the various branches or phases and on which way the source alternator may be rotating. Some use of this last fact has been made in determining what is called Direction of Phase Rotation.¹

It is proposed in this paper to investigate such floating neutral systems, under the following sub-headings:

- I. Description of Types of Circuits.
- II. Notation.
- III. General Expression for Current in any branch of an n -phase system.
- IV. Voltage to neutral for any branch.
- V. Voltage between geometrical and true neutral.
- VI. Discussion of Effect of Phase Rotation and Tabulation of operators to assist in calculations. Sample Calculation.
- VII. Discussion of Resonance. Some Test Results.
- VIII. Bibliography.

FIG. 1

I. Description of Types of Circuits. Referring to

1. W. V. Lyon, Determining Phase Rotation, See Bibliography No. 9.

T. W. Varley, Determining Phase Rotation, See Bibliography No. 8.

Presented at the Annual Convention of the A. I. E. E., Swampscott, Mass., June 25-29, 1923.

Fig. 1, ϕ stands for the number of branches or phases between lines and neutral, 0.

For example, for $\phi = 3$, there are three branches to neutral. Between 0 and 1 is located one branch which may contain resistance, inductance and capacity in any desired combination. Similarly the branches 02 and 03 may include any desired constants. In the general case there are ϕ branches all tied together at 0.

Fig. 2 shows the alternating-current sources corresponding to Fig. 1. In both Fig. 1 and Fig. 2 the

FIG. 2

branches are numbered in clockwise sequence around the circle.

II. Notation. The voltage from M to 1 will in all cases be taken as standard phase.

As the large majority of voltages, currents, impedances and admittances in this paper are complex numbers, ordinary type will be used for them. Script letters will be used for ordinary numbers.

Let $\alpha = \cos \frac{2\pi}{\phi} + j \sin \frac{2\pi}{\phi}$ for counter clockwise rotation.³

2. Defined in Part (V).

3. This definition takes the point of view of the vector diagram of the voltages. If the sequence in which 01, 02, 03, etc. receive the impulse of voltage is considered, then the terms counter clockwise and clockwise must be interchanged. It is worth noting that the A. I. E. E. has no standard definition for Phase Rotation.

$$\alpha = \cos \frac{2\pi}{\phi} - j \sin \frac{2\pi}{\phi} \text{ for clockwise rotation}^3$$

where ϕ = number of phases or branches.

$$E_1 = E \alpha^0 = \text{Voltage between } M \text{ and } 1.$$

$$E_2 = E \alpha^1 = \text{ " " } M \text{ and } 2.$$

$$E_3 = E \alpha^2 = \text{ " " } M \text{ and } 3.$$

$$E_n = E \alpha^{n-1} = \text{ " " } M \text{ and } n.$$

where E = numerical value of impressed voltage to geometrical neutral.²

$$Z_1 = \text{Impedance between } 0 \text{ and } 1.$$

$$Z_2 = \text{ " " } 0 \text{ and } 2.$$

$$Z_n = \text{ " " } 0 \text{ and } n.$$

$$Y_1 = \text{Admittance between } 0 \text{ and } 1.$$

$$Y_2 = \text{ " " } 0 \text{ and } 2.$$

$$Y_n = \text{ " " } 0 \text{ and } n.$$

$$I_1 = \text{Complex quantity expression for current in } \overline{01}.$$

$$I_2 = \text{ " " " " " " } \overline{02}.$$

$$I_n = \text{ " " " " " " } \overline{0n}.$$

$$E_{on} = \text{ " " " " voltage between true and geometrical neutral.}$$

III. General Expression for Current in any Branch.

Fig. 3 represents three receiver branches and three corresponding source branches of the general case

FIG. 3

where it is assumed that there are any number of branches up to n in number.

Applying Kirchhoff's Laws to this general case.

$$I_1 + I_2 + I_3 + \dots + I_n = 0$$

$$-I_1 Z_1 + E_1 - E_1 \alpha + I_2 Z_2 = 0$$

$$-I_1 Z_1 + E_1 - E_1 \alpha^2 + I_3 Z_3 = 0$$

etc.

$$-I_1 Z_1 + E_1 - E_1 \alpha^{n-1} + I_n Z_n = 0$$

Solving the above equations,

$$I_1 (1 + Z_1/Z_2 + Z_1/Z_3 + \dots + Z_1/Z_n)$$

$$= E_1 \left(\frac{1 - \alpha}{Z_2} + \frac{1 - \alpha^2}{Z_3} + \dots + \frac{1 - \alpha^{n-1}}{Z_n} \right)$$

$$I_1 =$$

$$\frac{E \alpha^0 \left(\frac{1 - \alpha}{Z_2} + \frac{1 - \alpha^2}{Z_3} + \dots + \frac{1 - \alpha^{n-1}}{Z_n} \right)}{Z_1 (1/Z_1 + 1/Z_2 + 1/Z_3 + \dots + 1/Z_n)}$$

In general then, for the p th current

$$I_p =$$

$$E/Z_p \left[\alpha^{p-1} - \frac{\alpha^0/Z_1 + \alpha^1/Z_2 + \dots + \alpha^{n-1}/Z_n}{1/Z_1 + 1/Z_2 + \dots + 1/Z_n} \right] \quad (1)$$

$$I_p = E Y_p \left[\alpha^{p-1} - \frac{Y_1 \alpha^0 + Y_2 \alpha^1 + \dots + Y_n \alpha^{n-1}}{Y_1 + Y_2 + \dots + Y_n} \right] \quad (2)$$

The use of this formula is illustrated by the problem of Part VI.

IV. General Expression for Voltage to Neutral for any Branch. Equations (1) and (2) give this quantity at once as

$$I_p Z_p =$$

$$E \left[\alpha^{p-1} - \frac{\alpha^0/Z_1 + \alpha^1/Z_2 + \dots + \alpha^{n-1}/Z_n}{1/Z_1 + 1/Z_2 + \dots + 1/Z_n} \right] \quad (3)$$

$$I_p Z_p = E \left[\alpha^{p-1} - \frac{Y_1 \alpha^0 + Y_2 \alpha^1 + \dots + Y_n \alpha^{n-1}}{Y_1 + Y_2 + \dots + Y_n} \right] \quad (4)$$

V. General Expression for Voltage between Geometrical Neutral and True Neutral. The geometrical neutral is defined as the center of the circle located by the potentials of the various lines. Thus in Fig. 1, if point 1 is taken as zero potential and if points 2, 3, 4, etc. are located on a circle a properly graduated scale will read the potential difference between any two lines.

The true neutral is fixed by the intersection of the various $I_1 Z_1, I_2 Z_2, I_3 Z_3$, etc. vectors and coincides with the geometrical neutral only in the case of a balanced load.

Since $I_p Z_p$ is the voltage between the p th line and the true neutral and since $E \alpha^{p-1}$ is the voltage between the p th line and the geometrical neutral, their difference is the voltage between the true and geometrical neutral. Hence from (4),

$$E_{on} = E \alpha^{n-1}$$

$$- E \left[\alpha^{n-1} - \frac{Y_1 \alpha^0 + Y_2 \alpha^1 + \dots + Y_n \alpha^{n-1}}{Y_1 + Y_2 + \dots + Y_n} \right]$$

$$E_{on} = E \frac{Y_1 \alpha^0 + Y_2 \alpha^1 + \dots + Y_n \alpha^{n-1}}{Y_1 + Y_2 + \dots + Y_n}$$

$$= E \frac{\sum_{n=1}^n Y_n \alpha^{n-1}}{\sum_{n=1}^n Y_n} \quad (5)$$

VI. Discussion of Effect of Phase Rotation and Tabulation of α -Operators to Assist in Calculations. Sample Calculations. With the purpose of giving some physical interpretation to the results above obtained, it is desirable to follow the wanderings of the true neutral in these floating neutral polyphase systems. The travels of this neutral are almost unlimited. It can take up any position from infinite distance from the geometrical neutral at resonance down to zero distance

from geometrical neutral for a balanced load. If the alternator supplying the system is stopped and brought up to speed in the opposite direction, then this E_{on} vector might in some particular case move from a 10:30 o'clock vector to a 6:30 o'clock vector of less than half its original magnitude. The locus of this true neutral when constant voltage but varying frequency is maintained on a given circuit will in some cases be a circle, in others a cusp, in others an ellipse. It has been only in recent years that attention has been called to the fact that phase rotation has such a pronounced effect on this E_{on} vector.⁴

To illustrate and to aid in the use of the formulas, the following example is solved:

Find the voltage between the true neutral and the geometrical neutral for a system where the line voltages

$$I_1 = 57.7 \times 1.0 \left[1 \right.$$

$$\left. \begin{aligned} & \frac{1.0 + (1.0 - j1.0)(-0.5 - j0.866)}{1.0 + (1.0 - j1.0) + (0.5 + j1.0)} \\ & + \frac{(0.5 + j1.0)(-0.5 + j0.866)}{1.0 + (1.0 - j1.0) + (0.5 + j1.0)} \end{aligned} \right]$$

$$= 57.7 (1 + 0.5928 + j0.1732)$$

$$= 92.1 + j10.0 = 92.6 \text{ amperes}$$

$$I_2 = 57.7 \times (1.0 - j1.0) [(-0.5 - j0.866) + 0.5928 + j0.1732] = -34.65 - j45.3$$

$$= 57.2 \text{ amperes}$$

$$I_3 = 57.7 \times (0.5 + j1.0) [(-0.5 + j0.866) + 0.5928 + j0.1732] = -57.35 + j35.3$$

$$= 67.6 \text{ amperes}$$

TABLE I.
CLOCKWISE OPERATORS

ϕ	α^{-5}	α^{-4}	α^{-3}	α^{-2}	α^{-1}	α^0	α^1	α^2	α^3	α^4	α^5
2					$-1 + j0$	1	$-1 + j0$				
3				$-0.5 - j.866$	$-0.5 + j.866$	1	$-0.5 - j.866$	$-0.5 + j.866$			
4			$0 - j1.0$	$-1.0 + j0$	$0 + j1.0$	1	$1.0 + j0$	$-1.0 + j0$	$0 + j1.0$		
5		$.309 - j.9511$	$-.809 - j.5878$	$.809 + j.5878$	$.309 + j.9511$	1	$.309 - j.9511$	$-.809 - j.5878$	$-.809 + j.5878$	$.309 + j.9511$	
6	$+0.5 - j.866$	$-0.5 - j.866$	$-1 + j0$	$-0.5 + j.866$	$0.5 + j.866$	1	$0.5 - j.866$	$-0.5 - j.866$	$-1 + j0$	$-0.5 + j.866$	$+0.5 + j.866$

COUNTER CLOCKWISE OPERATORS

ϕ	α^{-5}	α^{-4}	α^{-3}	α^{-2}	α^{-1}	α^0	α^1	α^2	α^3	α^4	α^5
2					$-1 + j0$	1	$-1 + j0$				
3				$-0.5 + j.866$	$-0.5 - j.866$	1	$-0.5 + j.866$	$-0.5 - j.866$			
4			$0 + j1.0$	$-1 + j0$	$0 - j1.0$	1	$0 + j1.0$	$-1.0 + j0$	$0 - j1.0$		
5		$.309 + j.9511$	$-.809 + j.5878$	$-.809 - j.5878$	$.309 - j.9511$	1	$.309 + j.9511$	$-.809 + j.5878$	$-.809 - j.5878$	$.309 - j.9511$	
6	$+0.5 + j.866$	$-0.5 + j.866$	$-1 + j0$	$-0.5 - j.866$	$+0.5 - j.866$	1	$0.5 + j.866$	$-0.5 + j.866$	$-1 + j0$	$-0.5 - j.866$	$+0.5 - j.866$

are 100 and where the constants of the three branches are, $Y_1 = 1.0$; $Y_2 = 1.0 - j1.0$; $Y_3 = 1/2 + j1.0$; (a) when phase rotation is clockwise and (b) when phase rotation is counter clockwise.⁵

Using equation (5) and Table I:

(cw) $E_{on} =$

$$57.7 \frac{1.0 + (1.0 - j1.0)(-0.5 - j0.866) + (0.5 + j1.0)(-0.5 + j0.866)}{1.0 + (1.0 - j1.0) + (0.5 + j1.0)}$$

(ccw) $E_{on} =$

$$57.7 \frac{1.0 + (1.0 - j1.0)(-0.5 + j0.866) + (0.5 + j1.0)(-0.5 - j0.866)}{1.0 + (1.0 - j1.0) + (0.5 + j1.0)}$$

$$E_{on} = -34.25 - j10 \text{ cw.}^6$$

$$E_{on} = 45.8 - j10 \text{ ccw.}^7$$

To further illustrate the use of the method of this paper, the currents are calculated.

The clockwise currents are, using equation (2).

The counter clockwise currents are, using equation (2),

$$I_1 = 57.7 \times 1.0 \left[1 \right.$$

$$\left. \begin{aligned} & \frac{1.0 + (1.0 - j1.0)(-0.5 + j0.866)}{1.0 + (1.0 - j1.0) + (0.5 + j1.0)} \\ & + \frac{(0.5 + j1.0)(-0.5 - j0.866)}{1.0 + (1.0 - j1.0) + (0.5 + j1.0)} \end{aligned} \right]$$

$$= 57.7 (1 - 0.7928 - j0.1732) = 11.93 - j10.0$$

$$= 15.6 \text{ amperes}$$

$$I_2 = 57.7 \times (1.0 - j1.0) [(-0.5 + j0.866) - .7928 - j0.1732] = -34.65 + j114.6$$

$$= 118.5 \text{ amperes}$$

$$I_3 = 57.7 \times (0.5 + j1.0) [(-0.5 - j0.866) - 0.7928 - j0.1732] = 22.7 - j104.8$$

$$= 107 \text{ amperes.}$$

A quicker way to solve problems of this type is to lay off to scale a triangle of the three line voltages and on this graph locate the true neutral from the calculated value of E_{on} . All phase voltages may then be scaled off as the distance from the true neutral to the corners of the triangle. A phase voltage times the phase admittance equals phase current.

VII. Resonance. Resonance in an n -phase circuit may be defined as the condition under which

$$Y_1 + Y_2 + Y_3 + \dots + Y_n = 0 \quad (6)$$

4. See Numbers 8, 9, 14 of Bibliography.

5. This problem is taken from page 377 of the 1917 Edition of Alternating Currents and Alternating-Current Machinery, by D. C. & J. P. Jackson.

6. The solution given in D. C. & J. P. Jackson's Textbook.

7. This solution is not mentioned in the above textbook.

With conditions approaching this, large currents will flow.

For the single-phase case, $\phi = 2$, resonance occurs when $Z_1 = -Z_2$. For the three-phase case, $\phi = 3$,

it occurs when $Z_1 = -\frac{Z_2 Z_3}{Z_2 + Z_3}$. For $\phi = 4$, it occurs when

$$Z_1 = -\frac{Z_2 Z_3 Z_4}{Z_3 Z_4 + Z_4 Z_2 + Z_2 Z_3}$$

As a resonant circuit will best illustrate the possibilities of a floating neutral system, the following test was carried out. A three-phase, star-connected circuit was prepared with the following constants: Number one branch an air-cored inductance of 0.1745 henry and 4.6 ohms d-c. resistance, number two branch a capacity of 106.2 microfarads, and number three branch a capacity of 105.6 microfarads. In each branch an ammeter was placed. A voltmeter was arranged to

FIG. 4

read the three-line voltages and the three-phase voltages. Line voltages were maintained equal by adjusting the currents taken by an auxiliary three-phase load from the same alternator.

Speeds were varied from 300 to 1400 rev. per min. and readings of currents and voltages were taken for each speed. The results were then reduced to a standard line voltage of fifty, as represented by the triangle of Fig. 4. On Fig. 4 is plotted the true neutral as found by swinging from the appropriate corners arcs equal to the phase voltages. The neutrals so found are shown by crosses with the corresponding alternator speeds close by. By using formula (5) and the constants above the locus of the true neutral was found to be two circles somewhat larger than the two circles indicated by the test data. The explanation of this is that the resistance during the tests, *i. e.*, with alternating current, was slightly greater than that given by a d-c. measurement. It is interesting to note that if the resistance could be reduced to zero the locus for both directions of alternator rotation would be a straight line upward from the top vertex of the triangle and downward from the center of the base of the triangle.

Discussion

C. W. Bates: At the bottom of page 1031, Prof. Doggett states:

"Resonance in an n -phase circuit may be defined as the condition under which the total admittance is equal to zero." I think that is subject to correction, the correct statement being "Resonance in an n -phase circuit may be defined as the condition under which the reactive component of the total admittance (or the total susceptance) is equal to zero." It is rather out of the question to eliminate the power component and, besides, that does not affect the question of resonance.

Just before that Prof. Doggett says: "A quicker way to solve problems of this type is to lay off to scale a triangle of the three line voltages," etc. The vector diagram should not be used for direct calculation except in very special cases but it should be used to interpret the complex quantities as they are determined. Having calculated the complex expression for the distance between the true neutral and the geometric neutral and consequently having located the true neutral on the vector diagram, it is a simple problem to determine the various voltages from the true neutral to the various phase terminals, by using the vector diagram as a visual aid to the expression of the proper terms whose algebraic sum will give the voltage desired. For this purpose the diagram does not need to be drawn with particular accuracy and the final results are obtained with no loss of accuracy whatever.

The graphical picture is a splendid thing and I think that this paper would be improved if the illustrative problem, which Prof. Doggett has on page 1031, were drawn out graphically, both to show to the man who is not familiar with all of the details what is going on and to serve as an aid to calculation. I think that Prof. Doggett is to be congratulated on having called attention to this method of locating the floating neutral. This problem is

one which occurs very often and there are very few men outside of the teaching staffs of the colleges and a very few recent graduates who can solve this problem (as well as some similar ones) without a great deal of trouble.

V. Karapetoff: Formulas equivalent to Prof. Doggett's final result (5) were deduced and published by me in 1900 in a little book entitled "Ueber Mehrphasige Stromsysteme bei Ungleichmaessiger Belastung" (Enke, Stuttgart), and I have given them to my students every year at Cornell. I am not raising any question of priority, but wish to indicate that a much more general result can be arrived at in a simpler manner than Prof. Doggett's, and that his eq. (5) follows directly from the more general formula.

Let a be the vector of the voltage between the two neutral points. Then the *net* voltage acting upon the load in phase 1 is $E_1 - a$, and the current in phase 1 is equal to $Y_1 (E_1 - a)$. Thus we have

$$\left. \begin{aligned} I_1 &= Y_1 (E_1 - a) \\ I_2 &= Y_2 (E_2 - a) \\ \dots\dots\dots \\ I_n &= Y_n (E_n - a) \end{aligned} \right\} \quad \text{(I)}$$

Adding these equations together and remembering that $\sum I = 0$, we find

$$\sum Y E = a \sum Y \dots\dots\dots \text{(II)}$$

from which

$$a = (\sum Y E) / \sum Y \dots\dots\dots \text{(III)}$$

Eq. (III) is the fundamental equation for any n -phase star-connected polyphase system, with unsymmetrical voltages and with an unbalanced load. Knowing a , the currents are found from eqs. (I). Doggett's eq. (5) is a special case of expression for a when the generator voltages are symmetrical.

Eqs. (I) and (III) have been found of inestimable value in many problems, especially in the study of V and T connections, because these connections may be considered as special cases of star-connected windings with unsymmetrical voltages.

L. A. Doggett: I quite agree with Mr. Bates' correction. Professor Karapetoff has in a few brief steps arrived at a very comprehensive expression for the vector voltage between the two neutrals. Its very generality, however, conceals many rather remarkable particular deductions. The particular aspect which is stressed in my paper is that of the effect of phase rotation on the location of the neutral. In reading Professor Karapetoff's 1900 monograph some seven years ago I failed to get any help on this question of phase rotation. It is easy to see that, given this general expression (III above) and Professor Karapetoff on hand to amplify and explain, many practical deductions would follow. He has given us one such in the last paragraph of his discussion.

In closing it appears to me that an old problem which has never satisfactorily been solved in the literature ordinarily available to the electrical engineer, has been resurrected. It is hoped that this paper and the accompanying discussion will make this problem of polyphase unbalanced circuits moderately easy of solution.

The Quality of Incandescent Lamps

BY JOHN W. HOWELL and HENRY SCHROEDER

Fellow, A. I. E. E.

Both of The Edison Lamp Works of the General Electric Company, Harrison, N. J.

Review of the Subject.—The new specifications for incandescent lamps determine their quality in terms of life to burnout at a specified mean efficiency. Formerly it was measured by the life to 80 per cent. of initial value. The new tests, therefore, conform more nearly to the actual practise in the use of tungsten filament lamps, as many of these lamps are above 80 per cent at time of burnout.

The data on carbon lamps in the paper are based on a life exponent originally determined by Mr. Howell, one of the authors of this paper. Curves showing the relation between life, efficiency and candle power was given by him in a paper presented before the Institute on April 10, 1888. Practically the same life-candle power relation has been found to apply to the GEM, tantalum and tungsten filament lamps. Nowadays the exponent used is that applying to the life-efficiency relation and is different for each kind of filament as they have different candle power-efficiency relations. All data are based on commercial ratings and guarantees.

The quality of tungsten filament lamps has greatly improved since their commercial introduction in 1907 as is shown by the fact that the 40-watt vacuum lamp is now over eight times as good as then.

There is a difference in the present relative quality of the various sizes of tungsten filament lamps. The 10-watt vacuum lamp, if operated at 10 mean lumens per watt, would live 190 hours and the 1000 watt gas-filled lamp 35,000 hours. The lives of other sizes of lamps at this efficiency is between these two extremes.

There has been an enormous improvement since Edison's first commercial carbon lamp of 1880. It is estimated that if the present 40-watt tungsten filament lamp were made for the same mean efficiency as the 1880 lamp, the tungsten filament lamp should have

a life of over a hundred and fifty thousand years. And this does not include the enormous improvement in the larger sizes of lamps due to Dr. Langmuir's invention of the gas-filled lamp. Owing to these enormous differences, the other term of quality measurement, indicating the mean efficiency for a given life, is therefore used to show the improvements since 1880. A table gives these data in chronological order.

It is estimated that in 1880 about 50 lumen-hours of light were obtained for one cent, covering the cost of current and lamp renewals. The amount now obtainable is very much greater, due to lamp improvements, reduction in their prices and reduction in rates for current. The public has utilized these by using more light. With the present 40-watt tungsten filament lamps and with current at the present approximate general average rate of $4\frac{1}{2}$ cents kw-hr., 1700 lumen-hours can be had for one cent. It is impossible to show what part of this actual increase is due to lamp improvements except to indicate what would have been obtainable with one factor without the other. Thus had there been no rate reduction, 432 lumen-hours would now be had due to actual lamp improvements. Without the lamp improvements 190 lumen-hours would now be had due to the reduction in the general average rate. To indicate the gain due to Dr. Langmuir's invention of the gas-filled lamp, in which the high wattage sizes are the most efficient, 3820 lumen-hours can be had with the 1000 watt lamp at $4\frac{1}{2}$ cents per kw-hr.

About half a billion dollars were spent in the United States in 1922 for current used for lighting. If the same amount of light were produced by the original 1880 bamboo carbon lamp, the cost would have been increased $3\frac{1}{2}$ billion dollars requiring about fifty billion extra tons of coal, equal to about ten per cent of the total coal production in the United States.

THE purpose of this paper is to show the improvements have been made in incandescent electric lamps since they first became commercially available.

Quality is the term used by incandescent lamp engineers in connection with the relative excellence of lamps. The two main factors which determine quality are efficiency and life. With a given quality these two factors bear a reciprocal relation to each other, that is, the life of a lamp can be increased but at a sacrifice of efficiency, and vice versa.

Attention is called to the fact that Mr. Howell, one of the authors of this paper, presented before the Institute on April 10, 1888, a paper entitled "The Maximum Efficiency of Incandescent Lamps". This paper gave, for the first time, data on the relation between the life and efficiency of incandescent lamps. Occasional reference to this paper will be made.

An improvement in quality might be reflected as an increase in efficiency or in life, without a reduction of the other factor. Quality, therefore, may be measured either in terms of efficiency for a given life, or in terms of hours life for a given efficiency. In the 1888 paper the latter term was used, the quality of lamps being

stated as "The life they will give when burned at a given efficiency."

The quality measure is useful to lamp engineers in determining the usefulness of suggested improvements in lamps, in comparing the performance of different types of lamps and in maintaining the product up to the highest possible standard.

STANDARD SPECIFICATIONS FOR DETERMINING LAMP QUALITY

The Bureau of Standards at Washington, D. C., have for some time established specifications on lamps for use by the various departments of the United States Government. These specifications were established by them after conference with manufacturers and engineers. The present specifications are different from those in use up to about two years ago.

The difference between the present and previous specifications can perhaps best be explained by quoting the introductory statement of Circular 13 of the Bureau of Standards:

"The most notable of these changes is the abandonment of the long-established provision that the life of test lamps shall be considered as ended when the candle power has fallen to 80 per cent of the initial value. The specification of such an end point is convenient and

Presented at the Annual Convention of the A. I. E. E., Swampscott, Mass., June 26-29, 1923.

reasonable in the testing of carbon lamps, because those lamps will often burn for a long period after they have become so blackened that they should not be continued in use. In tungsten lamps, however, means have been found to prevent excessive blackening of the bulbs, so that the lamps normally burn out before their efficiency has fallen enough to justify replacing them. The new tests will, therefore, be based on the total life to the time of burnout, thus conforming more nearly to actual practise in the use of lamps."

"The performance of the lamp throughout its life will also be taken into account through — the evaluation of life-test results on the basis of average efficiency throughout life, instead of the initial efficiency."

It will be noted that the inherent quality of lamps is now measured by the number of hours life to burnout at a given average efficiency throughout life. Lamps may be operated on test at an efficiency that will make the duration of the test about 500 hours. For purposes of comparison of different lots of each size of lamp and for a permanent historical basis of record, mean efficiencies are given in the specifications for each lamp, which efficiencies were originally based on an average life of 500 hours.

BASIS OF DATA

In Mr. Howell's 1888 paper, a curve was shown indicating the relation between the life and efficiency of carbon lamps, which at that time had untreated filaments. This curve was based on the author's calculations, obtained from the tests of many lamps during a period of over five years, that the life of lamps varied inversely as the 3.65 power of the candle power. This life-candle power exponent however was not given in the paper. In the intervening years, even with the tests of many more lamps, this exponent has remained unchanged. It has even been found that the same life-candle power exponent applies to the treated carbon, the Gem (metallized carbon) and practically to the tantalum and tungsten filament lamps.

Nowadays it is customary to make calculations on the basis of the life efficiency exponent. This exponent varies with the different lamps as the candle power-efficiency curve is different for each kind of filament. The life-efficiency exponents used in the calculations of the data given herein are as follows:

- 5.5 for the untreated carbon filament lamp
- 5.8 for the treated carbon filament lamp
- 5.8 for the Gem (metallized carbon) lamp
- 6.2 for the tantalum lamp
- 6.7 for the tungsten filament lamp

The exponent for tungsten filament lamps has been considered to be different for the different sizes of lamps, but it is now believed by many that the figure 6.7 applies to all sizes, so this figure is used herein.

IMPROVEMENT IN QUALITY OF TUNGSTEN FILAMENT LAMPS

Limitation of space prevents giving data showing the improvement in all the different sizes of tungsten filament lamps from their commercial introduction to date. The most important of the vacuum lamps is the 40-watt, 115-volt size. The suggested standard comparison efficiency given in the specifications for this lamp is 9.9 mean lumens per watt. The actual life obtained at this mean efficiency, based on the commercial ratings in effect at various times from the introduction of this size of lamp in 1907 to date, is as follows:

TABLE I.
QUALITY OF 40-WATT 115-VOLT VACUUM TUNGSTEN FILAMENT LAMP, 1907-1923

Date	Initial efficiency	Hours life to burnout	Spherical reduction factor	Mean Efficiency in percent of Initial	Inherent Quality
					Hours life to burnout at 9.9 mean L-P-W
Nov. 1907	1.25 w-p-h-c-p	800	78 %	85 %	63
Apr. 1910	*1.23 do	1000	78 %	85 %	78
Oct. 1912	1.17 do	1000	78 %	86 %	120
Jan. 1914	1.10 do	1000	78 %	87 %	196
Oct. 1914	1.03 do	1000	78 %	88 %	327
May 1917	1.35 w-p-s-c-p	1000	—	87 %	261
July 1917	1.33 do	1000	—	88 %	312
Aug. 1918	1.36 do	1000	—	87 %	250
Apr. 1920	1.35 do	1000	—	87 %	261
May 1921	9.9 l-p-w	1000	—	89 %	458
Oct. 1921	10.1 do	1000	—	90 %	564
May 1922	10.1 do	1000	—	89 %	524
May 1923	10.1 do	1000	—	89 %	524

*The International candle in use since April 1910 is 1.6 per cent less than the standard used prior to that date.

It will be seen that a great improvement in the quality of this lamp has been made since its introduction sixteen years ago; in fact the quality then was but 12 per cent of what it is now. Due to war conditions there were slumps, but the lamp is now about twice as good as it was in 1914. These data, derived from commercial ratings, show average figures—there are of course occasional fluctuations.

DIFFERENCE IN RELATIVE QUALITY BETWEEN VARIOUS SIZES OF TUNGSTEN FILAMENT LAMPS

A difference in relative quality between the various sizes of lamps is indicated by the difference in their rated initial efficiency. Table II shows the present difference in relative quality between the various standard sizes of 115-volt tungsten filament lamps as determined from their commercial ratings.

It is impractical to chart the relative quality given in the above table in terms of hours life at a given efficiency. A chart, Fig. 1, has therefore been prepared showing the present relative quality in terms of the mean efficiencies (given in Table II) of the various lamps for 500 hours life.

TABLE II.
DIFFERENCE IN RELATIVE QUALITY BETWEEN VARIOUS
SIZES OF 115-VOLT TUNGSTEN FILAMENT LAMPS

Lamp	Commercial Rating initial L-P-W	Mean L-P-W for 500 hours life	Relative Quality
			Hours life at 10 mean L-P-W
10 watt Vacuum	8.2	8.73	190
15 watt Vacuum	8.7	9.16	275
25 watt Vacuum	9.5	9.56	375
40 watt Vacuum	10.1	9.98	485
50 watt Vacuum	10.2	9.84	440
60 watt Vacuum	10.2	9.61	370
75 watt Gas-filled	11.8	11.9	1,600
100 watt Gas-filled	12.9	13.0	2,950
150 watt Gas-filled	14.3	14.3	5,400
200 watt Gas-filled	15.3	15.4	9,100
300 watt Gas-filled	16.5	16.6	15,200
500 watt Gas-filled	18.1	18.1	26,400
750 watt Gas-filled	19.1	18.0	25,300
1000 watt Gas-filled	20.0	18.8	35,000

FIG. 1. PRESENT MEAN EFFICIENCIES OF TUNGSTEN FILAMENT LAMPS FOR 500 HOURS LIFE

IMPROVEMENT IN THE MOST GENERALLY USED LAMP,
1880-1923

The first commercial incandescent lamp had a carbonized paper filament. About the middle of the year 1880, carbonized bamboo was used. The term "watts" had not been adopted at that time, so the bamboo lamps were made for an efficiency of "eight lamps per horse power". The lamps were designed to give 16 candle power in a horizontal direction when new and had a rated commercial life of 600 hours to burn out. Ex-

pressing these figures in the present international candle power standard, their quality was such that it is computed that they would have given a mean efficiency of 1.12 lumens per watt during 500 hours total life. In the latter part of 1881 lamps were made at a higher efficiency for use on lighting circuits having close voltage regulation. They were made "ten lamps per horse power" rated for 600 hours life to burn out. In the

FIG. 2. IMPROVEMENT IN LAMPS, 1880-1923

- years following the quality was improved by the experience gained in manufacture, the changes in the filament, etc. The most important improvements were in:
- 1888 Asphalted bamboo — carbon filament
 - 1893 Treated bamboo — carbon filament
 - 1894 Treated cellulose — carbon filament
 - 1905 Metallized carbon filament (Gem lamp)
 - 1906 Tantalum filament
 - 1907 Tungsten filament
 - 1911 Drawn tungsten wire
 - 1912 "Getters" (chemicals used to improve the lumen maintenance)
 - 1913 Gas-filled tungsten filament lamp.

The aggregate of these advances brought about by changes in type of filament and improvement in quality is staggering in amount. For example, the quality of the present 40-watt vacuum lamp is such that if it were made for the same mean efficiency as Edison's bamboo carbon lamp of 1880, it is estimated that the tungsten filament lamp would have a life of over one hundred and fifty thousand years. And this does not take into consideration the enormous improvement in the larger sizes of tungsten filament lamps due to Dr. Langmuir's brilliant invention of the gas-filled lamp.

Owing to such enormous differences, the improvements are therefore indicated in terms of their mean efficiencies for 500 hours life. Table III gives the mean efficiencies of the most popular size of vacuum lamp in use from 1880 to date. These data in chart form are shown in Fig. 2. To indicate the improvement made possible by Dr. Langmuir's invention, the present mean efficiencies of the 75 and 1000-watt gas-filled tungsten lamps are added at the bottom of Table III.

Due to these various improvements, the rated initial efficiencies were improved as will be seen from the figures in the third column.

TABLE III.

MEAN EFFICIENCIES FOR 500 HOURS LIFE OF CARBON, GEM, TANTALUM AND VACUUM TUNGSTEN FILAMENT LAMPS, 1880-1923

Date	Lamp	Rated Initial efficiency	Rated Hours life to burnout	Reduction factor	Mean efficiency (% initial)	Mean LPW for 500 hrs. life

*The International candle in use since April 1910 is 1.6 per cent less than the standard used prior to that date.

VALUE OF LAMP IMPROVEMENTS

The cost of current to the public is now very much less than in 1880. The public has increased the amount of light it has used with every reduction in rate for current and every improvement in lamps. It is difficult to determine the cost of current in the first few years, but it is assumed in the following calculations to have averaged 20c. per kw-hr., from 1880 to 1883, 15c. from 1883 to 1888 and 13c. from 1888 to 1890. Data beginning with 1890 are available on the general average rate for which current was sold so these figures are used in the calculations.

The 1880 lamp had a mean efficiency of 1.09 lumens per watt during its rated life of 600 hours, consumed about 93 watts and had a list price of one dollar. At 20c per kw-hr., about 50 lumen-hours could be obtained for one cent, covering the cost of current and lamp renewals.

The present 40-watt tungsten filament lamp has a list price of 32 cents. If it were of the same quality as the 1880 lamp it would have a mean efficiency of 1.01 lumens per watt during its rated life of 1000 hours. At the present approximate general average rate of 4½c. per kw-hr. such a lamp would produce 190 lumen-hours for one cent.

If on the other hand with no reduction in rate for current, the present 40-watt lamp, which has a mean efficiency of 9 lumens per watt during its 1000 hours rated life, would at 20c. per kw-hr., produce 432 lumen-hours for one cent.

With the combination of the reduction in rate and improvement in lamps, it is now possible at the approximate general average rate of 4½c. per kw-hr., to obtain

1700 lumen-hours for one cent. It is impossible to state exactly what part of the increase is due to lamp improvements and what part is due to reduction in cost of current, except to indicate what would have been obtainable with one factor without the other.

Table IV shows the number of lumen-hours obtained

FIG. 3. LUMEN-HOURS FOR ONE CENT AT APPROXIMATE GENERAL AVERAGE RATES FOR CURRENT, 1880-1923

from time to time for one cent with the most popular size of lamp used. It is based on the prevailing lamp quality and the prevailing approximate general average rate for current. This is shown diagrammatically in Fig. 3. At the bottom of Table IV is given for comparison, the number of lumen-hours now obtainable with the 75 and 1000-watt gas-filled tungsten filament lamps.

TABLE IV.

(a) 93.25 watts (b) 74.6 watts (c) 50 watts					

The amount of light now obtainable for one cent, with the 40-watt vacuum and the 75 and 1000-watt, gas-filled tungsten filament lamps at various rates for current, is given in Table V. As in Table IV, the cost of lamps is considered as their list price. Large consumers of current obtaining low rates are usually large purchasers of lamps and hence obtain them at less than list price. Under such circumstances the amount of light obtained for a given expenditure would be some-

what greater than stated. For comparison, the amount which would have been produced by the 1880 lamp is also shown. These data are shown diagrammatically in Fig. 4.

As previously mentioned, it is impossible to exactly state what part of the increase is due to lamp improvement and what part is due to the rate reduction. The improvement in lamps is indicated by the fact that the rated mean efficiency of the present 40-watt vacuum tungsten filament lamp is 8 1/4 times, the 75-watt gas-filled is nearly eleven times and the 1000-watt is 17 1/4 times that of the 1880 lamp. The rate reduction depends, of course, on the rate used.

EFFECT OF LAMP IMPROVEMENTS

Improvements in lamps may be utilized either to get more light for the same money or to get the same

amount for less money. The American public has chosen to get more light and each advance in lamp quality has resulted in increased intensity of lighting everywhere.

It is estimated that over half a billion dollars were paid in 1922 for electricity used in the United States for electric lighting. If the present day intensity of lighting were produced by using the bamboo carbon lamp of 1880, the cost of lighting in 1922 would have

been increased three and one half billion dollars. This would have required about fifty-billion additional tons of coal, about ten per cent of the total coal production in the United States, to generate the amount of light actually used.

Discussion

For discussion of this paper see page 877.

The Art of Sealing Base Metals Through Glass

BY WILLIAM G. HOUSKEEPER

Member, A. I. E. E.
Research Laboratories of the Am. Tel. & Tel. Co.
and the Western Electric Company

Review of the Subject.—Methods are described by which base metals may be sealed to and through glass, even though the metal and glass have different coefficients of thermal expansion. The method consists in providing a large surface of contact between the glass and the metal, and in so proportioning the metal that the stresses resulting from the difference in coefficients of expansion are less than the ultimate strength of the joint between glass and metal.

Four different types of seals are discussed:

First, the flattened wire seal for small electrical conductors.

Second, the ribbon seal for special purposes.

Third, the disk seal for commercial manufacture of seals for carrying currents of the order of 100 amperes.

Fourth, the tube seal in which metal and glass tubing are joined together.

BOTH incandescent lamps and thermionic tubes consist of certain electrical elements enclosed in glass containing vessels. These vessels are exhausted to extremely low pressures and are then sealed up so that the vacuum may be maintained. It is necessary for leads to be provided which will make electrical contact with the electrodes within the exhausted vessel and which will permit of energizing these electrodes by means external to the vessel.

In the incandescent lamp, the electrode consists of a fine wire which is heated to a high temperature by passing current through it. For many years platinum was used as that part of the electrical conductor, passing through the walls of the glass enclosing vessel, which carried current to and from the filament. There are two reasons why platinum was used. First, it does not oxidize while the glass is being applied; consequently, the glass comes in contact with a clean surface of platinum and this was thought to be a desirable feature. Second, of the metals readily available, ten years ago, platinum was the only one which had a coefficient of expansion approximately the same as that of the lead glass in use at that time. Both lead glass and platinum have a coefficient of expansion approximately 9×10^{-6} per deg. cent. Other metals, such as gold, silver, copper, iron, nickel, etc., have coefficients of expansion appreciably greater than that of glass. Consequently when attempts are made to cover round wires of these metals with glass, while good contact may be made with the glass hot, yet when the glass and wire cool down to room temperature, the metal contracts further than the glass, and separates from the glass, leaving very small

openings between the wire and the glass, through which air readily enters the vacuum container. Consequently, it became axiomatic, in the incandescent lamp manufacturing industry, that the seal wire, as that portion of the conductor coming directly in contact with the glass was called, must have the same coefficient of expansion as that of the glass through which it passed. In consequence, we find that when the price of platinum increased enormously several years ago, platinum substitutes were offered for use, which had approximately the same coefficient of expansion as the platinum which they replaced.

Alloys of iron and nickel have the property of a varying coefficient of expansion, depending upon the relative proportions of the two component parts. An alloy may be obtained having practically any coefficient of expansion from zero to 14×10^{-6} per deg. cent. One of the earliest platinum substitutes consisted of a core of a nickel iron alloy sheathed with platinum. Another substitute at present in use in the lamp manufacturing industry consists of an alloy core sheathed with copper and usually coated with dehydrated borax. In the substitution of either of these alloys for platinum, a larger diameter of the substitute wire is usually required. The alloy core is of considerably higher resistance than the platinum which it replaces. The copper sheathed wire in this respect is better than the platinum sheathed wire in that the copper is of lower resistance than the platinum. The high resistance is objectionable because, carrying the normal current, the wire heats and of course expands. If this expansion is sudden, that is, if the wire heats up before the surrounding glass, it is quite likely to split the glass from its internal wedging action. Consequently, it has been found advisable to

use only a short length of the platinum substitute and to weld copper wire to each end of the short length. The solid copper being a better heat conductor than the alloy wire itself, serves to take heat away from the wire and thus keep the resulting expansion at a minimum. Welding the copper wire to the substitute also serves to close up any small openings which may occur between the copper sheath and the alloy core which otherwise would give rise to very small leaks, developing after several days' or weeks' use. Thus we have the practically universal use of a round cylindrical wire which has approximately the same coefficient of expansion as that of glass, passing through the glass.

FIG. 1

Measurements made upon tungsten and molybdenum showed that they had coefficients of expansion approximately $\frac{1}{3}$ that of the ordinary lead glass. The well-known Pyrex glass has approximately the same coefficient of expansion as that of tungsten. Thus satisfactory seals are made between tungsten and Pyrex glass through the intermediate use, however, of a second glass which seals satisfactorily to the tungsten and to which the Pyrex glass is, in turn, attached.

In the telephone plant, thousands of tiny incandescent lamps are used for indicating the condition of subscribers' lines. These lamps are approximately $\frac{1}{4}$ in. in diameter (6 mm.) and $1\frac{3}{4}$ in. long (4 $\frac{1}{2}$ cm.). Several years ago, experiments were made to determine

FIG. 2

upon a practicable substitute if any, for the platinum used in these lamps. Trial lots of lamps were made up using various sizes of platinum and platinum substitutes at that time available. Exceedingly fine wires of copper and iron were tried, also copper wire covered with dehydrated borax was tried. As was expected, these showed slight leaks. No. 34 B & S gage copper wire was then prepared in a different way. Placed on an anvil, it was struck at right angles with the sharp edge of a hammer, thus flattening the wire locally to a section approximately 0.001 in. thick (0.025 mm.) and 0.030 in. wide (0.75 mm.). This wire was covered with dehydrated borax and the flattened portion placed

within the glass. Tests showed that a seal made in this way was vacuum tight. An experimental machine was soon put together, using a cam-actuated hammer to flatten the wire, after which the wire was drawn by motor-driven rolls through a borax coating bath and then through a dehydrating oven. Repeated tests showed that wire thus made sealed with lead glass without leaks. Larger sizes of wire were tried. Fig. 1 shows a 40-watt, 110-volt incandescent lamp made with the flattened copper. With the use of larger sizes of wire it became more and more difficult to flatten the wire by a single hammer blow. It was found that several successive blows were necessary. If the copper was not flattened sufficiently, separation occurred between the copper and glass. This separation could be seen easily, since it gave rise to interference fringes between the surface of the copper and the inner surface of the glass which had separated from the copper. Consequently, when it was found that wire, flattened to 0.002 in. (0.050 mm.) thick, $\frac{1}{8}$ in. wide (3 mm.) made a tight seal with glass, it was reasoned that copper foil having these same dimensions should also make a satisfactory seal. This was tried and found to be so. Sheet copper, 0.002 in. thick (0.050 mm.) and $\frac{1}{8}$ in. wide (3 mm.) covered with borax, made a tight seal with lead glass. Ribbons of copper foil 0.002 in. thick (0.050 mm.) and $\frac{1}{4}$ in. wide (6 mm.) were covered with

FIG. 3

borax and found to be tight. This thin ribbon, however, was mechanically weakened by oxidation outside of the seal. Consequently, ribbons were made from 0.004 in. (0.1 mm.) and 0.008 in. (0.2 mm.) sheet copper, $\frac{1}{4}$ in. wide (6 mm.), the ribbon being flattened locally at the sealing-in point, the increased thickness outside the seal making the ribbon mechanically stronger. All of these seals were covered with dehydrated borax.

The question arose as to the part played by the borax in the seal manufacture. Consequently, a seal was made with 0.002 in. (0.050 mm.) copper ribbon without borax. It was found that such a seal was tight, although the ribbon outside of the seal was exceedingly weak, due to oxidation. 0.004 in. ribbon (0.1 mm.), $\frac{1}{4}$ in. wide (6 mm.) apparently sealed in satisfactorily, though showing a slight leak under test. Ribbon 0.008 in. thick (0.2 mm.) by $\frac{1}{4}$ in. wide (6 mm.) when sealed in showed visible leaks along the edges of the ribbon, but not at the center. Fig. 2 shows a cross-section, not to scale, of such a seal. As previously explained, the leak is shown by interference rings produced in the small space between the glass and metal which are separated. We found that by tapering off the two edges of the strip by filing to a knife edge, tight

seals could be obtained between glass and 0.008 in. (0.2 mm.) copper ribbon, that is, the cross-section of the ribbon instead of being a rectangle, was made a parallelogram having two rather acute angles. Tight seals, using larger and larger sizes of copper were rapidly made in succession, until a ribbon 0.015 in. thick (0.38 mm.) and 1 in. wide (25.4 mm.) was sealed through glass without the use of borax, and without leaking. As before, the edges of the ribbon were filed to a knife edge. Such a seal is shown in Fig. 3 and a cross-section in Fig. 4.

The results of these preliminary experiments were so much at variance with belief and previous experience as to be open to considerable doubt as to the reliability of methods of test. Vacuum tight seals were, however, produced by different operators using material from different sources. As a result of these experiments and tests, a complete chemical and mathematical investigation was inaugurated as well as further experimental work either to prove or disprove the results of the initial experiments which have just been recorded.

In order that the explanation of the action of this seal, known as the ribbon seal, may be clear, the various steps in the manufacture will be explained somewhat in detail. A piece of 0.015 in. (0.37 mm.) sheet

FIG. 4

copper is cut approximately 1 in. wide (25.4 mm.) by 4 in. long (10.1 cm.). The edges of the sheet copper for a length of approximately 1 in. (25.4 mm.) at the center are filed away so that the angle at the edge is approximately 8 deg. or 10 deg. A glass tube is provided, into the end of which it is desired to seal the ribbon. The end is flattened to provide an opening approximately 1 1/8 in. (28 mm.) by 1/8 in. (3 mm.). The sheet copper is then heated in the glass working fires for several seconds to a good red heat. It is then so placed within the end of the glass tube that the glass will come in contact with that section provided with the sharpened edges. The glass is pressed in contact with the ribbon and melted in place at as high a temperature as can be maintained without injury to the glass or the copper. It is then annealed and finally allowed to cool off. It will readily be seen that this operation is the exact parallel to that employed in sealing in platinum or platinum substitute wires.

In previous attempts to seal base metals through glass, in practically every instance round or nearly round wires were used, that is, wires were used in which the perimeter of the cross-section was the minimum possible for the area of cross-section. In the case of the copper ribbon seal, with a ribbon width of 1 in.

(25.4 mm.) and thickness of 0.015 in. (0.37 mm.), the perimeter of the cross-section is very great compared to the perimeter of a circle of equal cross-section. In other words, for a given cross-section of metal, the ribbon affords a great deal more surface of contact between metal and glass than if a cylindrical conductor were used. Due to this great surface of contact, the stresses produced between metal and glass due to the difference in coefficients of expansion never become large enough to fracture either the joint between metal and glass or the glass itself.

In Fig. 4, *A, B, C, D*, is the cross-section of the copper ribbon, not to scale, and *E, F, G, H* is the enclosing glass. We find that the copper ribbon is actually stretched in the direction *AC*. The cubical contraction of the copper is practically the same as that of an unrestrained piece. Consequently, copper contracts in thickness in the direction of the line *JK* by that amount required by the cubical contraction of the copper. A few approximate figures may in this connection be interesting.

Assuming 525 deg. cent. as that temperature at which the glass commences to stretch the copper, room temperature of 25 deg. cent. coefficient of expansion for copper of 17×10^{-6} per deg. cent., and coefficient of 9.1×10^{-6} for glass, then the strain in a 1 in. length of copper will be approximately $(17.2 - 9.1) \times 10^{-6} \times 500 = 0.00405$ in. (0.1 mm.) Tests on soft copper show that this elongation corresponds approximately to a stress of 8700 pounds per square inch (612 kilograms per sq. cm.). The thickness of ribbon in the direction *JK* of Fig. 4, being approximately 0.015 in. (0.37 mm.), the force necessary to stretch a 1 in. length of the seal will be approximately 131 lb. (59.4 kg.). This stress may be assumed to be carried as shear between the glass and the copper along planes *AB* and *CD*. *AB* and *CD* are both approximately 5/32 in. (4 mm.) so that the shearing stress per square inch necessary to stretch the copper the required amount is approximately 840 pounds per square inch (59.1 kg. per sq. cm.). These figures are approximate only, since they neglect complications caused by the fact that the copper is in tension in three directions, in the directions *AC* and *JK*, and also in a direction at right angles to the cross-section of the figure. However, the figures indicate the order of magnitude of the stresses involved.

The stretching of the copper has been directly measured on a somewhat different type of seal, the disk seal, which will be described later. There can be no doubt that the glass is sucked in by the copper in the direction *JK*. Two parallel spots were lapped on the glass surrounding such a seal and the distance, *JK*, on Fig. 3, carefully measured with a micrometer. The copper was then dissolved in nitric acid, leaving only the surrounding glass shell. Subsequent measurements showed that the glass had sprung outwardly a measurable amount.

Glass may be regarded as a more or less viscous

liquid. It has no definite melting point such as simple materials have. Upon heating it becomes more and more fluid until at the temperature at which it is applied to copper, it has the consistency of rather thin molasses. Glass at this temperature wets the copper, just as at room temperature, water will wet glass. Apparently as the hot glass and copper cool off, the adhesion of the glass to the copper is stronger than the cohesion within the glass, since in every case of a seal properly made, fracture will occur, not between the glass and copper, but in the glass itself, a thin film of glass being left adhering to the copper. Consequently the shearing strength of the joint between the glass and copper may be taken as equal to the shearing strength of the glass itself. Now the adhesion of the glass to the copper is entirely independent of the thickness of the copper or the thickness of the glass. The stresses, however, which the joint may be called upon to resist, are directly dependent upon the thickness of the glass or the copper or both. It is not possible to seal a heavy block of copper to a heavy block of glass since the stresses which the joint will be called upon to resist will be greater than the strength of the glass near the joint. However, it is entirely possible to seal a very thin section of either substance directly to the other; for example, a circular microscope cover glass may be melted to and will adhere to a large block of copper and a disk of sheet copper of approximately the same dimensions may be melted to a large block of glass. In both of these cases the stress which the joint between glass and copper is called upon to resist is less than the strength of the joint. Consequently, again referring to Fig. 4, we are led to the conclusion, which is amply sustained by experiment, that no matter what the metal, the angle $B A D$ may always be made sufficiently acute so that the stress between the metal and glass is always less than the shearing strength of the joint; that is, it is entirely possible to seal any metal through glass, provided that the glass wets the metal when hot and further provided that the metal does not melt at the temperature necessary for it to be wetted by the glass. Seals have been made between lead glass and base metals, such as, iron, brass, and silver. Copper is peculiarly satisfactory for this service, since soft copper passes its elastic limit at a comparatively low stress per square inch. Consequently, for a given width of ribbon, thicker copper may be used than if other metals are used. This is fortunate, because copper has good electrical and heat conductivity.

Referring again to Fig. 4, attempts have been made to determine the most desirable cross-section of the copper ribbon. The various methods of considering the stresses indicate approximately the same most desirable cross-section. It has been previously stated that the copper ribbon is stretched in the direction $A C$. This occasions a compressional stress in the glass $A F C$ and under compression this glass may be assumed a column, or, again, it has been stated that

the glass $F C$ is drawn towards the glass $E D$ in the direction $J K$, by contraction of the copper ribbon in thickness. The glass $A F C$ then may be considered as a beam rigidly supported at both ends and deflected downwards under the load applied by the copper. In this case the deflection of the beam at each point throughout its length would be proportional to the thickness of the copper ribbon at that point. Under such conditions bending stresses will occur in the glass beam opposite points A and B at which points there is a change in rate of deflection. Preliminary consideration thus indicates the desirability of avoiding all corners on the cross-section of the ribbon.

Mr. T. C. Fry has made a very complete mathematical analysis of the stresses and strains occurring in a ribbon seal, in order to determine the best section of the copper, the "best section" being that having the maximum cross-section for a given width of ribbon. The curve indicated by Mr. Fry for cross-section of ribbon lies between the cosine curve of the glass considered as a column in compression and the curve of deflection of a beam rigidly fixed at both ends such that maximum fiber stress is nowhere exceeded. Thus in Fig. 4, the surface $A B$ should be curved and be approached by surface $A D$ tangentially, and surface $A B C$ should be a smooth curve without any sudden change in direction. The calculations, however, cannot be made with as great precision as might be desirable because of unknown factors in the calculation. We do not know the exact temperature at which solidification of the glass may be said to commence on cooling, nor do we know the elastic constants of glass and metals under various conditions of temperature and stress. Practically, if a ribbon seal fails, the angle at the edge is made sharper and a new seal made, rather than attempting to calculate the exact dimensions.

In the introductory paragraphs an advantage for platinum was claimed in that it did not oxidize and thus permitted closer contact between glass and metal. In the description of the seal manufacture it was stated that the copper ribbon was heated red hot before covering with glass. This heating of the copper ribbon of course oxidizes it and this oxide is not removed before being brought into contact with the glass. These two statements are at variance. As a matter of fact, perfectly good seals result when the copper has been oxidized as stated. If care is used to work in a reducing atmosphere and to use glass which does not reduce, as lead glass will, it is quite possible to make entirely satisfactory seals between glass and clean copper. Apparently, a reasonably thin coating of oxide does no harm, whatever, to the seal. When hot, this oxide is black, but as the seal cools off, the cupric oxide changes to cuprous oxide and it is this latter oxide which gives rise to the crimson color of the seal.

Fig. 5 shows a microphotograph of a section of the seal between copper and glass. The copper may be recognized from its etched surface. The black line

immediately next to the copper is a thin layer of cuprous oxide approximately 0.0003 in. in thickness (0.007 mm.) Immediately next to the thin layer of oxide will be seen a section of glass. This photograph is given to show the exceedingly close adhesion of the glass to the copper.

So far as we can find from consideration of the various factors entering the copper-lead glass seal, chemical reactions play a small and unimportant part. While certain reactions do occur, these are relatively slow and minute in comparison with the physical phenomena which make the seal possible.

Several interesting features of the ribbon seal are evident upon consideration. The copper ribbon with-

FIG. 5

in the glass, it will be remembered, is in tension in every direction. Heating the copper will thus initially reduce stresses because the copper will be expanded in the direction of the tension forces acting upon it. In other words, such a seal will not fail with sudden passage of current through the ribbon, because such heating as may occur in the ribbon actually lessens the stresses in the glass. A ribbon seal made from 0.008 in. sheet copper (0.4 mm.) and 7/16 in. wide (11 mm.) will continuously carry 40 amperes. It will, however, easily carry several hundred amperes for a short time. In fact it will carry enough current to make the ribbon visibly hot outside the seal. Again, various electrodes for

FIG. 6

use in vacuum apparatus may be formed from that portion of the ribbon within the enclosing chamber. Such an application may be seen in Fig. 6, showing the anode for a mercury rectifier tube made in one piece with the iron ribbon which passes through the glass member of the stem. Further applications may be easily imagined.

In the discussion of the ribbon seal it was assumed that the copper in Fig. 4 was stretched in the direction AC by the clamping effect of the glass upon the surfaces AB and CD . If this is the case, then it should be possible to construct a seal in which the glass comes only in contact with the copper ribbon at the edges of the ribbon and not along the center, that is, a

seal such as that shown in Fig. 7 should be possible of construction. Next consider that Fig. 7 is a cross-section, not of a ribbon, but of a circular disk, taken at right angles to the plane of the disk along the diameter of the disk. Since, according to our assumption, glass does not touch the copper near the center of the disk, it

FIG. 7

makes no difference what form the glass assumes where it is not in contact with the copper; that is, it should be possible to seal a circular diaphragm into a glass tube in the manner shown in Fig. 8. It will be remembered that in the discussion of the ribbon seal, the edges of the ribbon were sharpened in order to prevent

FIG. 8

separation of the ribbon and glass. If the disk has square edges, then whatever separation occurs between glass and copper will do no damage provided separation does not extend to the inside of the tube. Further, since the separation in this case is not objectionable, we might just as well leave off the glass from the edge

FIG. 9

of the disk and apply glass only to the two faces. This is shown in Fig. 9. This then results in two pieces of glass tubing, one end of each being flared and the two flares melted to opposite faces of a single copper disk. As a matter of fact, such a seal is entirely possible. The final step in the development of the disk

seal is shown in Fig. 10. A round copper wire is passed through a centrally located hole in the disk and is soldered to the disk. Tubing on one face of the disk is almost entirely removed, leaving only a torus of glass in contact with one face. Fig. 11 shows such a disk seal. This type of seal has certain advantages over the ribbon seal. First, the electrical conductor is round and thus of a shape easily obtainable commercially. It is more rigid than a corresponding section of copper ribbon. The disk can easily be punched out on a punch press and requires no filing or machining.

In this seal the stresses are more simple than in

FIG. 10

the ribbon seal. The copper disk is stretched radially in all directions upon cooling. The glass is subjected to compression only without bending stresses such as occur in the ribbon seal. The disk contracts in thickness by an amount sufficient to compensate for the restricted radial contraction.

Care must be taken to prevent glass on one side from running over the edge and making contact with glass on the opposite side of the disk, for if it should make contact, the seal will be broken, because the glass around the edge will not contract as far as the copper disk contracts in thickness.

FIG. 11

As in the ribbon seal, so also in this disk seal, the copper is under tension, though in two dimensions instead of in three. In consequence, when the disk is heated by passage of current through the central conductor, the copper when first expanded reduces the tension stresses so that the corresponding stress in the glass is actually lessened and passes through zero before any possible destructive stresses are applied to the glass by the copper. For example, a certain disk seal, made with a disk $1 \frac{3}{16}$ in. diameter (3 cm.) and No. 6 B & S gage copper wire, (0.162 in. diameter — 4.1

mm.) normally carries a current of 90 amperes. Such a seal will carry any current which the copper wire is capable of conducting short of fusing the copper wire. Such a seal will carry 1200 amperes suddenly applied, though a current of 700 amperes will fuse the wire in air if applied for several minutes. As a matter of fact, the disk seal will remain tight even with the copper conductor operating at red heat. Thus this type of seal has the very desirable feature of withstanding heavy overload. It, of course, has the further desirable feature that it has the full conductivity of the given size of copper wire, there being no intermediate portion having a higher resistance.

There seems to be no reason why disk seals of any desired conductivity cannot be made if it is found necessary to make them. $\frac{3}{8}$ in. diameter (10 mm.) of copper conductor, is as large as we have so far found it necessary to try out. For exceedingly heavy currents, still another type of seal is available, which will be referred to a little later.

The thickness of the disk is determined by the subsequent use to which the seal is to be put. For example, it is quite possible to seal a disk 1 in. in diameter (25.4 mm.) and $\frac{3}{32}$ in. in thickness (2.5 mm.) between two flared glass tubes. However, such a seal once cooled to room temperature will not withstand subsequent heating and cooling. The explanation seems to be that even though the copper is thoroughly annealed when red hot with application of glass yet the subsequent stretching of the copper as it cools off, hardens the copper to an appreciable degree, thus raising the elastic limit and thus increasing the stress which the copper passes through the joint to the glass. Thus in proportioning a seal which is to withstand a great number of repeated cycles of heating and cooling, it is necessary to decrease the thickness of the disk until the maximum stress which the copper can pass to the glass is less than the ultimate strength of the glass. In the case of the 1 in. diameter (25.4 mm.) disk, a convenient thickness is 0.020 in. (0.5 mm.) or 0.030 in. (0.75 mm.).

Glass may be sealed to opposite faces of a copper cent and if carefully annealed, the cent may be made a great circle of a glass sphere.

Theoretical calculations of the relation between thickness and diameter of a disk indicate dimensions of the same order of magnitude as those found by experiment, although here again, as in the case of the ribbon seal, the elastic constants of the glass and copper are not definitely known, nor is the temperature at which the glass may be assumed to solidify a definite quantity.

There are thus, three methods by which copper may be sealed through glass for use as electrical conductors; first, the borax-coated, flattened copper wire; second, the ribbon seal, and third, the disk seal.

The function of the borax in the case of the flattened wire seems to be to provide material next to the copper,

which by its low melting point decreases the temperature difference over which the copper is stretched upon cooling. For example, on a certain flattened seal wire with borax the thickness of the flat was 0.0015 in. (0.037 mm.) and without borax it was found necessary to decrease the thickness to 0.0009 in. (0.023 mm.). It is necessary only on the smaller seals where the copper should be as strong mechanically as possible. For ribbon seals and disk seals, borax is not used, the dimensions of the copper being sufficiently large to withstand ordinary handling.

FIG. 12

With the success attending the development of the ribbon and disk seals, further experiments were made to determine the possibility of joining metal tubing to glass tubing. For example, a $\frac{1}{2}$ in. diameter (13 mm.) copper tube was spun outwardly in a flange at one end and the resulting flange was sealed to glass tube in a manner similar to that employed in making disk seals. The over-all diameter of such a seal, however, is of course considerably larger than the diameter of the copper tube. Consequently the experiment shown in

FIG. 13

Fig. 12 was tried and found to be practicable. In this case a copper tube is machined at one end to provide a thin wall of copper. Glass is melted to the outside and joined to a glass tube of suitable size. Here, again, the copper is under tension as the seal cools, yet the adhesion of the glass to the copper is sufficient to stretch the copper as it cools. Further experiments showed that if the glass accidentally ran across the end of the tube, the seal failed at that point because the glass in this case impeded the contraction in thickness of the

FIG. 14

copper tube. To avoid this difficulty, the expedient used on the ribbon seal was adopted and the edge of the copper tube machined to a knife edge. Then should any glass pass over the edge, failure of the seal would not occur.

Fig. 13 shows a seal of this type in which the copper tube has been reduced to a knife edge at the open end. Here the glass is applied outside of the copper and in this form is known as an external seal. Fig. 14 shows glass tubing applied to the inside of the same sort of copper tubing. This is known as an internal seal.

It has been found that there is a difference in the behavior of internal and external seals made with the same dimensions of the copper tube. An internal seal will resist sudden heating much better than an external seal, while an external seal will resist sudden cooling much better than an internal seal. So far, there seems to be no limit to the size of copper tubing which can be joined to glass tubing.

Fig. 15 shows a seal between a $3\frac{1}{2}$ in. diameter (9 cm.) copper tube and a 5 in. (12.8 cm.) diameter glass tube. In this seal the copper tubing is materially reduced in thickness over that portion which comes in contact with the glass.

As in the case of the other forms of seal, the tube seal

FIG. 15

is not restricted to either copper or lead glass. Fig. 16 shows a seal made between lead glass having a coefficient of expansion of 9×10^{-6} , Pyrex glass with a coefficient of expansion of 3×10^{-6} , and copper with a coefficient of expansion of 17×10^{-6} . In this case a copper tube is sealed to a Pyrex glass tube at one end and to a lead glass tube at the opposite end.

If it should ever be necessary to seal exceedingly heavy copper conductors through glass, such, for example, as a copper shaft 2 in. or 3 in. in diameter, the easy way to accomplish this would be to select a copper tube slightly flared at one end, which would slide easily over the copper shaft. To the flared end of the copper tube

FIG. 16

the glass could be sealed and then after the seal was made, the copper tube could be brazed or welded to the copper shaft.

In conclusion, there does not seem to be any limit to the size of the seals which can be made between metal and glass, so long as the parts are properly proportioned. The practical limit is reached in the laboratory, due to the weight of the parts to be handled and the necessity for keeping the parts in the proper relative relation. This, however, is purely a matter of design of mechanical means for so supporting the weights that they may be moved into proper relative positions.

It has thus been shown that where the parts are properly proportioned the difference in coefficients of expansion of the metal and the glass may be made of no effect upon the strength of the resulting seals.

Discussion

THE QUALITY OF INCANDESCENT LAMPS

(HOWELL AND SCHROEDER) AND

THE ART OF SEALING BASE METALS THROUGH GLASS

(Houskeeper), SWAMPSCOTT, MASS., JUNE 29, 1923

C. F. Scott: About fifteen years ago the tungsten lamp was evolving quite rapidly. Mr. Houskeeper and I were associated in those days in the Westinghouse Lamp factory, trying to help along the progress of the lamp.

A common method of making the tungsten lamp then before the days of the present long wire was the mixing of fine powdered tungsten with carbon and some kind of glue and then squirting it through a diamond die and taking that soft thread catching it on a piece of paper which was moved back and forth, and then cutting the pieces into almost hairpin shaped filaments. These were then packed in boxes and placed in a carbonizing furnace. They went through a cycle of several hours of carbonizing to burn out the mucilage and leave a compact combination of carbon and tungsten particles.

These hairpins were then placed in some neutral gas, a mixture made of hydrogen and nitrogen, and the current was passed through the filaments, which burned out the carbon and sifted together the little tungsten particles forming a little tungsten hairpin, not very rigid, and a half dozen of these hairpins, more or less were assembled together in a lamp, each of these hairpins as an individual, individually measured, and so on.

Mr. Houskeeper devised a method by which that process, which usually took several days, passing through many hands, was reduced to a process of five minutes in which the squirted filament passing down through a few feet of tubing was carbonized by high temperature. Then a current passed through the filament and it came forth this continuous so-called wire of tungsten, which might be a thousand feet long with a uniformity which was otherwise, previously impossible. That led to a wire formed lamp, one filament wound continuously as they are wound now. I think Mr. Houskeeper's name would have been widely known in connection with that process which would have been a very important thing if the rate of progress had been less rapid. The wired lamp of the General Electric came at about the same time and was commercially developed at the same time that this was being developed, so that this stage of the tungsten filament lamp was shortlived on account of the progress.

Another important problem in this old incandescent lamp field has been the problem of getting the current from the outside to the inside of the enclosed lamp or bulb. It seems to me that many of the research processes which Houskeeper used in that earlier work have characterized this next development. There is no phenomenally new discovery. He takes the metals, the common metals, not platinum or some other particular thing, but the common metals and any kind of glass apparently, and by a little physical study of the way of combining, and the form, and the strength, and coefficient of expansion, he forms a new combination which is remarkable. The ability to take the things that we are familiar with, and get some new and almost startling outcome is to me as remarkable or possibly more remarkable than discoveries in new fields.

H. Lemp: In 1885 while connected with the Schuyler Electric Light Company of Hartford, Conn. Mr. Merle J. Wightman and myself were engaged in developing what we called the "Series Incandescent Lamp" for arc light circuits. The plan used before the advent of the series incandescent lamp was to use a number of the regular 100-volt lamps in multiple to absorb the current used in connection with arcs, and we then conceived the idea that it would be much better if a lamp could be made with a filament large enough to take the whole ten amperes of a commercial arc light circuit and be connected in series with arc lamps, instead of in groups of lamps in multiple requiring complicated compensating devices.

As all the early incandescent lamps were limited to something like a one-ampere current, to go from one ampere to ten amperes

at that time required some research work as to the manner of passing these relatively big currents through the glass sealing, and if one cares to look at past records one will find an early patent to Mr. Wightman and myself for the use of a platinum ribbon in place of the platinum wire, then commercially used for leading in conductors for incandescent lamps.

We thought that if we could make the conductor in such a form that its surface of contact with the glass would be very large in proportion to its thickness, any heat developed would be more easily absorbed by the glass without cracking and the relative expansion by heat of the metal and glass would be less, and so we started out to make these platinum ribbons to conduct the current through the seal for these series incandescent lamps. Many hundreds of these lamps were commercially exploited.

When we found that we were successful in that attempt we grew bolder. We said "Now, if the platinum in the sheet form will carry those heavier currents and not crack the glass seal, why not take some other metals, iron and copper," and then we tried thin copper ribbons and sealed them in the manner shown by Mr. Houskeeper this morning, without however thinning the edge, and we were very much astonished to see that the seals did not crack; they seemed all right, but after a while the air leaked in and destroyed the vacuum.

Mr. Houskeeper has told me this morning why we failed and I want to pay my tribute to him for this lesson.

I think that the method of sealing he has shown us today is a great step ahead in the art, particularly as it will enable us to manufacture larger electron tubes for the purpose of rectifying alternating currents of magnitude.

C. H. Sharp: With reference to the paper of Messrs. Howell and Schroeder I wish to call attention to one statement which I think should be added, and that is that 500-hour test criteria apply to, I believe, the Lamp Works and not necessarily to other lamp testing organizations which may use a different basic life value for determining the efficiency at which lamps are to be operated on life test.

Mr. Howell has been connected with the manufacture of incandescent lamps longer than almost any other man in the world. He has a familiarity with the history of lamp manufacture, with the romantic history of that art which few, if any, other men possess. It would be very desirable if we could have a record of Mr. Howell's knowledge and recollection of the circumstances of the evolution of the lamp; of the troubles, of the successes which the incandescent lamp manufacturers have experienced in the course of all the years of the development of this art.

A. L. Atherton: The very important work that Mr. Houskeeper has described opens up many possibilities. In thinking over the possibilities, a question comes up which I would like to ask. Some applications for this type of seal will doubtless require materials other than copper on account of chemical limitations. In trying to bond other metals to glass there has been some experience with what seems like an electrolytic action by which gas bubbles are evolved at the contacts. This is particularly true with metals like nickel which have other advantages over copper. I would like to ask Mr. Houskeeper if this sort of thing has been encountered in the work which he has referred to with metals other than copper, and if some preventive methods have been devised.

W. G. Houskeeper: In answer to the last question as to the sealing of other metals than copper into glass, if I understood the question correctly it was a question of the evolution of gas bubbles between the metal and the glass. That can be very satisfactorily taken care of by giving the metal a heating in vacuum before the glass is applied. If sheet nickel, for example, be maintained at approximately 800 deg. cent. for ten or twenty minutes in vacuum you can apply the glass to the surface any time in several weeks without bubbles between the glass and the nickel.

Transmission Line Transients

BY V. BUSH

Member, A. I. E. E.
Massachusetts Institute of Technology

Review of the Subject.—There is great need for a better understanding on the part of transmission engineers of the traveling waves on lines. The complete analysis of such waves is inherently complicated, but there are certain approximate relations by which the progress of waves on our ordinary systems may be readily studied. Before any theory is accepted for practical use, however, it is necessary to check it carefully by experiment. This paper gives quantitative checks of the principal aspects of the theory of the traveling waves due to suddenly applied continuous potentials, as originally given by Heaviside.

It is shown that this theory based on fixed line constants predicts accurately the progress of waves as far as magnitudes, speed of propagation, and shape of wave except at the wave front are concerned. The effect of steepness of wave front is discussed with relation to its practical aspects. It is proposed to follow this paper shortly with similar results on alternating-current transients.

Tests on artificial lines and on an aerial line in the field are compared with computed results. Working rules for considering the progress of transients are discussed, together with certain results that may be obtained by their use. An extension of approximate analysis is given in an appendix, which is sufficiently accurate for transmission lines of the present length, and which is sometimes easier to handle than the complete theory.

Reflections at apparatus, and at line junctures, is discussed qualitatively. There are several cases in which extreme potentials may arise. The most common case is when a cable and aerial line are used in conjunction. Another case occurs upon the sudden interruption of heavy current. The superposition of transients in a polyphase circuit, as affected by the sequence of closing of the switch points appears also to involve the possibility of difficulty.

The paper is non-mathematical. It attempts to gather together existing theory in simple form, rather than to extend analysis.

THE purpose of this paper is to present briefly the results of an investigation on transmission line transients recently performed in the Department of Electrical Engineering, Mass. Inst. of Tech., by Messrs. S. M. Jones, J. A. Scott, B. Van Ness, and D. C. Jackson, Jr., graduate students in the department. The object of the research was to check experimentally part of the theory of transients on transmission lines and cables, and to investigate qualitatively certain phenomena of reflection and wave form.

Qualitative experimental work has often been carried on along these lines. Quantitative work is attended with considerable difficulty in manipulation.

It is however, of great importance to our progress in the extension and operation of large systems that the theory of their electrical behavior be carefully checked in not only qualitative but also quantitative manner, in order that reliance upon the theory may be justified. The development of transient theory is particularly dependent upon the introduction of assumptions and approximations. The only final test of such theory is then a careful comparison with practice.

It is not ordinarily possible, for many reasons, to carry on accurate transient measurements on the actual transmission line. The use of artificial lines is hence imperative. The theory as so far developed is an approximation when applied to either one or the other. It is necessary that it be shown to give correct results to engineering accuracy on both.

The present research was made possible by the

Presented at the Annual Convention of the A. I. E. E., Swampscott, Mass., June 26-29, 1923.

development of a smooth artificial transmission line which is described in an accompanying paper by Prof. F. S. Dellenbaugh, Jr. Laboratory work was also supplemented by tests in the field on the Georgia-Alabama tie line, performed during the past summer by Prof. Dellenbaugh and Mr. Jones. This line was made available through the courtesy of the Georgia Ry. & Power Co. and the Alabama Power Co.

In presenting the results, some of the simpler transient theory is briefly reviewed. Certain generalizations are also drawn which it is believed will be of service to transmission engineers. Mathematics has been avoided in this paper in the hope that it may the better serve those who hesitate to attempt the careful reading of a mathematical paper. Plenty of mathematical analysis will be found in the references.

There have been several classifications of circuit transients, for example those of Steinmetz and Kennelly. For the present purpose it is convenient to divide them into two classes, which may be called traveling wave transients and machine transients. The first merges into the second. When a transmission network is, disturbed in any way, for example by a short circuit, events in the first instant are determined by the progress of traveling waves, which proceed over the circuit and are reflected and refracted at junctions and apparatus. This period is immediately followed by a second one during which the procedure is determined largely by the electrical and mechanical characteristics of the machines connected to the network. The first transient is caused by the readjustment of the energy stored in the lines, and the second by the readjustment of the

energy stored in the machines. The first is over in an interval usually so short that the second has hardly begun before it is over. Hence the two types may be considered separately without serious error. This investigation has to do only with the first type of transient, characterized by propagation of traveling waves of voltage and current.

All tests were made by suddenly applying or removing steady or continuous potentials. The results however, apply to most cases of the application of alternating potentials, for ordinarily the initial waves of voltage and current have become much attenuated before great change has occurred in an applied potential of commercial frequency. Thus if the line is 30 miles (49 km.) long, waves have time to travel over the system 10 times before an applied 60-cycle voltage has varied through one tenth cycle, and the most interesting effects are usually produced during the first one or two passages of the wave. The application of a polyphase voltage may be considered as the separate application of single-phase voltages, and the results added to obtain the total transient. It is, of course, necessary to include in the summary those waves which are induced in one wire by a wave in a parallel wire. This summation cannot be strictly carried out where the effects of iron, corona, etc. render the equations of the circuit nonlinear. Most of the polyphase transients of practise may, however, be qualitatively studied by means of the rules governing single-phase, continuous potential transients.

The transients of practise are often rendered seriously complicated by the presence of arcs, of which the resistance is not a constant. Progress even along these lines can, however, be expedited by examining the laws of simple cases.

SIMPLE WAVES AND REFLECTIONS

When a switch is closed, applying a potential E between a pair of wires of a transmission line or between one wire and ground, a wave of voltage of height E proceeds out along the line. Except for the effects of dissipation, due to resistance and leakance, this wave proceeds without attenuation or distortion, and at the speed of light, 3×10^8 km./sec. This means simply that the potential appears suddenly at points out on the line, the distance to which it has appeared at an instant t seconds after closing the switch being vt , where v is the velocity of light. Beyond this distance there is at this instant no effect whatever. This is called a rectangular wave, and may have a nearly perpendicular wave front. Such a wave is indicated as shown in Fig. 1.

A voltage wave of this sort is always accompanied by a wave of current of height $I = E \sqrt{\frac{c}{l}}$, where c and l

are the capacity and inductance per unit length of the line. The current is directed out along one wire, and

back along the other wire or ground, and similarly appears suddenly at distant points on the line.

On reaching the end of the line, these waves are reflected. If the end is open or short-circuited, reflection is complete. Reflection may be either with or without change of sign. The natures of the voltage and current wave reflections are always opposite; that is, if the voltage is reflected with change of sign, the current

FIG. 1

will be reflected without change of sign, and vice versa.

The progress of the voltage and current waves over a simple line may thus be mapped out, neglecting the effects of losses. In Fig. 2 is shown the progress on a line open at the distant end when a voltage is applied suddenly at the near end. The successive pictures are drawn for fractions of a period T which is twice the time

FIG. 2

necessary for a trip of the wave down the line and back. The nature of the reflections may readily be determined from the fact that the current at the open end must always be zero.

From such a diagram we may readily construct the diagram showing the time variation of voltage and current for any point on the line. Thus Fig. 3 shows the

variations at the midpoint of the line for the above example.

Strictly, when a switch is closed a spherical wave proceeds off into space, spreading out as do the waves from a radio antenna. The diagrams above show the effect at one part only of the field, namely at the wire. It is the effect at the wire in which we are usually interested. Such a diagram can, nevertheless, not tell the whole story of what happens, and it is well to bear this in mind. For example, the fact that the current on the wire at the wave front suddenly jumps to a value I does not at all mean that the magnetic field at a distance r from the wire suddenly jumps at the same instant

to $\frac{2I}{r}$. For this to happen would mean the propagation

of a plane wave in space instead of a spherical wave. At a long distance from the source the distinction disappears. When we speak of a wave on a wire, we usually mean the propagation of a plane wave in space and guided by the wire.

FIG. 3

WAVE FORM

Due to the effects of losses, a wave on a line will actually change shape as it progresses, and hence will not preserve the ideal rectangular form shown in Fig. 1. Mathematical solutions have been made for the shape of the distorted wave under certain simplifying assumptions. These assumptions are in brief that the line may be completely specified by four fixed constants $r l c g$, the resistance, inductance, capacitance and leakance per unit length of the line. This assumption postulates two straight isolated parallel conductors of which these constants are strictly fixed.

Under these assumptions, analysis shows that the wave front will remain strictly perpendicular, although the shape of the wave will depart from rectangular form. The voltage and current at any given point on the line will vary with complete suddenness on the arrival of waves. During the interval between wave advents the current or voltage at the point will vary slowly, due both to the attenuation of the wave, and its distortion in shape.

Heaviside first attacked this problem in a comprehensive manner. Some of the mathematical processes he used were lacking in rigor, but they are rapidly being put upon a firm foundation and extended by Carson¹

1. J. R. Carson. Theory of the Transient Oscillations of Electrical Networks and Transmission Systems. TRANS. A. I. E. E., Vol. XXXVIII, p. 345.

and a few others. A great deal has been written on the subject since the time of Maxwell and Hertz, but it is in general in such form as to be interpreted only with great difficulty for the cases in which the transmission engineer is interested.² Unfortunately the expressions which result from the analysis of traveling waves are complicated. Apparently this cannot be helped, except by the possible introduction of graphical methods, for the phenomena themselves are inherently complicated.

EXPERIMENTAL CHECKS ON THEORY

In Fig. 4 is shown the current entering a smooth

FIG. 4

artificial line with the distant end short-circuited, and a steady voltage suddenly applied at the home end. The oscillogram includes a 1000-cycle timing wave for convenience in measurement.

The artificial line used is one of those described by Dellenbaugh, and is shown in Fig. 5. It consists of 126 coils, having the capacity uniformly distributed by means of tinfoil and paper inserted between layers of wire. It represents 990 miles (1612 km.) of two No. 00 copper conductors, spaced 8 ft. 9 in. (267 cm.). This extreme length was used to better bring out in the oscil-

FIG. 5

lograms the wave forms of current and voltage. It will be noted, for example, in the oscillogram that, due to the very long length of line, the final steady current is less than the initial surge.

The transients were computed principally from Heaviside's³ and Carson's formulas, with Mr. Carson's much appreciated assistance in interpretation of difficult points in connection with some of the later work.

2. Consult for example H. Poincare, L'Eclairage Electrique, Vol. XL, 1904, p. 120.

3. Heaviside, Electromagnetic Theory, Vol. II, pp. 291, 378.

In Fig. 6 is plotted the computed curve, by the full line, for the above case. On this same diagram is plotted, dotted, a copy of the oscillogram of Fig. 4. The correspondence is seen to be excellent except immediately at the wave front. Reasons for the departure of theory from the observed form at the wave front will be discussed below. Several other oscillograms for various terminal conditions were also computed, the agreement being in general satisfactory.

These measurements may be considered a check upon theory as far as the amount and nature of reflections

Fig. 6

and the wave shape except at the wave front are concerned. With this confirmation of analysis we are justified in proceeding by the same methods to more complicated cases. We should, however, give particular consideration to the departure from expected results at the wave front.

OSCILLOGRAPH DATA

Possible oscillograph errors were studied.

We have, due to Kennelly, a treatment of the correction factors for an oscillograph vibrator of measured constants, which may be applied for oscillograms taken

Fig. 7

of steady state phenomena. These will show the errors present at each frequency of harmonic. There is no similar method available by which corrections may be applied to oscillograms of transients except for perpendicular changes. The best that can be done in other cases is to estimate the probable deviations.

The overshoot and lack of perpendicularity of the oscillogram were studied for cases where a voltage was applied directly from a battery, and known to be "rectangular". This was done for various vibrators and damping fluids. A typical curve is shown in Fig. 7.

This was taken at the same drum speed as used for the other oscillograms. The approximate amount of overshoot when present could then be subtracted from a perpendicular rise in the curves to be analyzed. It will be noted that the vibrator follows even a perpendicular rise with very little deviation. This deviation in the case of a perpendicular rise of current can also be calcu-

Fig. 8

lated from the measured mechanical frequency and damping of the vibrator and shown to be small. The behavior of an oscillograph vibrator to a suddenly applied steady force is, in fact, exactly analogous to the behavior of a series resonant circuit under suddenly applied constant e. m. f. Having measured by Kennelly's methods the vibrator constants,

Fig. 9

it is possible to predict accurately its behavior under such a sudden force. Its deflection plotted against time will give a damped sinusoid. The initial rate of deflection is given by the applied torque divided by the moment of inertia. The overshoot is given by the final deflection and the decrement.

Since the errors in a perpendicular rise were small,

Fig. 10

it was assumed that oscillograph errors in other parts of the curves could be neglected.

SHORTER LINES

Fig. 8 shows a curve taken with an artificial line 330 miles (537 km.) long. It is similar to the preceding except that reflections come at more frequent intervals, and the final steady current builds up to a higher value.

The oscillogram of Fig. 9 gives the home end entering

current for a suddenly applied constant voltage when the distant end of the 990-mile (1612 km.) line is open. In this case the current reverses in sign, and flows alternately into and out of the line, subsiding to a steady value of zero current since the leakage is negligible. Fig. 10 is for a line 330 miles (537 km.) long under the same conditions.

FIG. 11

Finally in Fig. 11 is shown the current for an artificial line only 96 miles (156 km.) long with the distant end open. Here the reflections follow so rapidly that the curvature of wave front soon masks the theoretically sharp cornered form.

FIG. 12

FIELD TESTS

Oscillograms for comparison taken on the Gadsden-Lindale tie line are shown in Figs. 12, 13 and 14. The first was taken with the distant end grounded, and the others with it open.

The method of taking these curves was the same as

FIG. 13

that used on the artificial line. A low value of applied e. m. f. was used, and the oscillograph connected directly in the line. The voltage was applied between two wires of the three-phase power line. The line constants were determined from separate a-c. measurements.

Computations again showed these curves to agree

with theory as well as could be expected in view of the experimental difficulties involved; Fig. 15 shows a computed curve superposed on the beginning of one of the enlarged oscillograms.

Several points of interest may be noted. One is the shape of wave front, which here again appears rounded and masks the rectangular appearance given by simple theory. Another point is the slight indication of stepped wave front appearing in Fig. 13. Apparently two

FIG. 14

transients were here superposed. This is the only curve which shows enough detail to clearly bring out the effect, although it appears slightly in Fig. 14. This appearance is probably due to induced transients in either the third wire or the ground wire loop. Similar curves have recently been produced on parallel artificial lines in the laboratory. The theory of such induced transients is being developed, and it predicts stepped waves of this form. It is hoped that this work will warrant later publication.

FIG. 15

In Fig. 14 the initial amplitudes are abnormally low. The experiment was repeated many times in the attempt to locate the cause of this departure from theory, and only one case was obtained in which the effect was absent, which is the curve of Fig. 13. Various expedients were tried, such as using a storage battery instead of a generator to supply the constant potential, applying a large capacity across the source of voltage and with its center point grounded, and so on. Curves of

applied voltage taken simultaneously indicate that the initial low value is not due to terminal apparatus, for the drop of applied voltage on closing the switch is very slight. Different pairs of line conductors were tried, but always with the same result. There was apparently some disturbing effect in the system usually present. It may be noted that the second wave being larger than the first represents net energy supplied from the line to the battery.

The line on which these curves were taken consisted of three No. 3/0 conductors flat spaced 14 ft. (427 cm.). The part of the line used was 37 miles (60 km.) long. Located as shown in Fig. 16 were two overhead ground wires consisting of No. 3/0 stranded steel wire grounded at each tower. Towers were spaced about 600 ft. There were no transpositions.

FIG. 16

LINE CONSTANTS

Neither the artificial line nor the actual line of practise corresponds exactly to the ideal line which is mathematically analyzed. This ideal line is considered to have four constants which are absolutely fixed, and which are the same at every point of the line. Hence it is to be expected that there will be a departure of experimental results from those indicated by this basic theory. No case in which these simplifying assumptions are not made has ever been completely analyzed mathematically.

Our experimental results indicate, except for the peculiar initial departure noted above, that the actual progress of waves in practise follows that predicted by theory except at the wave front. Simple theory indicates wave fronts that diminish in height but remain strictly perpendicular. The wave fronts of practise are rounded off.

The physical aerial line departs from the simple case assumed in analysis in the following particulars:

1. *Skin Effect.* This is better designated as the imperfect penetration of current into the wire at the wave front. Due to this imperfect penetration the front of the wave meets a resistance greater than the continuous current resistance of the conductor. This effect undoubtedly changes the wave front slightly.

2. *Ground Effect.* This includes the effect of the ground, the ground wires, parallel lines, or other neigh-

boring structures. In each of these there will be induced accompanying transients, due both to electrostatic and electromagnetic induction. But little is now known of the extent of the modification introduced by these factors. The effect of a short-circuited ground wire loop is probably worth considerable study. The presence of the ground offers in practise the possibility of transients between wire and ground as well as between wires. These can only occur if the terminal apparatus is grounded, or contains sufficient capacity to ground. The constants which apply for such a transient are doubtful on account of the imperfect conductivity of the ground.

3. *Radiation from the Line.* This factor has recently received considerable attention. A paper by Manneback⁴ shows its effect on single waves to be negligible to engineering accuracy.

4. *Periodicity in the Line.* This is due to several causes such as the sag of the line wires, the lumping of leakance and, to a small extent, capacity, at the towers, etc. This probably gives the line a slight filter effect and tends to remove high frequencies from the wave front.

5. *Corona.* The height of voltage waves is probably greatly affected in practise by corona. This is of much importance practically, for the high-voltage line is thereby relieved of some of the grief due to traveling waves. The effect of corona on transients has not as yet been investigated. An experimental study of voltage and harmonic distribution on a line due to corona was recently made at the Institute, but has not yet been reported upon. This work was carried on by means of artificial corona leaks applied to an artificial transmission line in the steady state. These leaks were built of thermionic tubes or triodes so controlled as to pass current in a manner similar to that passed by corona on an aerial line. It is thought possible to throw some light on the effect of corona on transients by using these leaks in a transient investigation.

For transients on power cables there is an additional modifying factor:

6. *Effect of Solid Dielectric.* The loss in the dielectric appears as a leakance on the line. Assuming a constant phase angle of dielectric, the corresponding leakance is proportional to the frequency, and not a constant. This again tends to remove high frequencies from the wave front.

The artificial line used in the tests is practically free from factors 1, 2, 3 and 5. It includes factor 4, periodicity, in a somewhat different manner from, and to a greater extent than the real line. The capacity and resistance of the artificial line are strictly distributed. Its inductance is to a certain extent lumped in sections due to the mutual inductance between turns. This introduces a filter action, the amount of which is now being studied. It also undoubtedly results in a

4. Chas. Manneback. Radiation from Transmission Lines. Jour. A. I. E. E., Feb. 1923.

higher speed of propagation of the extreme front of the wave than would be found on the line being represented. Both effects influence principally the steepness of wave front.

The artificial line also includes factor 6, and to about the correct extent to simulate cable action. The leakance of both real and artificial lines is negligible except for the effect of loss in the dielectric. This again modifies wave front.

It is hence not yet possible for the artificial line to yield complete information regarding the steepness of wave front to be found on physical lines. In other respects it gives reasonably accurate duplication, and its use will probably increase for the study of all kinds of transients upon networks which are too complicated for mathematical analysis. It is of importance to inquire how important in practice is this matter of steepness of wave front, which cannot be either experimentally or theoretically determined at present.

WAVE FRONTS AND OVERVOLTAGES

During the system transient characterized by traveling waves we are interested primarily in the abnormal voltages which may appear at various parts of the network, their duration and the number of times they are repeated. Later, during the second class of transient, when machine constants enter as a controlling factor, we are principally interested in abnormal currents, and in the mechanical stresses and the switch duty thereby imposed. During the first part of the disturbance following a switching operation, however, we are interested in waves of current only in so far as they may result in abnormal voltages.

It is this first transient that we are here studying. It is ordinarily over long before a relay or a switch can act. Mechanical stresses due to high currents which might appear in this brief interval are also of such short duration that they cannot produce mechanical breakdown with the usual amount of inertia present. The only factor capable of causing damage during the brief interval of the first transient is an overvoltage. We are interested in traveling waves only in so far as they may result in high-voltage stresses, long maintained, or often repeated.

Much has been written about steepness of wave front, and an exaggerated idea of its importance has as a result been popularly produced. We need consider the steepness of a wave only as it affects the voltages produced by the wave. Steepness of wave front even of a current wave can in itself produce no harm.

The transformer is the usual terminal apparatus on physical lines. This is a system with decidedly distributed constants, containing capacity both between turns and to ground. The impact of an incoming wave of voltage over a line upon a terminal transformer is in the first instant exactly equivalent to the sudden application to the terminal or terminals any other means of the same voltage as that pro-

duced by the incoming wave. By the first instant, in this connection, is meant the time during which the transformer transient is determined by its capacity between coils and to ground, and before appreciable current has begun to flow in the windings. It is during this period that the maximum potentials ordinarily occur. It makes little difference in the effect produced whether the voltage thus suddenly applied grows to its maximum value in one or one hundred microseconds. The worst case that can happen, for a given maximum voltage, is to apply it directly and suddenly to the transformer terminals without an intervening line. The effect of the line on the wave front can be only in one direction, namely to decrease slightly the suddenness of application. As far as voltage waves are concerned, therefore, we have nothing to fear on account of steepness even when the strictly perpendicular wave front impinges upon a terminal transformer.

The presence of a long transmission line may indeed have an important influence in connection with the effect produced on terminal apparatus during switching, but this influence is usually entirely apart from any question of the steepness of wave front. When a continuous voltage, E say, is suddenly applied directly from a generator to a pair of transformer terminals, the voltage across the terminals very rapidly arrives at the value E and stays there. Due to the inductance of the source and the distributed electrostatic capacity of the transformer, the terminal voltage will, in fact, rise instantaneously to nearly double, and then oscillate about its final value E . The duration of this oscillation is fortunately exceedingly brief, as it is determined by the natural period of a circuit consisting substantially of the inductance of the leads in series with the distributed capacity of the transformer and of the source. Hence in switching a transformer onto a generator, we do not ordinarily have to consider, as far as insulation is concerned, that there is any overvoltage produced at all. It takes time as well as excess voltage to produce a breakdown.

If now, however, a long transmission line be introduced between the source and the terminal transformer, a new condition must be considered. Upon closing the switch a wave of voltage of height E runs down the line. Upon arriving slightly attenuated at the transformer, this wave is reflected in the first instant nearly as though the end of the line were open, for at first the transformer inductance prevents it from drawing appreciable current. The voltage wave is thus reflected and nearly doubled. This doubled voltage then persists across the transformer until the arrival of the next wave, or until the flow of current into the transformer drags it down. We thus have across the transformer terminals an overvoltage which can last for a considerable period, and hence may be capable of producing breakdown. The presence of the line, while it has been able to affect the amount of voltage produced or the suddenness of its application only in a

favorable direction, has nevertheless introduced a longer duration of the overvoltage which may be serious.

The distribution of potential in a transformer during the interval after the sudden application of a terminal voltage is determined by the distribution of capacity, much as is the case with a string of suspension insulators. End coils will hence receive more than a proportional share of the overvoltage. This is the reason for wider spacing on transformer end turns. When current begins to flow in the windings a redistribution of voltage occurs, as well as a decrease in the voltage at the terminals. This matter has been treated by Blume and Boyajian.⁵

A wave does not progress into the transformer in any such manner as it progresses along the line, for the mutual inductance and capacity both between coils and to ground profoundly modify the action.

Thus far in this section we have considered incoming waves of voltage only. It remains to discuss the effect of the accompanying incoming waves of current, for a voltage wave is always accompanied by a current wave approximately proportional to it. This matter can, however, be dismissed without a detailed separate investigation.

The voltages produced throughout a piece of terminal apparatus by an incoming wave of voltage may be completely analyzed from a knowledge of the voltage only. Any failure to compute the voltage produced at any point will be due to lack of analytical ability, and not to deficiency of premises. The system is completely fixed once the constants of the apparatus and of the line, and the amount of voltage, are given. The wave of voltage is accompanied by a wave of current. Can this wave of current, penetrating the apparatus, produce disastrous effects? Obviously it can produce only those voltages which have already been found from an analysis of the effect of the voltage wave. We are interested in overvoltages. Hence if we will completely treat the effect of an incoming wave of voltage, we can forget about the accompanying wave of current, knowing that we have completely taken it into account.

It follows, therefore, that the steep wavefront of current is entirely innocuous, in any case where the sudden application of the corresponding voltage does no harm. This may seem strange, for the impact of a perpendicular wave of current on a piece of highly inductive terminal apparatus looks dangerous offhand; but reflection will show that the danger is very likely to be entirely visionary.

A perpendicular rise of current in a coil entirely devoid of distributed capacity would indeed result in an infinite voltage between turns. But such a condition can never exist, first, because we cannot build an inductance which is devoid of distributed capacity, and second, because even if we could, we could not cause an instantaneous rise of current in the windings by any means whatever. It is well to remember that the current can

never change with entire suddenness by any finite amount of change, however small, in any finite length of conductor, however short, or however connected.

A perpendicular wave of current traveling down a line and meeting a terminal inductance with negligible distributed capacity will be entirely reflected in the first instant and not penetrate at all. The accompanying voltage wave will be completely reflected and doubled. After the production of this double voltage, the current will begin to flow in the coil, beginning at an initial rate of $2E/L$ amperes per second, where E is the height of the incoming voltage wave. As current flows, the terminal voltage will drop.

When the capacity between turns of the coil is considerable, and the capacity to ground negligible, an incoming wave of voltage will at first be reflected with change of sign, and the terminal voltage will be instantaneously zero. The current wave will be reflected and doubled. This is because the lumped capacity across the line acts in the first instant like a short circuit. The period during which it thus acts is exceedingly brief, for it soon charges to a potential $2E$. Thereafter reflection is as though it were not present, and the same effect is produced as in the preceding paragraph.

When capacity to ground is also considerable, reflection will be incomplete and of either sign, depending upon the relation of inductance and capacity.

An incoming voltage wave may thus be reflected at terminal apparatus in such manner as to practically double. The accompanying current wave can produce no greater voltage than this doubled voltage, but it may produce it in unexpected places. If, for example, an air core choke coil is inserted in the line, with very little distributed capacity to ground, then the advent of a steep wave may throw nearly doubled voltage across the turns of the coil. The effect is nearly the same in the first instant as though the line at the far end of the coil were short-circuited. The effect of the incoming waves can be analyzed much more easily in nearly every case by considering the effect of the voltage wave only. The current wave which accompanies it can produce no other voltages than those determined by this analysis.

It is not meant by this discussion to indicate that steepness of wave front can always be entirely ignored. Sometimes the lack of entire suddenness of voltage application is important. In most cases in practise, however, it may be considered to be only a modifying factor, the influence of a line upon which is always in the advantageous direction and increasing with length of line.

We may thus conclude that the principal factors to be considered in traveling waves are the magnitude and the duration of the voltage produced, and the portions of the apparatus which receive the overvoltage. In regard to these factors, experiment both upon the artificial line and the physical line checks reasonably well with elementary theory.

5. TRANS. A. I. E. E., Vol. XXXVIII, p. 577.

ATTENUATION

A wave of voltage arriving at the open end of a line is entirely reflected without change of sign, and hence completely doubles. The end of the line experiences momentarily a maximum voltage of twice the value of the incoming wave. This maximum voltage is altered after the first instant by attenuation and change of wave form.

This is illustrated in Fig. 17, which is an oscillogram of voltage at the distant end of an open artificial line of length 330 miles (537 km.). The voltage here does not initially rise to twice its final steady value because of

FIG. 17

attenuation in this long length of line. This oscillogram, and others of the voltage on the line, were taken by means of the thermionic tube repeater attachment described by Dellenbaugh, in order to avoid disturbing the electrical condition of the line. For a shorter line the voltage would more nearly double. The attenuation factor is

$$E - \left(\frac{r}{2l} + \frac{g}{2c} \right)^t$$

For an aerial line g is usually negligible. In the case of the No. 00 conductor line spaced 8 ft. 9 in. which is represented by the artificial line here used, the ratio of r to l is 216, and hence the exponent α is 108. The time

FIG. 18

of propagation over 330 miles (537 km.) is approximately 0.00177 seconds. The duration of overvoltage at the receiving end is thus 0.0036 seconds. This may be checked by the timing wave on the oscillogram. The damping factor for one run over the line is

$$e^{-108t} = e^{-0.191} = 0.826$$

In the oscillogram Fig. 17 we find by measurement that the voltage at the end rises instantaneously to approximately the value given by this attenuation factor, that is by $2 \times 0.826 \times E = 1.65 E$, where E is the suddenly applied potential.

It would appear offhand that it should rise to a value much less than this because of distortion. A wave when running over a line assumes the shape shown in Fig. 18,

even on the ideal line with fixed uniform constants. The decrease in height of wave front is given by the attenuation factor. In the appendix is derived an expression for this wave form which it is felt may have some utility on account of simplicity.

For a short line the attenuation factor is small. Hence on a short line the voltage at the open receiving end will reach very nearly double the applied voltage. The high voltage will of course persist for a much shorter period than on the longer line, but it will be more frequently repeated.

REFLECTION AND REFRACTION AT JUNCTIONS

When a wave meets a junction between lines of different constants it is partially reflected and partially refracted into the second line. If we write

$$\gamma = \sqrt{\frac{c}{l}}$$

FIG. 19

and use subscripts for the two lines, the coefficients of reflection and refraction are

$$\frac{\gamma_2}{\gamma_1 + \gamma_2} \text{ and } \frac{\gamma_1 - \gamma_2}{\gamma_1 + \gamma_2}$$

The resistance of each line is assumed small, as will always be the case in practise. One is the coefficient of reflection and the other the coefficient of refraction. The coefficient of reflection for the voltage wave is the coefficient of refraction for the current wave, and vice versa. The voltage is always increased on passing into a line of smaller γ . These rules are sufficient to map out the progress of waves over junctions when attenuation and distortion are neglected.

When a power cable and aerial line are joined, the ratio of inductance to capacity is so widely different for the two parts that γ for the aerial line may be neglected to a first approximation compared to γ for the cable. Reflection and refraction are thus practically complete at the junction during the first instant. Neglecting attenuation and distortion the progress of waves over such junctions may hence be readily mapped. In Fig. 19 is shown the progress for an aerial line and cable in

series, a voltage being suddenly applied to the cable, and the distant end of the line being open. For short lines where attenuation and distortion are small, it will be seen that several times normal voltage may be produced in this manner. Very little current penetrates into the aerial line, although of course the ratio between voltage and current waves in each line is always γ for that line.

REFLECTIONS AT APPARATUS

A wave impinging upon a lumped inductance devoid of distributed capacity will be in the first instant completely reflected.

FIG. 20

The effect of the distributed capacity in the coil is to make this reflection in the first instant incomplete, the reflection coefficient being roughly that given above for junctions between lines.

When time has elapsed sufficient for the inductance to show appreciable current through its windings, it reflects less of the wave. Finally it may reflect with reversed sign if the line is long enough for this effect to have time to occur before the next wave arrives.

In the oscillogram of Fig. 20, taken on a line with an inductance load, this effect is clearly shown. The curve

FIG. 21

is of current at the home end. The initial surge of current is identical with that of Figs. 4 and 9, for until the arrival of the reflected wave back at the home end, the conditions at the distant end can exert no influence on the home end current. The first incoming reflected wave of Fig. 20 is comparable in the first instant with that of Fig. 9 where the distant end is open, but is somewhat less in height on account of distributed capacity in the terminal inductance. This wave, however rapidly reverses as the inductance begins to draw current, and before the arrival of the second wave has become of opposite sign, and nearly the same as the

corresponding part of the wave of Fig. 4, differing from it also on account of the resistance of the terminal inductance. The second incoming wave repeats this effect with opposite sign and attenuated by an additional trip down the line and back. Fig. 21 shows the voltage produced across the inductance during this transient.

Fig. 22 shows the corresponding behavior with a terminal condenser. Such a condenser acts in the first instant like a short circuit, so that the wave of current comes back without change of sign. This condition is reversed as the condenser accumulates a charge.

The relation of inductance to capacity in the termi-

FIG. 22

nal load may be such that no reflection at all occurs in the first instant. The same effect may be obtained by a terminal resistance equal to $1/\gamma$ of the line. This effect is shown in Fig. 23, which is an oscillogram of entering current under this condition. There is a slight remaining indication of a reflection, due probably to a capacity in the resistance used, and only approximate equality between the terminal resistance and $1/\gamma$ of the line.

OPENING OF CIRCUIT

When a line is opened, by a switch or by a wire breaking, the current is suddenly decreased at that

FIG. 23

point from the previous value I to zero. A wave of current, a depression in this case, then runs over the line and reduces the current to zero on the line as it goes. This wave of current is accompanied by a wave of voltage of height I/γ , which is superimposed upon the voltage previously existing on the line. The voltage appearing across the line just outside the break is hence in the first instant equal to $E - I/\gamma$, and may be large or small, positive or negative, according to the value of the current broken.

This is shown in Fig. 24 and Fig. 25. In the former,

taken on the full length of the line, and interrupting short-circuit current, the value of I/γ is less than E so that the voltage at the break remains positive, but nearly zero. In the latter, using one-third the length of line, the current is three times as great so that the voltage rises to nearly twice E negative. The voltage of the curves is the voltage between lines just outside the switch. It was measured by the thermionic tube attachment, for otherwise the line conditions would have been much affected by the presence of the oscillograph.

FIG. 24

The voltage across the break is different. If the break occurs in the middle of the line, as by breaking a wire, the voltage that appears is $2I/\gamma$. If at the end, it may be instantaneously approximately $E + I/\gamma$, for the voltage applied by the source will nearly double for an instant due to its inductance.

The voltage appearing at a break may be very large, and has nothing to do directly with the normal voltage of the circuit. Thus if the line tested above were made 33 miles (54 km.) long, the voltage appearing on opening a short circuit would be about 9 times the voltage existing before the switch was opened.

FIG. 25

In ordinary alternating-current switching the oil switch holds the arc for several cycles, and then snuffs out at the zero of current. This prevents such effects as just described occurring in normal switching. When a wire breaks, the case is different.

The maximum voltage on breaking a circuit need not appear at the point of breaking. The voltage wave running over the line may be nearly doubled at an open end or a transformer winding. There may be open ends present even when heavy currents are broken, for the line may divide into branches, one of which is open. Reflections and refractions at bifurcations may

be computed by the usual reflection and refraction coefficients, using γ for the parallel combination of the two lines into which the wave passes.

A special case may occur when a line, terminating in a transformer at the distant end and carrying a heavy current, is suddenly interrupted at the near end. In this case the wave of voltage running over the line is reflected without change of sign at each end, and hence builds up continuously, and to a large extent, particularly if the line is short in length. Some of these cases have been discussed by Wagner.

An oscillogram for this last condition is shown in Fig. 26. The voltage measured is that at the distant end of the line across the terminal inductance. The switch opened at the home end during the straight portion of the curve. The first wave of voltage arrived at the distant end and approximately doubled by reflection, producing a voltage instantaneously of about five times the previous value due to resistance drop. The second wave which arrived was of the same sign and tended to continue to build up the voltage. The third and fourth waves may also be seen. In this case

FIG. 26

the line was very long, 990 miles, so that the drop in voltage due to the change of current in the terminal inductance, which occurred in the interval between wave arrivals, prevented the voltage from actually building up in value by reason of the successive reflections. In fact the current change in the inductance actually caused the terminal voltage to reverse in sign. With a shorter line the reflections would have arrived at more frequent intervals and less attenuated, there would have been little opportunity for the inductance to alter its initial value of current, and the voltage would have built up to a high value. In practise such an effect would be likely to result in a circuit breakdown, and very probably at a point distant from the initial break.

EFFECTS IN POLYPHASE CIRCUITS

The above discussion has been confined to single-phase circuits and with continuous applied potentials. The commercial polyphase circuit introduces two new factors for consideration.

If the line is short, then the first transient is practically over before the applied potential can have varied much at commercial frequencies. In this case continuous potential analysis suffices to give an excellent idea of the transient. On the other hand if the line,

or combination of lines forming the system, was 750 miles long, a trip down the system and back would occupy one half-cycle. Thus a wave started by a potential of one sign would, on its return, become superimposed upon a voltage of opposite sign. If long cables are involved, the speed of propagation is decreased so that this effect is more likely to at least partially appear. If the dielectric constant of the cable paper is taken as 4, the speed of propagation will be approximately halved.

Also in polyphase circuits several single-phase circuits are involved and may carry transients simultaneously. A wave in one circuit will, in general, be accompanied by an induced wave in a parallel circuit. The presence of ground provides other circuits in which transients may occur. The combined effect of these transients may, for the case of assumed fixed constants, be obtained by analyzing each one separately and combining the results. Interesting cases may easily arise.

For example, take the case of closing a three-phase oil switch on a long line. The switch points do not close exactly simultaneously. When the first point closes, a transient follows between the wire thus excited and ground. When the second point closes this is followed by a second transient line to ground, and a transient between wires. The third point produces a transient wire to ground and two transients between lines. There are also induced transients. Suppose the points close in a particular sequence and at intervals corresponding to the reflection interval. The separate transients may easily superpose in such manner that voltages are produced much in excess of those produced by one transient alone.

Little has been done on polyphase transients of this type as yet. They offer an attractive field for investigation. It is quite possible that the occasional mysterious breakdowns which occur in systems upon closing a particular switch may result from especially unfortunate combinations of primary transients, and that some of these effects might be considerably modified by a slight change in an oil switch.

Appendix

The analysis of waves on lines as found in the literature usually makes certain simplifying assumptions in the mathematics, which amount to neglecting changes in wave form.⁶ The result is a solution which is expressed in terms of rectangular waves, and which hence gives no information, for example, concerning the maximum voltages produced on reflections. Carson's extension of Heaviside's analysis gives exact solutions, which unfortunately involve laborious computations in order to attain numerical results. In communication circuits, which are electrically very long, it is usually necessary to adhere to exact solutions, and Carson's mechanical methods greatly reduce the labor involved.

6. For example consult Wagner, *Elektromagnetische Ausgleichsvorgänge in Freileitungen und Kabeln*—Pub.

The power transmission circuit is in general of much less electrical length. It hence appears desirable to develop solutions which are approximate, but in which the degree of approximation is carried one step further than is usually the case. Such solutions will be sufficiently accurate for the transmission line of lengths now in service, and will be more easily employed than the complete solution. This note will outline how this can be done for one case of interest, namely the propagation of waves on a line open at the distant end when a steady voltage is suddenly applied at the home end.

The differential equations are

$$\begin{cases} \frac{\partial i}{\partial x} = -c \frac{\partial e}{\partial t} \\ \frac{\partial e}{\partial x} = -R i - L \frac{\partial i}{\partial t} \end{cases} \quad (1)$$

when the line is assumed without leakance, as is warranted in the case of the aerial line. A solution of these equations for e is then

$$e = e^{-\alpha t} \sum_n (A \sin n t + B \cos n t) (a m \cos m x - b m \sin m x)$$

$$\text{where} \quad \alpha = \frac{R}{2L} \quad (2)$$

$$\text{and} \quad m^2 = LC(\alpha^2 + n^2) \quad (3)$$

Determining the constants A , B , a and b of integration for the terminal conditions above outlined, we have

$$e = E - \frac{4E}{\pi} e^{-\alpha t} \sum_k \frac{1}{2k+1} \sin m_k x (\cos n_k t + \alpha/n_k \sin n_k t) \quad (4)$$

where $m_k = \pi(2k+1)/2l$, l is the length of line and K is given the values 0, 1, 2, 3 At this point it is usual to introduce the approximation of assuming α/n_k negligible in comparison to unity. With this assumption equation (4) may be written

$$e = E - \frac{4E}{\pi} e^{-\alpha t} \sum_k \frac{1}{2k+1} \sin m_k x \cos n_k t \quad (5)$$

which can be altered into the form

$$e = E - \frac{2E}{\pi} e^{-\alpha t} \sum_k \frac{1}{2k+1} \sin(m_k x + n_k t) - \frac{2E}{\pi} e^{-\alpha t} \sum_k \frac{1}{2k+1} \sin(m_k x - n_k t) \quad (6)$$

and again neglecting α^2 in expression (3) we may write

$$e = E - E/2 e^{-\alpha t} 4/\pi \sum_k \frac{1}{2k+1} \sin m_k (x + v t) - E/2 e^{-\alpha t} 4/\pi \sum_k \frac{1}{2k+1} \sin m_k (x - v t) \quad (7)$$

This solution states that the voltage on the line after closing the switch is given by a constant value E less the sum of two waves, each of height $E/2$ and wave length $4l$, of rectangular form, one of which moves to the left and the other to the right at the velocity of

light v . At the time $t = 0$, the two waves coincide as shown in Fig. 27, and the voltage on the line is given as everywhere zero. At the end of an eighth period we have the conditions shown in Fig. 28, with a wave of voltage out to the distance vt . Further diagrams will show the course of reflections, etc. The diagram of Fig. 28 is drawn neglecting the factor $\epsilon^{-\alpha t}$. When this

FIG. 27

is included the rectangular waves will shrink in size as they proceed. A discrepancy will now be immediately noted. Redrawing the diagram for this instant and adding the waves we see that the solution predicts a small voltage out on the line at distances beyond the front of the wave. This we know to be contrary to fact, and it is produced by the neglecting of α/n_k in the derivation. In fact to the same approximation we could have written unity in place of $\epsilon^{-\alpha t}$.

FIG. 28

The solution also gives no correct information regarding the voltage produced at the first reflection at the end of the line, and we are interested in the correct value of this voltage.

Let us therefore review the derivation and retain the terms α/n_k but neglect $(\alpha/n_k)^2$ compared to unity. For the line reviewed in the paper α/n_k has a maximum value of about 0.2 for a length of 500 km., and $(\alpha/n_k)^2$

FIG. 29

ing value of 0.04. The neglecting of the is hence seen to be warranted in a typical the neglecting of the first power is liable to error.

ay hence continue to write (3) as

$$m_k v = n_k$$

The term of equation (4)

$$(\cos n_k t + \alpha/n_k \sin n_k t)$$

may be written

$$\cos (n_k t - \alpha/n_k)$$

for neglecting $(\alpha/n_k)^2$ we have

$$\cos \alpha/n_k = 1$$

(8)

$$\sin \alpha/n_k = \alpha/n_k$$

The expression (4) thus becomes

$$e = E - \frac{4E}{\pi} \epsilon^{-\alpha t} \sum_k \frac{1}{2k+1} \sin m_k x \cos (n_k t - \alpha/n_k)$$

FIG. 30

and transforming as before

$$e = E - E/2 \epsilon^{-\alpha t} 4/\pi \sum_k \frac{1}{2k+1} \sin m_k (x+vt-\phi_k) - E/2 \epsilon^{-\alpha t} 4/\pi \sum_k \frac{1}{2k+1} \sin m_k (x - vt + \phi_k) \quad (9)$$

where

$$\phi_k = \frac{\alpha}{m_k n_k} = \frac{\alpha}{m_k^2 v}$$

FIG. 31

We have as before two waves which run in opposite directions over the line, attenuated by a factor $\epsilon^{-\alpha t}$, but they are no longer of rectangular shape. The shape of the component waves is constant, so we shall examine it at time $t = 0$. The wave of equation (9)

$$- E/2 4/\pi \sum_k \frac{1}{2k+1} \sin (m_k x - m_k \phi_k)$$

FIG. 32

may, by the use of (8), be written

$$- E/2 4/\pi \sum_k \frac{1}{2k+1} \sin m_k x + E/2 4/\pi \sum_k \frac{1}{2k+1} m_k \phi_k \cos m_k x \quad (10)$$

The first term gives the previous rectangular wave shown in Fig. 29. The second term is a correction term to be added to take account of distortion. It may be written

$$E \frac{4 \alpha l}{\pi^2 v} \sum \frac{1}{(2k+1)^2} \cos m_k x \quad (11)$$

This is plotted in Fig. 30. It consists of a fundamental term of wave length $4l$ and height $E \frac{4\alpha l}{\pi^2 v}$, plus a 3d harmonic of $1/9$ the amplitude, and so on.

The combination of Fig. 29 and 30 gives the complete

FIG. 33

wave shape shown in Fig. 31. Similarly the other wave of equation (9) is plotted in Fig. 32. The progress of the voltage on the line may now be obtained by combining these component waves as before.

The positions at $t = 0$ are shown in Fig. 33. The voltage on the line again adds up to zero everywhere as it should at this instant. Move the waves slightly

FIG. 34

in position as shown in Fig. 34, and we have the conditions one eighth-period after closing the switch. It will be noted that beyond the point to which the wave of voltage has progressed we now have very approximately zero voltage on the line.

A quarter-period after switch closing we have the position of Fig. 35. Summing the waves we have the

FIG. 35

resultant voltage as shown in Fig. 36. This is the instant that the voltage has just arrived at the distant end of the line. An instant later, reflection has occurred, and the combination of the waves gives Fig. 37, and so on.

The voltage produced at the distant end on the first reflection is given by adding the values of the compo-

nent waves for this instant. This gives for the instant just before reflection

$$e_B' = E + E/2 \epsilon^{-\alpha t} - \epsilon^{-\alpha t} E \frac{4\alpha l}{\pi^2 v} (1 + 1/9 + 1/25 + \dots) \quad (12)$$

$$- E/2 \epsilon^{-\alpha t} - \epsilon^{-\alpha t} E \frac{4\alpha l}{\pi^2 v} (1 + 1/9 + 1/25 + \dots)$$

But

$$(1 + 1/3^2 + 1/5^2 + \dots) = \pi^2/8$$

FIG. 36

and hence (12) may be rewritten

$$e_B' = E \left[1 - \epsilon^{-\alpha t} \left(1 + \frac{\alpha l}{v} \right) \right] \quad (13)$$

At the instant under consideration

$$t = l/v$$

Also

$$\alpha t = \frac{\alpha l}{v} = \frac{\pi \alpha}{2 n_0}$$

and $\epsilon^{-\alpha t}$ may be written to the same degree of approximation as before

$$\epsilon^{-\alpha t} = 1 - \alpha t$$

Inserting these in (13) we have

$$e_B' = E [1 - (1 - \alpha t) (1 + \alpha t)]$$

and thus to the same approximation

$$e_B' = 0$$

FIG. 37

which is physically evident for the instant before the wave arrives.

Similarly an instant after reflection we have

$$e_B'' = E [1 + (1 - \alpha t)^2]$$

$$\text{or } e_B'' = 2E [1 - \alpha t]$$

and as before

$$e_B'' = 2E \epsilon^{-\alpha t}$$

The voltage produced at the distant end on the first reflection is thus given by applying the attenuation factor $\epsilon^{-\alpha t}$ and doubling the resultant voltage. The expression for the current is unaltered by this second approximation.

Other cases of interest may be treated by the same method of approximation.

Discussion

A. Boyajian: I believe one of the puzzling discrepancies, viz., the nature of the wave front, mentioned in this paper is capable of a comparatively simple physical explanation.

Professor Bush states that theory shows the wave front ought to be perpendicular, regardless of the losses; that is, although the wave front will gradually diminish in amplitude due to losses, yet it should always remain perpendicular, but that contrary to theoretical considerations the oscillograms show a sloping and rounding of the wave fronts.

Of the factors that are mentioned as affecting wave front, one is skin effect. Professor Bush says that it is expected to influence the wave front slightly. I believe that skin effect is one of the two dominant factors in influencing wave front, and that for this reason. To get a steep wave front, we need infinite frequency. Now, skin effect increases with frequency, and for infinite frequency skin effect is infinite; that is, the resistance of a conductor for an infinite frequency is infinite. Since the voltages of the harmonics constituting the steep wave front are finite but the impedance of the line to them is practically infinite, therefore the infinite frequency which an absolutely steep wave front represents will be wiped out instantly. It, therefore, is impossible to maintain a rectangular wave front on a line of which the resistance increases with frequency, wiping out the higher harmonics faster than the lower harmonics and rounding out all corners, as the oscillograms show. A very good illustration of this is afforded by water waves. By throwing a pebble into a pool we can create an infinitely complex jagged wave at the very point where the stone falls into the water. What do we expect to notice five or ten feet away? An almost pure sine wave, free from all the steepness and jaggedness of the original wave. Here also the higher harmonics which are responsible for the steepness and jaggedness of the original wave are wiped out very fast, and only the lower harmonics reach any considerable distance, and the wave is then nicely rounded.

The second dominant factor in rounding steep wave fronts is the dielectric loss. According to the theory of the so-called "distortionless circuit," if the resistance and dielectric losses of a transmission line are equal, it transmits waves without distortion even though with a large degree of attenuation. This theory, however, is true only if the losses are the same for all frequencies, otherwise it is not true, and the presence of dielectric loss will further aid distortion. In telephone work the range of frequency necessary for transmission of clear speech is quite narrow, and the total conductor resistance including skin effect may be considered constant in that range of frequencies without serious error. The same assumption may also be made for the dielectric loss, assuming it as leakage loss. For these reasons it is possible to improve purity of speech-transmission on a telephone line by suitably loading it by inductances. However, when we come to the general problem of a steep front on a rectangular wave, which covers the range from direct current in the main body of the wave to practically infinite frequency at the very wave front, the increase of both resistance and dielectric losses with frequency can not be ignored, and the distortionless circuit does not exist. At the higher frequencies the loss in the dielectric is not leakage but true dielectric hysteresis loss which increases with frequency and has a distorting and rounding influence similar to skin effect. If the conductor and dielectric losses are or may be assumed equal to each other for any given frequency (although of a different value at each different frequency) the calculation of the distortion is considerably simplified.

In this connection I also wish to point out an inherent limitation of lumped artificial transmission lines. So far as operating frequency phenomena are concerned, lumped laboratory models are no doubt entirely satisfactory to duplicate the phenomena occurring on uniform lines, but when the problem is that of very frequencies, steep wave fronts, reflections, etc., is the labora-

tory model with lumped constants still an exact equivalent of the transmission line with distributed constants? A paper entitled "Abnormal Voltages in Transformers" presented before the Institute a number of years ago by Blume and Boyajian, analyzed in considerable detail the behaviors of lumped coils to very high-frequency voltages and steep waves. It was shown there that coils ordinarily treated as a pure inductance react as a complex network of inductance and capacity at the higher frequencies, and that for rectangular wave fronts they initially react as a condenser not as an inductance. Evidently, the study of very high-frequency waves and transients of transmission lines (which have distributed constants) by laboratory models (which have lumped constants with varying characteristics at increasing frequencies) is inherently limited and difficult.

Both Professor Bush and Professor Dellenbaugh deserve much credit for their painstaking investigations on artificial transmission lines.

J. F. Peters: In Professor Bush's paper I was rather surprised at the disagreement between the calculated surges and those recorded by oscillograms, Figs. 6 and 15. I note that the author states the mathematical solutions are based on the assumption that the line may be completely specified by four fixed constants, r, l, c, g ,—resistance, inductance, capacitance and leakance, per unit length of line. Calculations apparently are based on one value of resistance for all frequency components. Since a rectangular wave is made up of a large number of frequency components and resistance varies widely with frequency, especially high frequency, and all components of a traveling wave are of high frequency, it would be interesting to know what frequency the resistance used corresponded with.

Referring to the appendix, equations I do not restrict R to the same value for all frequency components. The solution of I, therefore, should have the summation sign included $e^{-\alpha t}$

Equations I are linear the same as I/R , representing voltage across a resistance is linear. In the latter case, if we want to determine the I/R of a distorted current accurately we resolve I into its harmonic components, multiply each component by the value of R that corresponds to that particular frequency and then add up the component voltages. In the same way, if for each frequency component in equation 9, corresponding to the different values of k , we use the value of α corresponding to that frequency, much better agreement will be found between calculated and measured values and in no way will we have violated the restrictions imposed by equations 1.

Joseph Slepián: I found the discussion on page 884 on wave fronts and over-voltages very valuable although some statements contained therein I think require modification.

It has come to be realized in the last few years that steep wave front surges have in them elements of danger to apparatus not possessed by more slowly increasing voltages and many may imagine that there will be something of a proportionality between the steepness of a wave front and its dangerous potentialities. But Professor Bush points out that the measure of the dangerous quality does not go up indefinitely with the steepness, but that even with an infinitely steep wave front only a finite degree of danger is imposed upon the apparatus.

This feeling that the steeper the wave front the more disastrous the effect of the wave on insulation has been responsible for numerous arguments as to the value of high-resistance lightning arresters. It is argued although such arresters do not have enough discharge capacity to reduce the energy or the voltage in the surge in any marked degree, they do taper off the wave front and thus remove the very dangerous character of the wave. However, even with infinitely steep waves there is a limit to the measure of this dangerous character.

Whether a wave front is steep or not, is of course a relative matter. A wave can never be infinitely steep; there must be

some slope to it. To be precise the steepness should be referred to some interval of time.

In all the cases, the time interval that the steepness of the wave should be referred to is the period of some natural oscillation of the apparatus being considered. For example, in the case of a transformer, when a voltage is suddenly impressed and maintained, the voltage distribution within the transformer will differ from the final voltage distribution; and the readjustment of voltage from the initial distribution to the final distribution will ordinarily take place in the form of an internal oscillation.

It is the time of this internal oscillation that is the determining factor as to whether a wave is to be referred to as steep or tapered, when its effect on the transformer is being considered. If the time in which the applied voltage rises to its maximum value is short, compared to the natural period of the internal oscillation, the internal oscillation will have practically its maximum amplitude and the maximum abnormal concentration of voltage on the internal parts of the transformer will be produced. But if the time in which the voltage rises to its maximum value is long compared to the natural period of these oscillations, the amplitude of these oscillations will be very much reduced and the distribution of voltage in the transformer will be more nearly the normal distribution.

The same thing is true as regards the multiplication of voltage on a transmission line, due to reflection at its end. The transmission line also has a natural period, namely: the time for the wave to run down to the end and back again.

Professor Bush states that with short lines a doubling of voltage will be produced just as in long lines at the remote end—assuming the remote end is open or connected to inductive apparatus. However, since lines are usually energized through inductive apparatus, the natural period of the line is going to come in in determining whether actually a doubling will be obtained or not, due to the transient of the line. That is, to produce a surge on a line requires something of the order of several amperes per kilovolt of surge. Inductive apparatus cannot deliver this current instantly; the surge produced by switching on a generator or transformer must build up relatively gradually, because of the inductance of the apparatus. If it builds up slowly compared to the natural period of the line, a doubling of voltage at the far end over that at the near end will not be produced. There may be an abnormal rise of voltage due to a transient including machine constants, but not one due to the line alone.

In practise, there usually are transformers, inductive apparatus at both ends, at the near end the inductance of the apparatus and at the far end the capacity of the apparatus will both operate to prevent a rise in the voltage at the far end due to switching at the near end, provided the line is not too long.

That is, if the natural period of the line is short, compared to the transients involving the machine constants, the line itself will introduce no new element of danger in raising voltage.

The only case that I can see where this doubling on short lines may be obtained is in the case of short-circuits. In the case of a short circuit, there is of course practically no inductance at the point where the short-circuit occurs and so waves may be produced sufficiently steep to double by reflection even on short lines. Fortunately, the polarity of the voltage induced by the short circuit is usually such as to merely reverse the voltage at the reflection point instead of doubling the normal voltage; that is, the voltage changes from plus normal voltage to minus normal voltage. Thus, the amplitude of the surge at reflection is twice normal voltage, but the actual voltage to ground is only normal. However, as regards its effect on the internal distribution of voltage within the reflecting apparatus it is still a surge of twice normal voltage.

Modern transformers are designed so as to be able to stand the sudden application of normal voltage. Hence if a surge does not greatly exceed normal voltage, we do not need to worry about its wave front provided the transformer is properly designed.

V. Bush: In regard to Mr. Boyajian's discussion, there is one point that I wish to emphasize. We have at present an analysis of waves on transmission lines only under the assumption of strictly constant R , L , C and G for the line, and we have no analysis for any other condition. If we could have an analysis which would take into account skin effect, for instance, or many other disturbing factors, it would be very valuable; but apparently such analysis is beyond the range of our present analytical ability. It is hence the purpose of this paper to show what an analysis, based on recognized limited assumptions, corresponds to in the actual case; and how far experiments on smooth artificial lines may be expected to yield reliable information in regard to the transient surges of practise.

In regard to Mr. Peters' comments: We can get a closer approximation to the observed waves if we will correct alpha, that is the attenuation factor, term by term in accordance with the frequency, but that procedure is hardly legitimate from a mathematical standpoint. If we have made a complete analysis on certain premises and then proceed to arbitrarily introduce into our answer certain new assumptions, we may come nearer to an observed result; but we are hardly rigorous in our mathematics.

In regard to Mr. Slepian's comments, there are many cases where we encounter waves that are very nearly perpendicular, and I am pleased that he has enlarged upon this particular point. For example, when an arc breaks, the wave which ensues is initially very nearly a perpendicular wave except for the correction which is due to the passage from the spherical wave to a plane one.

The Standardization of Electrical Measuring Instruments¹

BY H. B. BROOKS

Member, A. I. E. E.

Physicist, Bureau of Standards, Washington, D. C.

Review of the Subject.—This paper points out the advantages, both to the maker and the customer, of national standard specifications for manufactured articles. The history of standardization in England is outlined. British specifications for electrical instruments appeared first in 1909, and in improved and enlarged form in 1919. French specifications were adopted in 1921, German in 1922.

The outstanding features of the three foreign specifications are compared. The British go into much detail concerning scale construction and marking, the French concerning definitions and temperature rises. The German specifications contain very good definitions of instruments and their parts, principles, etc. They prescribe severe tests for mechanical and thermal robustness, and have an elaborate scheme of symbols to indicate the grade, operating principle, kind of current, test voltage, etc.

An account is then given of the consideration which the subject of instrument standardization has received in this country. The National Meter Committees have done a related piece of work by

having the Meter Code prepared and revised, and have made recommendations to the makers from time to time concerning matters of instrument standardization. The Instruments and Measurements Committee of the Institute has considered the foreign specifications, and has determined by a personal canvass that a majority of American makers are in favor of standardization. However, this canvass also showed that most of them would have felt much freer to discuss proposed standard specifications rather than the abstract question as to whether specifications should be formulated. The Instruments and Measurements Committee therefore appointed a subcommittee of four members to prepare such tentative specifications, which are given as an Appendix to the paper. The specifications omit some important topics because the Subcommittee wished to include at the start only those on which general agreement could be had without difficulty.

The paper concludes with a discussion of some of the features of the tentative specifications.

INTRODUCTION

WHILE the United States has led the world in applying the principles of interchangeability of parts and of quantity production to its manufacturing processes, it has only recently begun to appreciate the advantages of national standard specifications. The outbreak of war brought this question forward in very unmistakable fashion, and there is good reason to believe that at no distant time the advantages of "national uniformity of buying and selling requirements" will be as much appreciated here as abroad.

The purposes to be served by such specifications may be regarded from two standpoints. The manufacturer is benefited because he can devote his energies to certain definite lines for which the demand can be confidently anticipated. With the limitation of his output largely to standard grades, ranges, and finishes, unit-costs are decreased, demands can be more closely estimated, raw materials can be bought in fewer kinds and sizes and in larger quantities, and overhead costs are reduced. If the national specifications under which the maker works have attained a good standing abroad, a further important advantage is secured, in that surplus stocks are immediately available for export instead of goods made up specially with the attendant increased cost.

From the purchaser's viewpoint, standard specifications are useful in selecting the most suitable apparatus for given requirements, and in obviating the necessity for individual study and the preparation of independent specifications. It is only when the articles

bid on have been made under the same requirements as to quality and performance that an intelligent selection can be made from a number of bids. As an illustration of the condition that is produced by lack of standard requirements, we may cite current transformers. As now made, these are classified by each manufacturer in such general terms that a purchaser can readily pick out the extreme grades, especially with the relative prices as a guide. But it is not possible for him to choose the best transformer from the offers of several manufacturers, for the rating "50 volt-amperes, compensated for 25 volt-amperes," for example, does not throw much light on the matter, in the absence of uniform practice as to permissible ratio and phase-angle errors. The purchaser is compelled to fall back on his impressions of the relative standing of the manufacturers concerned.

Both manufacturer and purchaser lose in the absence of national specifications, on account of which different individual specifications necessarily arise. The diversity of requirements that may thus arise increases engineering and manufacturing costs and hence the cost to the purchaser. A case in point is that of Government specifications. The Navy Department, which very properly buys its supplies on definite specifications, is compelled to go to the expense of preparing complete specifications for electrical instruments, both for power-plant use and for radio purposes. If American standard specifications were in existence, the Navy Department could use them, with only a few added clauses to take care of the special requirements which exist only in naval work.

INSTRUMENT STANDARDIZATION ABROAD

The work of national standardization in Great Britain began in 1901 when the Council of the Institu-

1. Published by permission of the Director of the Bureau of Standards.

Presented at the Annual Convention of the A. I. E. E., Swampscott, Mass., June 26-29, 1923.

tion of Civil Engineers appointed a committee to consider the advisability of standardizing various kinds of iron and steel sections. The cooperation of three other British societies (Mechanical Engineers, Iron and Steel Institute, Naval Architects) was at once secured, and the work of preparing specifications was begun. A year after the formation of the "Engineering Standards Committee" it was suggested that the subject of electrical machinery and apparatus be included in its scope, and with the cooperation of the Institution of Electrical Engineers this work was begun. That the results of the labors of the Standards Committee have been appreciated is shown by its growth from a single committee of seven members to a great organization, the British Engineering Standards Association, consisting of a Main Committee of 24 members. The Report of the Association dated July 1, 1919, showed that 26 sectional committees appointed by the main committee were functioning, and that they had appointed 78 subcommittees and 144 "panel committees," making a total of 249 committees with an aggregate membership of over 1100. Another indication of the importance of the work is found in the range of subjects for which specifications have been prepared or are under way. As given in reports of January 1, 1923 these included:

Civil Engineering and Building Trade.....	25
Mechanical.....	36
Electrical.....	76
Automotive (Aircraft and Automobile)....	164
Transport.....	16
Ships and Their Machinery.....	42
Ferrous Metals.....	10
Non-Ferrous Metals.....	46
Chemical, Including Chemical Engineering	14
General.....	4

The first British Standard Specification for electrical instruments was No. 49 on ammeters and voltmeters, adopted in 1909, as the result of nearly two years of work by a subcommittee. Shunts, resistors, and instrument transformers were not included in this specification.

In 1919 this specification was superseded by No. 89 on indicating ammeters, voltmeters, wattmeters, frequency and power factor meters. At the same time two other related specifications were issued; No. 81 on instrument transformers and No. 90 on recording (graphic) ammeters, voltmeters, and wattmeters. Specification No. 89 was a very distinct advance over its forerunner, No. 49.

French standard specifications for electrical measuring instruments, instrument transformers, and shunts were prepared by a Technical Committee² with the collaboration of representatives of the makers, the Laboratoire Centrale d'Électricité, and a consulting engineer (Mr. A. Iliovici) specializing in electrical

instruments. These specifications³ were adopted by the Chambre on January 20, 1921.

German specifications for electrical instruments were prepared by a committee of the Verband Deutscher Elektrotechniker. A proposed draft was published⁴ in March, 1921, and was intended to become effective on July 1, 1922. This draft evoked criticisms and suggestions which were used in preparing a considerably revised one, which appeared⁵ a year later. This revised draft was adopted by the Verband at its 1922 meeting, and is to go into effect on July 1, 1923.

German specifications for instrument transformers⁶ were prepared by the Verband, and went into effect on July 1, 1922.

It is of interest to compare the outstanding features of these three national specifications. In general, the British specifications are probably the most satisfactory from the American viewpoint, though they leave some important points untouched. They treat with considerable detail the important question of scale construction and marking. Three classes as regards accuracy are provided, called Sub-standard, First Grade, and Second Grade respectively. Insulation and dielectric strength are carefully specified. Limits of error are given for the three grades, and limiting values of influences of operating conditions (temperature changes, frequency changes, external magnetic fields, etc.).

The French specifications open with an elaborate set of definitions, which in the main are very good. Instruments are classified first into two groups, Laboratory and Industrial, the former including special or delicate devices used either to measure very small magnitudes or to measure ordinary magnitudes with high precision.⁷ The second broad classification is denoted Industrial Instruments, and is further divided into Standard Instruments, Control⁸ Instruments, Switchboard Instruments, and Ordinary Instruments, of which latter all that is said is "This group includes all measuring instruments of which the essential quality is a low price." Requirements stated for the other classes include accuracy, damping, mechanical robustness, heating, and dielectric strength. The French specifications are the only ones which give a list of recom-

3. They were published in *Revue Générale de l'Électricité*, vol. 9, pp. 119c-134c, May 28, 1921.

4. *Elektrotechnische Zeitschrift*, vol. 42, p. 324, March 31, 1921.

5. *Elektrotechnische Zeitschrift*, vol. 43, p. 290, March 2, 1922. Some minor corrections and changes were published in the same journal, vol. 43, p. 1074, August 17, 1922.

6. *Elektrotechnische Zeitschrift*, vol. 42, pp. 209, 836; Mar. 3, July 28, 1921.

7. Actually, the French specifications do not cover these special laboratory devices, nor do either of the other national specifications.

8. This is a literal translation; "working-standard" is perhaps a better rendering.

2. Of the "Chambre Syndicale des Constructeurs de gros Matériel Électrique."

mended ampere ranges⁹ for the current coils of instruments.

The French specifications go into great detail in regard to the permissible temperature rises of conducting materials and various kinds of insulating materials in instruments.

The German specifications divide instruments as follows:

Precision Instruments,	first class
"	" second "
Operating	" first "
"	" second "

They contain a very good set of definitions of instruments and their parts, operating principles, ranges, kinds of cases, etc. They introduce a concept not found in either of the other specifications, namely, "minimum creeping distance," which is defined as the shortest path along which current can flow over the surface of an insulator between metal parts which have a difference of potential between them.

In addition to prescribing limits of accuracy and for the effects of temperature change, etc., the German specifications are unique in specifying a maximum distance of the pointer from the scale, and in requiring switchboard voltmeters and ammeters to be capable of carrying continuously a voltage or current 20 per cent greater than full-scale value. When it is considered that this overload means a heat loss in the instrument 44 per cent more than that caused by rated voltage or current; that voltmeters are ordinarily installed to work on about three-fourths of full-scale value; and that even full-scale value on a switchboard ammeter usually corresponds to an overload condition of the associated apparatus, it seems that the German requirement will involve some economic waste of materials in the construction of instruments.

In addition to the stipulated accuracies of precision instruments, the German specifications permit additional errors in the following cases:

For instruments having voltage circuits exceeding 250 volts, 0.1 per cent additional;

For instruments with interchangeable series resistors, 0.1 per cent additional;

For instruments with interchangeable shunts, 0.2 per cent additional.

Another outstanding feature of the German specifications is the extent to which they carry the use of symbols to serve as concise statements of certain features. In addition to the letters *E*, *F*, *G*, *H* denoting the four classes above mentioned, symbols are provided for the following kinds of current: d-c., a-c.; two-phase, balanced three-phase, unbalanced three-phase, and four-wire three-phase. Position symbols show that instruments are for use in horizontal, vertical, or oblique position. Another set of symbols denotes the kind of

9. The same values are also recommended as the primary ranges of current transformers. For voltage transformers a list of recommended transformation ratios is given.

mechanism (moving-iron, induction, etc.). This is a desirable feature in instruments for general laboratory work, because it assists the user to select the most suitable instruments for such cases as unusual frequencies, for example. The use of a black, brown, red, blue, or green star denotes that the instrument is for a particular operating voltage, the black denoting "not over 40 volts," and the green "901 to 1500 volts."

The French and German specifications impose tests for robustness, while the British specifications ignore this important point. The French requirement of "twice the current corresponding to full-scale deflection, applied suddenly and for a very short time" is virtually a mild test of *mechanical* robustness only, because the thermal inertia of current windings would make the resulting rise of temperature very small. The German requirement is much more severe, and may properly be called a test of mechanical and thermal robustness. It specifies that the test current shall be 10 times that corresponding to the maximum value of the range of measurement, and that it shall be applied as follows:

9 impulses of 0.5 second in intervals of 1 minute each, then

1 impulse of 5 seconds duration.

With this current, which generates heat in the windings at 100 times the normal rate, the instrument receives a severe mechanical test and a searching test for any thermally weak spots.

The question of damping is variously handled. The British specifications require the pointer to settle to a definite indication "in a reasonable time," and in an appendix the "extreme limits of reasonable time" are given as follows:

Scale length in inches	Time in seconds
Not over	
4.5	2.5
7	3
12	5

The German requirement is more logical in that it bases the time to come to rest on the length of the pointer, and on the class of instrument, as follows:

Precision instruments, both classes, $3 + L/100$ seconds,
 Operating " first class, $3 + L/50$ "
 " " second " $4 + L/50$ "

where *L* is the length of the pointer, measured in millimeters.

The French specifications characterize damping by two quantities:

1. The ratio of the first swing to the steady deflection when the appropriate current is suddenly passed through the instrument.

2. The time required for the pointer to come to rest, under the same conditions.

Incidentally, for practical purposes the pointer is assumed to come to rest when it is within 1 per cent of the steady deflection.

The British specifications require zero adjusters on (spring-controlled) sub-standard and first-grade instruments. The German specifications require them for precision apparatus of both grades, and the French make no mention of the matter.

CONSIDERATION IN THE U. S.

The Meter Committee of the Association of Edison Illuminating Companies has used its influence to encourage the standardization of watt-hour meters. With the corresponding Committee of the National Electric Light Association, it inaugurated the preparation by Electrical Testing Laboratories of the Meter Code, which has been of great service to the meter industry.

Since the checking of watt-hour meters involves the use of indicating instruments, it is only natural that the national Meter Committees should at times make recommendations concerning them. Among these the following work of the N. E. L. A. Meter Committee and Apparatus Committee may be noted:

Proposed Standardization System of Connections for Instruments and Meters used with Current and Voltage Transformers, 1913 and 1914 Reports.

Standardization of Shunts for Instruments and Meters, 1914 and 1915 Reports.

Standardization of Design and Maintenance Method for Instrument Transformers, 1916, 1917, and 1918 Reports.

Standardization of Meter and Instrument Design, 1921 and 1922 Reports.

Standardization of Instrument Transformers, 1922 Report.

The Instruments and Measurements Committee of the Institute has a keen interest in all questions relating to instrument standardization. At the request of this committee, the writer presented a paper¹⁰ three years ago, in which the British Specifications were mentioned, with a table of required accuracies for various kinds and classes of instruments. A little later this committee took up the question of instrument terminology. A list of words relating to instruments, their operating principles, parts, functions, etc., was drawn up, and the various divergencies and inconsistencies were discussed with the hope of establishing a list of recommended terms which might eventually supersede the imperfect terminology in use. While some useful points were brought out in the discussion, the committee felt that the standardization of the terminology of instruments was a part of a larger job and the matter was therefore held in abeyance.

In 1921 the proposed German specifications for instruments and for instrument transformers were published. In order to get these specifications in convenient form for discussion, they were translated into English. Copies of the translation were sent to

the members of the Instruments and Measurements Committee and the Meter Committees of the N. E. L. A. and the Edison Association. The Instruments and Measurements Committee appointed the writer as a subcommittee of one to canvass the sentiment of the instrument manufacturers of this country as to the necessity or desirability of American standard specifications covering their products.

Before this canvass was begun, the French specifications were translated, and copies were sent to the above-named committees. Copies of the French, German, and British specifications were sent out early in 1922 to the American manufacturers of electrical instruments and accessories, and soon after the personal canvass was begun. In all, twenty-one concerns were visited. Some of them make a complete line of instruments and accessories, while others make accessories (for example, instrument transformers) as adjuncts to other lines, such as watt-hour meters.

The results of the canvass showed that a majority of the makers were in favor of standard specifications, though some questioned the necessity or advisability of their preparation at the time. Two important ideas, however, came to the surface. The first was that many of the manufacturers would have felt much freer to express opinions if proposed American standard specifications had been placed before them, instead of only the abstract question as to the desirability of formulating such specifications. The second was that it would be entirely proper for the A. I. E. E. Instruments and Measurements Committee to prepare such specifications to serve as a basis for criticisms and suggestions.

Following out this suggestion, Chairman Sawin of the Instruments and Measurements Committee appointed a subcommittee for this purpose. The membership of this subcommittee included Mr. F. P. Cox of the General Electric Co., Mr. G. L. Crosby of the Roller-Smith Co., Mr. P. MacGahan of the Westinghouse Electric & Mfg. Co., and the writer, as chairman. The three foreign specifications were carefully considered, and what appeared to be the best features of each were woven into a preliminary draft. This was carefully revised by the subcommittee. The final draft, as here given, was prepared in a joint session of the subcommittee and the Instruments and Measurements Committee.

The Instruments and Measurements Committee authorized the writer to prepare a paper presenting the tentative specifications, in order to get them before the entire membership of the Institute. They are given as an Appendix herewith. All makers and users of electrical instruments are earnestly invited to send written comments, and criticisms of the scope and subject matter of the specifications to the writer, care Bureau of Standards, Washington, D. C., for the guidance of the subcommittee in the further development of these tentative specifications.

10. The Accuracy of Commercial Electrical Measurements, *Jour. A. I. E. E.*, vol. 39, p. 495, 1920.

It will be noted that a number of important topics are not covered in these specifications, though they are carefully treated in the foreign ones. This is not because the subcommittee considers these topics unimportant, but rather because it is felt best to begin with things about which general agreement can easily be reached. On the matter of accuracy of calibration, for example, considerable difference of opinion exists. Probably no customer would care to buy instruments concerning which absolutely no statements or guarantees of accuracy are given by the maker. However, since undue importance is sometimes attached to high accuracy, and because the accuracy of instruments in service is so largely under the user's control, it was felt that for the present the specifications should leave it to the maker and customer to agree on the accuracy required in each case. The same statement applies to the permissible limits for the various influences of operating conditions.

Some specific comments on other features of the appended specifications will now be given.

I-2. *Kinds of Instruments Included.* Under this heading the German specifications limit current and voltage capacities to 1000 amperes and 20,000 volts, because "With larger values of current and voltage it is difficult to keep within the prescribed limits of accuracy, and the checking of the accuracy becomes difficult."

III-1. In defining the words "instrument" and "indicator" the subcommittee followed the example of the British specifications, but with an important difference in the definition of "indicator". There is no question as to the need for the distinction between instrument and indicator, and the only argument against taking this step was that early in the history of electric lighting in this country the word "indicator" was sometimes¹¹ used to denote a device of low accuracy. It was finally agreed that this usage was now practically obsolete, and was therefore no bar to the use of the word "indicator" in its new sense.

Attention is invited to the distinction between the terms "series resistor" and "multiplier". These terms should not be confused.

III-4. *Damping.* For the present this term is simply defined. Section 8302 of the Standards of the Institute prescribes the method by which damping shall be measured. Three quantities are to be observed, as follows: The number of swings made by the pointer in coming to rest; the time (in seconds) required for the pointer to come to rest; the overshooting, in per cent of the angular displacement due to the initial disturbance.

III-5, 6. *Torque and Weight.* For the present these sections are limited to simple definitions of these quantities and a statement of the units employed. In view

11. This was not the general practise, however, for the device by which early Edison stations measured the voltage at feeder-ends was known as the Howell indicator.

of the extensive mention of the ratio of torque to weight as a criterion of the degree of excellence of an instrument as regards frictional error, it should be stated that this time-honored criterion is now known to be incorrect save when the moving elements of the instruments to be compared have equal weights. (Equality of excellence of pivots and jewels is assumed). The use of the simple ratio of torque to weight is based on the incorrect assumption that the area of pivot in contact with the jewel is independent of the weight, whereas it must necessarily increase with the weight. By the simple rule of torque to weight, certain small American instruments having very light coils would be expected to stick so badly as to be useless, whereas actually they work very well. If we use the expression, torque divided by weight to the n th power, and take for n a value greater than unity and less than 2, more concordant results will be obtained. A prominent German specialist¹² in electrical measuring instruments gives as a satisfactory criterion, based on practical experience, the quotient, torque divided by the 1.5-power of the weight.

IV-1. It is not felt opportune to make a subdivision of instruments as to "class" or "grade". A suggested classification, which it was not thought advisable to adopt at this time, was as follows:

1. As to use:

- | | | |
|-----|-----------------------|-----------------|
| (a) | Portable Instruments, | Precision Grade |
| (b) | " | " Utility " |
| (c) | Switchboard | " High " |
| (d) | " | " Industrial " |

It was also suggested that "laboratory-standard" instruments form a third class (in addition to portable and switchboard).

IV-2c. The adjective "electrodynamic" is advanced for consideration as a logical substitute for the lengthy term "electrodynamometer-type" and the abbreviated (and not strictly correct) term "dynamometer"¹³. The French, Germans and Italians use the forms corresponding to "electrodynamic" (électrodynamique, elektrodynamisch, elettrocinamico).

It should be emphasized that in drawing up these specifications the effort has been made to maintain a harmony of treatment and of substance with the Standards of the A. I. E. E. It should also be noted that the present specifications are not put forward as a finished product. In their present form, however, it is felt that they will be valuable for their intended use as a tangible basis for discussion and as a nucleus about which finished specifications may in due time be realized. Such specifications should be prepared with the approval of the Institute, and in accordance with the

12. Dr. G. Keinath, of the Siemens & Halske A. G. of Berlin. See his book "Die Technik der elektrischen Messgeräte," second edition, pages 20-22.

13. The term "dynamometer" means "that which measures force." A spring balance is a dynamometer, and some forms of spring balance are called dynamometers.

procedure of the American Engineering Standards Committee.

 4. Scale and Pointer
 5. External Shunts
 6. Marking

I. INTRODUCTION

1. *Origin and Purpose.* These specifications were prepared for the Instruments and Measurements Com-

mittee of the American Institute of Electrical Engineers by a subcommittee appointed for the purpose. In their present form they are intended to serve as a tangible basis for discussion on the part of makers, users, and laboratory men engaged in testing electrical measuring instruments, in order to determine whether American standard specifications of this general nature would be of advantage to all concerned, and if so, what changes in and additions to these specifications are required to make them suitable for the purpose.

The objects of these specifications are as follows:

1. To standardize the principal terms used in describing instruments and their parts, functions, operating principles, etc.
2. To promote a more complete understanding between the maker and the user concerning the essential characteristics of instruments for definite applications.
3. To eliminate diversity of purchase specifications for instruments for similar uses.

The limitations of the specifications may be stated as follows:

1. They are of necessity limited to certain broad classes of electrical instruments, and there will always be special devices not falling entirely within their scope. In many cases, however, the specifications may be used together with certain additions to cover the special features.
2. They are subject to revision from time to time as the art of instrument making advances, or as the requirements of practise change. They are not intended to restrict development or prevent improvement, but rather to guide progress along the most efficient lines.
3. They are not intended to cover the necessary legal provisions of a contract, but only the technical requirements of a purchaser in ordering or a maker in bidding.

2. *Kinds of Instruments Included.* These specifications apply for the present to the following kinds of indicating electrical instruments for direct current and for alternating current:

Ammeters,
Voltmeters,
Wattmeters,
Frequency Meters,
Power-Factor and Phase Meters,
Reactive-Factor Meters.

These specifications are not intended to apply to indicating instruments provided with arrangements for curve drawing, contact making, etc. They do not apply to the following kinds of instruments:

- (a) Small instruments of types and sizes which are used where the requirements are not severe, and where low cost is essential; for example, small polarized-vane ammeters used on automobiles, battery-charging outfits, etc.
- (b) Instruments constructed for very special requirements.

II. STANDARDS

1. *General.* Electrical measuring instruments shall conform to such general requirements of the Standards of the American Institute of Electrical Engineers as shall be applicable to instruments, when such requirements are not definitely covered in the following specifications.

2. *Units, Legal Standards.* The accuracies specified by maker and purchaser are to be based on the legalized international electrical units.

3. *Reference Temperature.* The standard temperature of reference for instrument characteristics shall be 20 deg. cent.

4. *Standard Ambient Temperature.* For purposes of rating instruments, the standard ambient temperature shall be 40 deg. cent. See definition of rating, below.

III. FUNDAMENTAL DEFINITIONS

1. *Instruments and their Parts.* An *instrument* is a measuring device which indicates the present value of the quantity under observation. The term "instrument" includes the indicator (as defined below) together with any accessory apparatus such as shunts, shunt leads, resistors, reactors, condensers, or instrument transformers.¹⁴

The *mechanism* is the arrangement for producing and controlling the motion of the pointer. It includes all the essential parts necessary to produce this result, but does not include the base, cover, scale, or any parts, such as series resistors or shunts, whose function is to make the readings agree with the scale markings.

The *moving element* includes the pointer and the parts which move with it.

The *indicator* is the mechanism and the scale, built into the case, including any accessory devices (resistors, shunts, etc.) which are built into the case or non-removably attached to it.

Examples: An instrument (ammeter) for 500 amperes direct current consists of the indicator (which may be thought of as essentially a millivoltmeter) together with a 500-ampere shunt and a pair of shunt leads. Another instrument (wattmeter) consists of the indicator (which is essentially a 5-ampere 110-volt wattmeter) together with a current transformer and a potential (voltage) transformer.

An instrument is said to be *self-contained* when all accessory apparatus necessary to cause the scale reading to correspond with the numerical value of the quantity measured is enclosed within or permanently attached to the indicator case.

The *current circuit of an indicator* is that winding (or other conducting path) of the indicator which carries the current to be measured, or a definite fraction of it, or a current dependent upon it.

The *voltage circuit of an indicator* is that winding of the indicator to which is applied the voltage to be

measured, or a definite fraction of it, or a voltage dependent upon it.

The *current circuit of an instrument* is that winding (or other conducting path) of the instrument which carries the entire current to be measured.

The *voltage circuit of an instrument* is that winding of the instrument to which the entire voltage to be measured is applied.

Example: An a-c. wattmeter for 1000 amperes, 6600 volts, consists of an indicator (which is essentially a 5-ampere, 110-volt wattmeter with its scale marked to read primary power) together with a current transformer of 1000: 5 amperes and a potential (voltage) transformer of 6600:110 volts. The current circuit of the indicator is its 5-ampere winding, and its voltage circuit is its 110-volt winding. The current circuit of the instrument is the 1000-ampere winding of the current transformer, and the voltage circuit of the instrument is the 6600-volt winding of the potential (voltage) transformer.

A *series resistor* is a resistor forming part of the voltage circuit of an indicator or an instrument.

A *multiplier* is a particular type of series resistor which is used to extend the voltage range of an instrument beyond some particular value for which the instrument is already complete.

A *shunt* is a resistor connected in the circuit to be measured and in parallel with the current circuit of an indicator.

A *reactor* is a device used for the purpose of introducing reactance, and usually has a high time-constant.

Shunt leads are leads which connect the current circuit of an indicator to the shunt.

2. *Rating.* The *rating of an instrument* is a designation assigned by the manufacturer to indicate its operating limitations. The full-scale marking of an instrument does not necessarily correspond to its rating.

3. *Scales.* The *indication range* is the range within which the electrical quantity (current, voltage, power, etc.) is to be indicated without reference to accuracy.

The *measurement range* is that part of the range of indication within which the requirements for accuracy are to be complied with.

The *scale length* is the length of the arc described by the end of the pointer in moving from the zero position to the end of the scale.

4. *Damping.* This is a term applied to instrument performance to denote the manner and the rapidity with which the pointer settles to its steady reading after a change in the value of the measurement quantity.

5. *Torque.* The *torque* of an instrument is defined as the turning moment which is developed by its mechanism when holding the pointer in the position of full-scale deflection. Torque is to be expressed in millimeter-grams, and should be accompanied by a statement of the angle corresponding to full-scale deflection.

14. It is proposed to cover instrument transformers by separate specifications.

6. *Weight.* The *weight* of a moving system includes one-half the weight of the springs, if any. It is to be expressed in grams.

7. *Error and Correction.* The error of indication is the difference between the indication and the true value of the quantity being measured. It is the quantity which must be algebraically subtracted from the indication to get the true value. A positive error denotes that the indication of the instrument is greater than the true value.

The correction has the same numerical value as the error of indication, but the opposite sign. It is the quantity which must be algebraically added to the indication to get the true value. If T , I , E and C represent respectively the true value, the indicated value, the error, and the correction, the following equations hold:

$$E = I - T$$

$$C = T - I$$

Example: A voltmeter reads 112 volts when the voltage applied to its terminals is actually 110 volts. Then

$$\text{Error} = 112 - 110 = +2 \text{ volts}$$

$$\text{Correction} = 110 - 112 = -2 \text{ volts.}$$

8. *Influences of Operating Conditions.* (a) The *temperature influence* is defined as the percentage change in the indication which is caused solely by a difference in room temperature of ± 10 deg. cent. from the reference temperature (20 deg. cent.)

(b) The *frequency influence* (in other than frequency meters) is defined as the greatest percentage change in the indication which is caused solely by a change of ± 10 per cent from the rated frequency.

(c) The *voltage influence* (in other than voltmeters) is defined as the greatest percentage change in the indication which is caused solely by a change of ± 10 per cent from the rated voltage.

(d) The *external-field influence* is defined as the percentage change in the indication which is caused solely by an external field of an intensity of 5 gauss produced by a current of the same kind and frequency as that on which the instrument operates, with the most unfavorable phase and position of the external field.

(e) The *power-factor influence* (in wattmeters) is defined as the percentage change of the indication which is caused solely by the lowering of the power factor from unity to 0.50, current lagging, at the rated voltage and frequency.

(f) The *position influence*, in other than gravity-controlled instruments, is defined as the maximum displacement of the pointer which is caused solely by an inclination of 30 deg. in any direction from the normal position of use. It is to be expressed as a percentage of the scale length.

IV. CLASSIFICATION

Electrical instruments may be classified as follows:

1. As to Use:

- (a) Portable instruments
- (b) Switchboard "

2. As to Principle of Operation:

A. Electromagnetic

- (a) Dynamometer (Electrodynanic)
- (b) Permanent-Magnet Moving-Coil
- (c) Moving-Iron
 - (1) Plunger
 - (2) Vane
 - (3) Repulsion

(d) Induction

B. Electrothermic

- (a) Expansion
- (b) Thermocouple

C. Electrostatic

NOTE: Instead of "permanent-magnet moving-coil" the following terms were also suggested: "d'Arsonval," "fixed-field." Instead of the principal heading A, "Electromagnetic," the term "electrodynanic" was also suggested.

3. As to Kind of Protection:

- (a) Dust-Proof
- (b) Moisture-Proof
- (c) Rust-Resisting
- (d) Water-Tight (Submersible)

The terms "portable" and "switchboard" are self-defining. A third classification as to use is suggested, namely, "laboratory-standard."

In *dynamometer (electrodynanic) instruments* one or more coils move within the field produced by a fixed coil or coils.

In *permanent-magnet moving-coil instruments* a coil moves within the field of a permanent magnet.

In *moving-iron instruments* one or several pieces of soft iron are caused to move by the magnetic field of a fixed coil or coil system. Various forms of this instrument (plunger, vane, repulsion) are distinguished chiefly by mechanical features of construction.

In *induction instruments* the torque is produced by fixed coils acting upon moving conducting parts (disks, drums, etc.) in which currents are produced by electromagnetic induction.

Electrothermic instruments depend for their operation on the heating effect of a current. Two distinct types are (1) the expansion type, including the "hot-wire" and "hot-strip" instruments; (2) the thermocouple type, where one or more thermocouples which are heated directly or indirectly by the passage of a current supply a direct current which flows through the coil of a suitable direct-current mechanism, such as one of the permanent-magnet moving-coil type.

Electrostatic instruments depend for their operation on the forces of attraction and repulsion between bodies charged with electricity.

A *dust-proof instrument* is provided with a case which excludes dust from the mechanism.

A *moisture-proof instrument* is one in which moisture is excluded from the mechanism, or which is so constructed that moisture will not damage the mechanism.

A *rust-resisting instrument* is one whose case and parts are made of rust-resisting materials, or are specially finished to resist the corrosive effects of moist air.

A *water-tight (submersible) case* withstands for one hour complete immersion in a tank containing sufficient water to cover all parts to a depth of at least three feet, without any visible trace of penetration of water into the interior.

V. REQUIREMENTS

1. *Construction.* The construction of electrical instruments shall be mechanically sound, suitable to their class and purpose, and shall be such as to give assurance of permanence in the accuracy of the indications. All materials must be suitable for the purpose for which they are used.

2. *Rating.* The rating of the circuits of an instrument shall be equal to, or less than, the maximum current or voltage to which they may be continuously subjected without exceeding the permissible temperature rises. These rises are to be those specified for the various classes of insulating materials by the Standards of the A. I. E. E., and refer to the standard ambient temperature of 40 deg. cent.

If the rating of an instrument differs from the full-scale marking, the rating shall be marked on the instrument.

The limiting observable temperature of shunts shall not exceed 120 deg. cent. It shall be measured by mercury, alcohol, or resistance thermometers or by thermocouples, any one of these devices being applied to the hottest accessible part of the shunt. *Exception.* This rule shall not apply to shunts having no soldered joint and made of material which is not permanently changed in resistivity if continuously subjected to a higher temperature.

3. *Insulation Resistance and Dielectric Strength.* Tests for insulation resistance and dielectric strength shall be made on finished instruments.

The *insulation resistance* between all the electrical circuits of an indicator connected together and the case shall not be less than 20 megohms, as measured with a d.c. test voltage of 500 volts. The insulation resistance between the current circuit and the voltage circuit of an indicator (where both exist) shall not be less than 5 megohms.

When indicators are specified to have one or more of the circuits internally connected to the case, the necessary exceptions to these requirements are allowed.

Dielectric strength tests shall be made with a wave form which is nearly sinusoidal and of a frequency between the limits of 15 and 65 cycles. Tests shall be made between all the electrical circuits of the device

connected together and the case. *Instruments having a voltage circuit* shall withstand for 60 seconds a test of twice rated voltage plus 1000 volts. *Instruments without a voltage circuit* shall withstand for 60 seconds a test of 1000 volts. These are effective (root-mean-square) values.

4. *Scale and Pointer.* The preferred value of each scale division should be either 1, 2, or 5 of the units measured, or any decimal multiple or submultiple of these numbers. In the case of multiple-range instruments exceptions to this rule may be necessary, but should be avoided where reasonably possible.

The angle subtended by a scale division shall preferably not be less than 0.5 degree in portable instruments, or 1 degree in switchboard instruments. When smaller angles are used, the legibility is decreased.

The numbers marked on the scale, except in the lower part of non-uniform scales, shall preferably be by steps of 1, 2, or 5, or a decimal multiple or submultiple of any of these numbers. The figures shall be of such shape as to minimize the risk of different figures being confused with one another, and shall be so spaced as to render individual numbers clearly distinguishable from adjacent numbers.

In determining the influences of operating conditions (a) to (e) inclusive, page 8, ammeters and voltmeters should be tested with rated current or voltage respectively. Wattmeters should be tested with rated voltage and such a current (not exceeding the rated current) as will give a suitable deflection, preferably not less than that corresponding to one-half of the maximum reading. Frequency meters (except in the test for voltage influence) should be tested at rated voltage. Power-factor meters and reactive-factor meters should be tested with rated voltage and rated current, unity power factor.

5. *External Shunts.* The main terminals of the shunt shall be so constructed that slight variations in the manner of connecting it in the circuit (such as might occur in an average workman-like installation) shall not alter the indication of the instrument by more than 0.25 per cent.

The *thermal electromotive force* produced by continuous operation of the shunt at rated current shall not exceed the value which would cause a change in the reading (at rated current) of 0.25 per cent. The connections to the circuit should be made so that the opportunity for the escape of heat will be the same at both terminals.

6. *Marking.* The indicator shall be distinctly marked with the following particulars in such a way that they will be visible from the front of the case: Name (or symbol) of manufacturer; serial number; designation of the quantity measured; the words "direct-current" or "alternating-current" or their abbreviations; the rated current, voltage or frequency (or the ranges of these quantities) or such of these as apply; the maximum

current and voltage, in the case of wattmeters, power-factor meters, and reactive-factor meters. Of these, only the scale marking itself and the designation of the quantity measured shall be conspicuous.

In the case of alternating-current instruments the following additional items are required: Ratio of the appropriate current transformer expressed thus: 1200:5 or 1200/5; ratio of the appropriate potential (voltage) transformer expressed thus: 6600:110 or 6600/110.

The indicator of an ammeter having separate shunts shall also be marked with the drop of the shunt with which it is to be used, corresponding to full-scale deflection.

Instruments having separate shunts or series resistors should be marked to indicate this fact.

Separate shunts, if not interchangeable, shall be marked as follows: Name (or symbol) of manufacturer; serial number of the indicator with which it was calibrated; the line current corresponding to full-scale deflection of the indicator; the rated current, if this is less than the preceding, and the drop at rated current. When the shunts are designed to be used with devices taking sufficient current to be an appreciable proportion of the whole, this fact shall be indicated.

Interchangeable separate shunts shall bear the above markings, except that the serial number may be omitted.

Discussion

W. B. Kouwenhoven: On the fifth page of Mr. Brooks' paper, where he lists the proposed types as portable and switch-board instruments of various grades, I think that it would be advisable to add a third grade under the portable class. This third grade might be known as laboratory instruments. It should include instruments that can be used in rough, ordinary work; something better than an indicator but not a precision instrument. I feel that a sub-classification giving the type of controlling force employed in the instrument would be of value and interest to the user. The controlling forces found in common use in deflection meters are:

1. Resisting force of a spring; 2. Torsion of a filament; 3. Attraction of gravity; 4. Attraction or repulsion of permanent magnet.

On the eighth page, item d under heading 8, where Mr. Brooks discusses the effects of the external field on the deflection of the instrument, I think the last clause of that paragraph might well be modified to read as follows: That the external field be placed in such a location as regards phase and position that it will cause the maximum error in the instrument.

One point that I think should be added to these specifications, is: What is the effect on the deflection of standing under load for one hour? A great many instruments change considerably on that test.

Another requirement that might be added is that an instrument should be insect proof.

C. M. Green: There is one point at which I have been very much perplexed in connection with the use of instruments and in this connection I would particularly refer to "Standards of the Institute of Electrical Engineers" under date of 1922, page 25, "Kinds of Current," Rule 3104—Direct Current, 3108—Pulsating Current and 3112—Continuous Current. To my mind these apparently are normally rules or definitions without any actual defining.

It seems to me that our book of standards is in a most deplor-

able condition in reference to the definition of the various kinds of currents, and if there is a single member here who can from these rules determine definitely where direct current leaves off and a pulsating one begins, I surely should appreciate it if he would help me out.

I have heard complaints regarding some half-wave tungar rectifiers not fulfilling their rating, the rectifier being rated at 6 amperes and the customer claimed that it gave 11, which was more than he wanted. However, with two ammeters connected in the circuit with the batteries which are being charged from the half-wave tungar rectifier, the d'Arsonval type of instrument, which gives the average value of the current which is effective in charging the battery, recorded 6 amperes, the rating of the outfit, whereas an inclined-coil instrument giving the r. m. s. value of the current, or its heating value, recorded 11 amperes. Can anyone tell from our rules 3104 and 3108 whether the current flowing through this circuit was a direct or pulsating current? For all intents and purposes the battery was being charged just as effectively at 6 amperes as though it had been from a normal d-c. source, and as such was the current flowing into the battery a direct or pulsating one as determined by the above rules?

A. E. Kennelly: I would like to call attention to one point, namely, that if this work is going to be serviceable to the American Institute of Electrical Engineers, it must be serviceable to our fellow groups of engineers in other countries than this, and therefore it must be expressed in one and the same system of units. The units employed in these specifications are in the main metric, as I think we will all agree that they should be, but there are a few of the specifications such as for example appear in the immersion problem on the ninth page, which call for immersion under three feet of water.

It seems to me that in order to make the specifications universally suitable to all possible parts of the world, one and the same system of units should be used throughout.

J. R. Craighead: On the fifth page of Mr. Brooks' paper he states that the Committee was fully agreed that the word "indicator" is obsolete as indicating an instrument of somewhat inferior accuracy. It has not seemed to me that the word is obsolete in that sense. I was glad to note that Professor Kouwenhoven, requested that there should be inserted in the table on the fifth page a place for an instrument which would come between the grades indicated. He said that it should have an accuracy "better than an indicator, but somewhat less than a precision instrument." The language would suffer a loss if we cut out the use of the word "indicator," for that purpose because its use is active at the present time.

On the seventh page the definitions of the circuits of indicators and instruments are so drawn that they do not refer to definite mechanical parts of the apparatus; rather, they refer to the circuit connections. I cannot say that this is necessarily objectionable, but it is a fundamental change from the way that such definitions have usually been made. That is, if we build a five-ampere instrument and set it on the shelf and we have a current transformer for use with that instrument, in any given case the transformer may or may not be used. If we use the instrument alone, the current circuit of the instrument is then both the indicator circuit and the instrument circuit. The instrument and the indicator are identical. If, on the other hand, we connect this circuit to the secondary of the current transformer, the circuit becomes the indicator circuit, and it is no longer correct to refer to it as the instrument circuit. The primary circuit of the current transformer then becomes the instrument circuit.

Similarly in attaching a millivoltmeter to a shunt, the instrument becomes the shunt plus the parallel circuit made by the millivoltmeter winding. The indicator circuit is the millivoltmeter winding, but if you use the millivoltmeter direct, the millivoltmeter winding becomes the instrument circuit.

I am mentioning this to call attention to the action this com-

mittee has taken and to note that it is considerably different from previous practise.

Paragraph 8 on the eighth page is divided into a, b, c and d. The word "greatest" implying a maximum error is implied in paragraphs b, c and d but omitted in paragraph a. It would seem that as this case is strictly parallel to the others the error should also be defined as a maximum.

Under paragraph d the statement regarding the location of the field is not quite complete. That is, if we form a field of five gaussses and intrude an instrument into that field, the field is then more intense than five gaussses at some points and less intense at other points. There should be some other closer definition as to the point at which the five gaussses are to be maintained in order to get a definite thing which can be repeated at different places. That is, the resultant field would be very largely affected by the size of the coil used to maintain it, and by the exact way in which the coil was placed with relation to the instrument itself.

H. B. Brooks: I am sure that the favorable comments made by Dr. Kouwenhoven and Dr. Kennelly are appreciated by the Subcommittee which has had the task of preparing these specifications.

Dr. Kouwenhoven suggestion for a third grade of portable instrument is in line with recent developments. The General Electric, Weston, and Westinghouse companies have all produced smaller portables for general purposes, such as trouble location.

The comments of Dr. Kouwenhoven and Mr. Craighead about the specification with respect to the effect of external field are very good and the specification should be modified accordingly.

In regard to Dr. Kouwenhoven's question about the rating, it may seem puzzling that we have two standard temperatures for instruments. The explanation is that the twenty-degree requirement refers to instrument performance; that is, to accuracy and other operating characteristics, with the exception of ability to stand overloads. The forty-degree requirement refers to the rating; that is, an instrument must be capable of carrying the specified load for the specified time with the external temperature at the unfavorable point of forty degrees centigrade.

I agree with Dr. Kouwenhoven's suggestion, at least as far as portable instruments are concerned, that there should be a requirement limiting the permissible change in accuracy caused by standing in circuit. In the case of switchboard instruments

it might be sufficient to specify that they should stand in circuit with a given load for say one hour before the accuracy test is begun.

Mr. Green reports the interesting circumstance that two perfectly correct ammeters connected in series in the output from a rectifier may show values as different as six and eleven amperes. It is unfortunate that there is not available in standard text books a good discussion on the subject of the measurement of pulsating currents. There are only two things in print about this, of which I am aware. The first is a discussion by Mr. P. MacGahan and was published only for the engineering department of the Westinghouse Company. The second is an article on "Selecting Ammeters for Various Current Measurements," by Mr. V. H. Todd of the Westinghouse Company, in *Electrical Review* (Chicago), October 30, 1920. It is really quite important to choose the proper ammeter and it depends upon whether you are interested in the effective value of the current or in the average value. If you are charging a battery with a pulsating current you want an instrument which measures the average value; when operating lamps or heating devices an ammeter which measures the effective value should be used.

Dr. Kennelly is quite right in saying that if American specifications are to be most useful for American engineers, they must also be suitable for foreign engineers, and I am sure the committee will make the necessary corrections.

As to Mr. Craighead's comments about the word "indicator," I believe that word is no longer used in instrument catalogs or in technical articles, but I am glad to be corrected if such is not the case.

There is a very good reason for using the word in the sense that the committee proposes. We have tried in vain to find another English word which will express the thought and still leave the word instrument for the complete measuring equipment; that is, the indicating device with all of its accessories.

As to the suggestion of Mr. Craighead that the word "greatest" should appear on page 901 in connection with the definition of temperature influence, I would say that to the best of our knowledge temperature effects on instruments within a range of a plus or minus ten degrees centigrade are always linear. For that reason we did not feel it necessary to put in the word "greatest," but the effect of frequency, for example, is often quite different from linear, and the effect of the other quantities may also be safely specified by putting the word "greatest" in the three definitions.

Pellet Type of Oxide Film Lightning Arrestor

BY N. A. LOUGEE

Associate A. I. E. E.

Stone and Webster, Inc., Boston, Mass.

Formerly with General Electric Co., Schenectady, N. Y.

Review of the Subject.—Practise has confirmed the theory that a valve type of lightning arrester is the best; that is, one which has a very large resistance or impedance at rated voltage, but which has a resistance of only a comparatively few ohms at say double rated voltage. The aluminum arrester was the first of this type and its success is well known. Somewhat later the oxide film (OF) arrester was developed to overcome the disadvantage of charging, and this type too has had remarkable success.

A modification of this "OF" type is now announced. Briefly, pills or pellets of lead peroxide, the chemical powder used in the present "OF" type, are made and coated with an insulating film of powder. They are about the size of the familiar sugar coated pills. These are simply poured in an insulating tube,

terminals put on each end in contact with the pellets, a series gap added, and the arrester unit is complete.

In action, each pellet is a miniature "OF" cell, so the arrester tube contains a number of them in series and parallel. The over-voltage surge discharges through the pellets, which have a low resistance after the powder film is punctured, and sealing occurs at the contact of the various pellets. No dynamic or normal frequency current passes.

The characteristics are similar to those of the present "OF" arrester, giving it the fundamental characteristics a successful arrester must have. The pellet construction permits of a simple, flexible and comparatively cheap design.

THE theory and principle of the oxide film lightning arrester have been pretty thoroughly taken up in previous papers¹ and its successful operation in thousands of installations has proved the results obtained in the laboratory. From the first, efforts have been directed toward applying this principle to a form of construction other than the present one, so that a less expensive unit

FIG. 1—LEAD PEROXIDE PELLETS BEFORE BEING COATED WITH AN INSULATING POWDER

could be made. For small capacity of power apparatus, there is a limit to the money which can be expended for protective apparatus, and it is for such conditions that the type of arrester to be described, was developed.

The main difference between this new pellet type of oxide film (OF) lightning arrester and the present "OF" cell is based upon a relation explained by colloidal chemistry.

A small part of the subject of colloids deals with grains, and states that a small grain will adhere to a larger one and cover it. As a familiar example, sugar adheres and coats blueberries, when the two are shaken together. Also in the extreme, it is for the same reason that lead pencils write on paper, and chalk on boards, that is, the plane surface in these cases is the larger grain.

This principle has been made use of in applying the basic principle of the oxide film arrester to this new pellet type. If lead peroxide (PbO_2), the filler of the "OF" cell, be made into a round pill or pellet, and

shaken up with a fine powder, the pellet will become coated with this powder. This then is what is done: Lead peroxide pellets are shaken up with an insulating powder and thoroughly coated. Fig. 1 shows the pellets before being coated and Fig. 2 after being coated. Each pellet is now a miniature "OF" cell, consisting of an outside film, which is the insulating powder, and the active internal filler, which is the original pellet. To make a lightning arrester these covered pellets are placed in an insulating tube, of say porcelain, and bare electrodes attached to each end of the tube in contact with the pellets. The electrodes act both as terminals and covers for the container. Between the terminals of the container, there are hundreds of these miniature "OF" cells in series and parallel. The over all length of the container depends upon the voltage rating of the arrester desired, and the chosen diameter of the tube is related, (to a certain extent), upon protective value and life of the arrester.

FIG. 2—LEAD PEROXIDE PELLETS AFTER BEING COATED WITH AN INSULATING POWDER AND BEFORE BEING USED IN A LIGHTNING ARRESTER

The film of insulating powder apparently acts as a porous spacer and not as a solid insulation. This is shown in Fig. 3, in a way, by the microphotograph of a covered pellet magnified to 25 diameters. In the photograph, due to the high magnification, only the center of the pellet is in focus. The insulating film, acting as a spacer and not as a solid, eliminates the objectionable time lag of establishing a spark, that solids have. This fact is borne out in tests—the equivalent sphere gap (E. S. G.) being low. A high-voltage impulse discharge goes through this pellet arrester in a number of

1. TRANSACTIONS, A. I. E. E., 1918, Vol. XXXVII, page 871.

TRANSACTIONS, A. I. E. E., 1920, Vol. XXXIX, page 1981.

Presented at the Annual Convention of the A. I. E. E., Swampscott, Mass., June 26-29, 1923.

parallel paths and sealing or recovery occurs at the contact surfaces of all pellets effected by the discharge in the path of the discharge current.

While the basic principle of this pellet arrester is the same as the present used "OF" unit, the difference in construction of the pellet type causes some modification in the film action. The leakage current is very much less in the pellet type. It is less than one milliamper when new, and contrary to expectations, continued

FIG. 3—A LEAD PEROXIDE PELLET AFTER BEING COATED WITH AN INSULATING POWDER

Magnification is 25 diameters. Only a central ring is in focus.

service does not increase it. It seems that sealing or recovery is more complete between peroxide surfaces than between a lead peroxide and a metal surface, — the condition which exists in the present "OF" cell. This fact is of course beneficial. The pellets become a bit irregular due to continued use and the sealing surfaces can be easily seen on each one. Fig. 4 shows a picture of a lot of pellets taken from a 2300-volt arrester which had been given repeated discharges from a lightning generator² while also connected to a 2300-

FIG. 4—LEAD PEROXIDE PELLETS AFTER BEING COATED WITH AN INSULATING POWDER AND AFTER EXTENSIVE USE IN A LIGHTNING ARRESTER

volt 60-cycle circuit of high kw. capacity. The worn condition of the pellets can be readily seen.

It might be expected that such small contact surfaces would be quickly worn away, but such does not seem to be the case. A contact surface once punctured by the discharge, and sealing having occurred, is still available for further use; that is, the life of the contact surface between pellets is great. The pellets do become a

2. *General Electric Review*, 1921, Vol. 24, page 946.

bit irregular in shape from service, but they are amply strong to carry a heavy impulse discharge. Although dynamic does not follow the impulse, over voltage dynamic tests show the pellets also to have ample strength to carry a heavy dynamic discharge. Life tests show hardly any deterioration although an excess of the insulating covering of the pellets becomes blown or shaken off. The necessary amount of covering seems to adhere regardless of service. This fact, however, is beneficial rather than harmful as it improves the protective value.

The construction and size of the pellets for both successful and best operation is of course important. A successful arrester must (1) discharge the surge freely at some definite voltage above normal; (2) the free discharge must be sufficient to relieve the voltage strain;

FIG. 5—PELLET TYPE OXIDE FILM LIGHTNING ARRESTER FOR 2300-VOLT SERVICE

FIG. 6—PELLET TYPE OXIDE FILM LIGHTNING ARRESTER FOR 15,000-VOLT SERVICE

(3) the insulating film on the pellets must reseal, that is, prevent the dynamic from following the abnormal surge and (4) it must have endurance and life. All of these factors are related to the size of pellet, and the best size has been determined by extensive laboratory tests. Pellets, as now used, are about one eighth of an inch in diameter.

The electrical characteristics of this pellet arrester are very similar to those of the present "OF" arrester, therefore oscillograms of representative tests are not shown, as they would simply be duplicates of those published heretofore in the papers already referred to.

The future of this type of lightning arrester appears to be very bright—it has all the characteristics demanded by the basic theory of lightning arresters, and the mechanical form of pellets lends itself to a convenient, flexible and relatively cheap construction. Fig. 5 shows a 2300-volt arrester and Fig. 6 a 15,000-volt arrester.

Discussion

K. B. McEachron: The pellet arrester represents an extension of the oxide film principle in an ingenious manner. The problem of making, commercially, small pellets of lead peroxide, and coating them with litharge has been solved in a satisfactory manner.

In design it is possible to increase the discharge rate by increasing the number of pellets in parallel and to increase the operating voltage by increasing the number of pellets in series. The arrester is simple in construction and offers some advantages over the cellular type in the matter of assembly.

A large number of tests have been made on the arrester while in the developmental stage and also after being put in production. A volt-ampere curve (expressed in r. m. s. values) taken on a group of 3000-volt arresters using the discharge from a lightning generator is shown in Fig. 1. It will be seen that the voltage across the arrester at currents below 100 amperes lies between 4 and 6 kv. This value is practically the same as obtained from other good arresters of the same voltage rating. With an instantaneous current, 1500 amperes, the voltage is approximately 8.5 kv. This voltage is considerably lower at these higher currents than any other arrester we know of.

It is probably true that under lightning conditions in service on a distribution circuit, that most of the discharges will be of low current value, but the reserve capacity is present in the pellet arrester if needed.

FIG. 1—VOLT-AMPERES CHARACTERISTIC OF PELLET ARRESTERS (3000-VOLT)

V. E. Goodwin: It has been a source of gratification to me to note the interest and progress which has been made in recent years in the methods of test and in the development of lightning arresters. This is a line of work in which we can have no prejudice and no favorites.

It is only a few years ago that arresters were tested with a static machine and Leyden jars. A little later the lightning generator was brought out with larger condensers operated at 100 kv. and later at 250 kv. At that time we entered what might be termed the wood splitting age as blocks of wood could easily be shattered by discharges of this magnitude. Recently we have all heard of the 2,000,000-volt generator.

Great improvement has likewise been made in the methods of measurement of these impulse voltages. First these measurements were made with needle gaps and later by sphere gaps which were more capable of measuring the crest values of voltage. Recently we have been able to study the decrement as well as the crest values of voltage. This decrement in voltage is of great importance as it gives a fair idea of the value of the voltage at any time during the discharge of the arrester. This is accomplished by means of gaps having greater and known time lags, such as gaps with shunt capacitance and resistance.

A few months ago we had an excellent paper by Mr. Atherton

describing the development of a new type of valve arrester. Today we have this paper by Mr. Lougee which gives a general description of pellet type oxide film arrester. This is another valve type arrester. Valve type arresters have ideal characteristics from an operating standpoint as they allow little or no dynamic current to follow the lightning discharge. Any flow of dynamic current is objectionable and should it continue for over a cycle or so a serious interruption to service is liable to follow. The chief difference between it and the standard oxide film arrester is that the cell element in the former is the individual pellet. The operating voltage per cell is much lower which allows of great flexibility in design.

The pellet design has an excellent volt-ampere characteristic, as Mr. White has just shown by the curve on the blackboard. This means that the arrester has low impedance to lightning impulses and will handle heavy discharges without excessive rise in voltage. The arrester also has a high dynamic voltage failure point. This is another important consideration since arresters are frequently called upon to function during line troubles when the line regulation may be momentarily very bad.

C. P. Steinmetz: The pellet type of oxide film lightning arrester, adequately fills a gap for which no economically suitable lightning arrester was heretofore available, namely that of primary distribution circuits of 2300 volts and over, up to 13,200 volts and more.

The first great advance in lightning arrester engineering was made by Alexander J. Wurtz, in his investigation of the non-arcing metals. This gave us the multigap lightning arrester. Its characteristic is, that the dynamic which follows the static discharge is cut off at the end of the first half wave, and therefore does not disturb the circuit. The multigap arrester remained the standard of the best type of arrester until electric transmission voltages had increased to values at which arcing grounds could exist. Then the multigap arrester failed, for these higher voltage circuits, as it is almost instantaneously destroyed by an arcing ground, and for sometime the protection of transmission lines against lightning appeared almost hopeless indeed.

The problem was solved by the development of the aluminum cell arrester. Its characteristic is, to let the static pass freely, but not to allow the dynamic to follow at all. Therefore the aluminum arrester can take care of arcing grounds for a reasonable length of time. It quickly became the standard of excellency, used wherever protection was of importance. Its only disadvantage is, that it requires attention, that is, systematic charging. This disadvantage was overcome by the development of the oxide film arrester. This also is a counter-e. m. f. or valve type of arrester and like the aluminum cell, has the same high discharge rate, the same ability to cope with arcing grounds, and the other good features of the aluminum arrester, but it requires no attention. It therefore rapidly replaced the aluminum arrester.

For low voltage primary distribution circuits, such as 2300 to 13,200 volts, and more particularly for the protection of smaller apparatus, such as lighting transformers, distributed on such circuits, the standard forms of aluminum and of oxide film arresters were not economical, in view of the relatively low cost of the individual protected apparatus. The problem therefore arose, to produce an arrester of the type of oxide film, which is economically suited for these circuits. This has been solved by Mr. Lougee in making this arrester economical for lower voltages by putting it into pill form, as we may say. But though in pill form, it is a real lightning arrester; it has the same high discharge rate, the same self-healing qualities, etc. It has lost none of the advantageous features of the standard oxide film arrester.

In its present form, the pellet arrester is a development

which had been practically completed some years ago; with apparatus as lightning arresters, where the final decision of excellency after all is the practical experience, it is our fixed policy to try it out thoroughly for years, first in our laboratories, and then in industrial circuits, by the installation and operation of numerous arresters, so that, when we finally present it to you, our statements are not the expectation and hope based on limited laboratory experiment, but are the result of years of experience on hundreds of arresters in real industrial service.

A. L. Atherton: There is one interesting and very significant point which is illustrated, or rather emphasized, by the description by Mr. Lougee of this new form of the oxide film lightning arrester. That point, fundamental to the lightning arrester industry, is that the manufacturer for whom Mr. Lougee speaks, and the one for whom I am speaking, the Westinghouse Company, are both striving in lightning arrester development toward pretty much the same thing.

This is important in lightning arresters because some other manufacturers are not striving toward those same ideals. The special significance of the basic agreement of these two companies lies in the fact that both are fundamentally manufacturers of what we might call primary or working equipment, and are only suppliers of lightning arresters and other accessory types of equipment because it is realized that these are necessary if the systems for which apparatus is supplied are going to perform in such a way as to promote the growth of the electrical industry as a whole.

Lightning arresters are a minor part of our business. The engineers who develop and design lightning arresters are charged primarily with the problem of protecting apparatus and only secondarily with the provision of apparatus which will be a profitable business.

That the two organizations which approach the problem from this broad viewpoint aim at the same characteristics as a fundamental, is significant because it is a rather clear proof that those characteristics are the right ones. There are quantities of devices made and sold and used with the idea that they are protective devices, but in the design of which all of the principles that have to do with correct protective equipment are completely neglected.

This point is stressed because I believe that the cause of the use of these inferior devices is the lack of general understanding of the requirements for lightning arresters to give performance. I don't think very many people make poor investments knowingly and willingly.

In this connection I would like to make a suggestion in regard to the presentation of information on lightning arresters. Such information should be in very definite, specific, quantitative terms, which it has not very generally been in the past. When we speak about resistance of an arrester, it is better to say so many ohms than to say it is a low resistance. This sort of information is lacking in Mr. Lougee's paper, probably justifiably, but was supplied to some extent in one of the discussions.

There are one or two points in connection with the arrester itself on which I would like to comment. Every one has found it very difficult to make solid dielectrics in which the breakdown voltage is reliable, particularly when the voltages required are low. Mr. Lougee probably has a very vivid realization of this from work in development, to a reliable point, of the varnish film on the older form of oxide film arrester. In this case the voltage that was aimed at was something like three hundred volts breakdown per film.

The dimensions of the pellet arresters are not shown, but judging from the cut, Fig. 5, there is a column of pellets, something like six or seven inches long, in the 2300 volt arrester. This would mean something like sixty pellets in series, or sixty

miniature oxide film cells, as they are called by Mr. Lougee, in series for 2300 volts.

This represents a normal voltage rating of forty volts or so per cell and means that the breakdown per dielectric film has to be of the order of forty or fifty volts to give a reasonable total breakdown voltage.

It certainly is an accomplishment if solid material has been provided which is reliable in breakdown at voltages of that order. Of course, the curve given in discussion has no bearing on this point since it indicates only characteristics after breakdown.

The matter of life of arresters under discharge, referred to on page 1020, is one of particular importance. More definite information about the conditions in the tests referred to would be of interest.

An arrester, even of the distribution type, has to carry several hundred amperes and sometimes even a thousand amperes of surge current. Laboratory tests which we have made indicate that the life of any kind of arrester varies very greatly with the current. Types that fail after two or three thousand discharges, at an overload condition of 5000 amperes, seem to last indefinitely with currents of the order of two hundred to five hundred amperes. The reference in the footnote describes tests in which the currents are of the order of fifty amperes. It would be interesting to know further about these tests, in order to know their significance, and to have data on life under conditions which approach service conditions in severity.

This point is of particular importance in the type of arresters described. The gradual change toward a condition of open circuit, which is taken care of in the older type with the cell testing device, presumably takes place in this arrester also, since the same chemical action is the basis of performance in both cases. After some length of service it would seem that this gradual change will result in an arrester which is practically open-circuited but which appears from visual inspection to be intact and operative. Inspection by testing is not feasible with distribution arresters. The idea is pretty well established that lightning arresters, particularly for this class of service, must indicate very clearly whether operative or not, even by an inspection from the ground. It would be interesting to know whether this has been taken care of and how.

E. R. Stauffacher: On the first page the statement is made—"To make a lightning arrester these covered pellets are placed in an insulating tube, of say, porcelain, and bare electrodes attached to each end of the tube in contact with the pellets."

I should like to inquire whether the construction of a commercial arrester is such that the wire which connects between the line and the column of pellets goes directly to the column or whether there is an air gap interspersed. Probably I can illustrate this on the board. In the construction as shown in A, or as shown in Fig. 2.

If the B construction issued, the leakage would be constant, although it would be only of a very small amount, "less than one milliamperes when new, and contrary to expectations, continued service does not increase it."

However, if there should be a gradual deterioration of these pellets, or if the leakage remains the same as when new and you had a great many of these arresters, for example, several hundred connected on a distribution circuit, there will be a condition of a multitude of slight grounds on this circuit. This would cause considerable annoyance when every effort is being made to keep the system clear of grounds and confusion would result if each circuit had a ground detector connected to it.

As I understand it, this is primarily a distribution type of arrester used for the protection of transformers at industrial plants and at small pumping plants, for example, such as exist in considerable numbers in Southern California.

The statement is made that the tests of the pellet arresters show practically the same characteristic as that of the oxide film cells with which we are so familiar. However, is there any quantitative value which could be placed upon them? The standard oxide film cell has a certain discharge capacity. A column of pellets has another certain discharge capacity, depending upon the diameter and the length. What is the relation between the two? In other words, would it be possible to substitute a number of these pellet type arresters for one of the oxide film arresters to protect the transformers at a large capacity substation? At some of our smaller substations it is found more convenient to mount an arrester on a pole. If several of these distribution type pellet arresters could be mounted in parallel in place of the ordinary oxide film arrester, probably the construction would be much cheaper.

I would appreciate very much hearing from Mr. Lougee, or any of the discussers as to whether they have any information on this point.

N. A. Lougee: Mr. Atherton has asked several questions relative to the protective value and life of the pellet arrester. While it may be of interest to know that in spite of so many miniature cells in series, the 60-cycle or low-frequency voltage breakdown is very sensitive, it is the impulse breakdown which we are interested in with lightning arresters. The curve shown by Mr. McEachron gives the maximum voltage drop across the

arrester during high-voltage impulse discharges with large values of current. This voltage, measured by a sphere gap, records the maximum voltage appearing across the arrester, and which may be either the initial breakdown voltage or the voltage drop across the arrester during discharge. The results which have been obtained as illustrated by this curve show unusually low voltages, insuring a high degree of protection. As stated in the paper the sensitivity of the arrester, although composed of many films in series, may be due to the fact that the litharge film acts principally as a spacer and not as a solid dielectric.

Mr. Atherton's reference to a former paper may be somewhat misleading. Some of the tests referred to in this paper were surges of arcing ground characteristics and were used to help determine the life of the regular *OF* arrester. The lightning generator has since been developed and is the criterion, of course, in all types of tests. The pellet type has successfully withstood thousands of discharges on this circuit. This older test referred to, the arcing ground, is still of value, as there are very few types of lightning arresters which can successfully withstand this sort of test for any length of time.

Extensive laboratory tests show that testing will not be required. This is apparently due to the number of pellet cells in parallel and because they are affected even less by discharges than the regular *OF* cells.

Mr. Stauffacher asked if a series gap is used. It is used, even though the leakage current is extremely minute, and it is used principally to prevent grounding the circuits and to eliminate the small ground currents which would occur. Although the pellet type was developed primarily for low voltage distribution circuits, extensive tests prove that it is the equal of the *OF* type, and we see no reason why it can not be used to protect any type of apparatus and on any type of circuit.

FIG. 2

A Continuous-Current Generator for High Voltage

BY S. R. BERGMAN

Associate A. I. E. E.
Consulting Engineer, General Electric Company

Review of the Subject.—Of all electro-dynamic machines, the direct-current machine probably is the best understood. It was the first machine to be commercially utilized and it is an interesting matter from an engineering standpoint to follow the evolution which this type of machine has passed through. The first great improvement to be incorporated in this type of machine was the application of commutating poles. As is the case in any radical development, engineering opinion was much divided as to the usefulness of such a construction. At first it was held that commutating poles were only useful where the service was severe, as, for example, in adjustable speed motors covering a large speed range. Today, however, it is well realized that commutating poles are advantageous in all kinds of direct-current machines, except in very small machines of fractional horse power output.

It is well understood in the art that commutating poles alone do not offer a perfect solution of the direct-current problem, since there exists in such machines troublesome flux distortions. Many attempts have been made to overcome this by aid of distributed windings, and in this paper is described a form of such windings, which

have given excellent results both from an operating and an economical standpoint. This distributed winding consists of two parts, one of which may be considered a counterpart of the armature, and is called a compensating winding. This winding opposes the armature reaction in every point around the circumference and effectively prevents any distortion of the flux. There is also a second winding for supplying the excitation and as is described in the paper, this winding is also distributed.

By aid of such field windings, it is possible to meet very extreme conditions of service, for example, as is met with in high-voltage machines. In the machine that is described, the voltage between bars runs up to about 100 volts, or nearly four times the conventional value; nevertheless, the commutation is perfect. Machines rated 15 kw. have been built successfully up to 15,000 volts.

One of the mechanical difficulties in building high-voltage, direct-current machines lies in the building of the commutator. A novel type of commutator is described in the paper. This commutator construction provides simple means for holding the segments together, and at the same time secures high insulation qualities.

A PROBLEM of long standing in electrical engineering, which offers many difficulties both from an electrical and from a mechanical standpoint, is that of producing continuous-current machines for very high voltages. The application of high-voltage continuous current to power transmission has been seriously considered, and to a small extent carried out abroad by Thury. The Thury system consists of a number of series-excited generators coupled in series, each generator being designed for a moderate voltage of a few thousand volts. While this system has been actually carried out in a few instances abroad, it has not had any application in this country, and since the generators are only of moderate voltage, their structural features, viewed from the standpoint of high voltage, do not appear to be of any great interest since the voltage that we are considering ranges as high as from 12,000 to 20,000 volts per generator.

In the early development of arc lighting, machines for high voltage were produced to give unidirectional, but pulsating current. The voltage ran as high as 10,000 volts per circuit. Examples of this type are the well-known Thomson-Houston arc generator and the Brush arc machine. These machines cannot, however, be considered continuous-current machines since they produce a pulsating current. They are of the open coil type and come nearer to that type of apparatus known as rectifiers. A very marked arcing occurs on the rectifying segments, and since the current is pulsating, this type of machine cannot be used for any purpose requiring a non-pulsating voltage.

Lately, a demand has been created for continuous current machines of high and steady voltage for wire-

less work. By means of vacuum tubes, the direct current is converted into high-frequency alternating current. This system has proved to be successful and possesses a great many advantages. The purpose of this article is not to discuss the system as a whole, but to describe the design and construction of continuous-current generators built for wireless applications and ranging in voltage from 12,000 to 20,000 volts. It is believed that this type of machine possesses a number of novel features of general interest.

Early experiments with high-voltage, continuous-current machines for wireless work have shown that under certain conditions, difficulties arose due to pulsations in the current wave. At first, it was thought that this was due to the fluctuations inherent in any commutator machine, since the resultant voltage in such machines is, in reality, a rectification of a large number of coils. However, these fluctuations often became much larger than the theoretical value, and an investigation disclosed that these fluctuations were mainly due to faulty commutation. If the current is not properly commutated, it is a well-known fact that the extra currents react magnetically upon both the exciting and commutating circuits, resulting in changes in the induced voltage. It is, therefore, essential that the commutation should be absolutely perfect.

Another difficulty that is met with due to the characteristics of the tubes, is the possibility of dead short circuits. The machine must, therefore, be built to withstand short circuits without flashing, since flashing at this high voltage may seriously damage the commutator and brush rigging.

Another difficulty in designs of this nature lies in the mechanical limitation of the number of segments in the commutator. It is generally considered that in con-

Presented at the Annual Convention of the A. I. E. E., Swampscott, Mass., June 26-29, 1923.

tinuous-current machines, the average voltage between bars should not exceed 25 volts. In order to limit this voltage, two armature windings are employed, each winding connected to a commutator at each end of the armature. An investigation of the mechanical dimensions of a 15-kw. generator showed that by employing the largest number of segments that were practical per commutator, the average volts per bar become about 90 volts, or nearly four times the conventional value.

One of the serious questions is, therefore, whether it is possible to build a continuous-current machine having 90 volts per bar which will withstand instantaneous short circuit without flashing.

It is well understood that where commutation conditions are severe, as in motors which must operate over a wide range of speed, or in machines which have to endure heavy and sudden fluctuations in load, the operation of direct-current machines can be greatly improved by employing a compensating winding for neutralizing the armature reaction. A well-known form of a compensated machine consists of a concentrated form of exciting winding with definite poles and a compensating winding laid into the pole faces. Experiments have shown that a still better operation can be obtained if both the exciting and the compensating windings are distributed. Windings of this type were, I believe, first proposed by Deri, but, as far as I am aware, this type of winding has not been

FIG. 1

employed to any large extent in the industry due to the additional expense of such windings, both due to material and labor. The writer has, however, found that by distributing the compensating and the exciting windings in a certain way, it is possible to obtain results which are electrically perfect, mechanically simple and economical with respect to material.

In order to explain the arrangements proposed by the writer, reference is made to Fig. 1, representing a two-

pole machine. The inner circle represents the conductors of the armature winding, the middle circle represents the conductors of the compensating winding, and the outer circle represents the conductors of the exciting winding. The current distribution in the conductors is shown by means of the usual convention in which crosses and dots applied to the conductors indicate respectively that the current is flowing away from or toward the reader. The direction of the armature reaction is obviously indicated by the line *AB*. The

FIG. 2—FIELD WINDING FOR 12,000-VOLT, D-C. GENERATOR

compensating winding is so arranged that the current in each conductor is flowing in the opposite direction to the current in the opposite conductor in the armature. The compensating winding accordingly produces a resultant magnetomotive force in the direction *BA*, opposite to the armature reaction. The exciting winding should be so arranged that its magnetic polarization is along the line *EE*, *i. e.*, displaced 90 electrical degrees in space from the line *AB*.

Referring again to Fig. 1, it is indicated that the armature winding is a full-pitch winding. The compensating and the exciting windings would, most naturally, also be laid out as full-pitch windings in which case the end connections would be represented by the dotted line in Fig. 1, in such case the compensating winding would be a counterpart of the armature winding mechanically as well as electrically. The writer, has, however, found that exactly the same distribution of the field winding can be obtained by the use of a 50 per cent pitch winding, one single coil being indicated by the full drawn line in Fig. 1. In Fig. 2 all of the coils are shown, and it will be observed that in each slot there is a compensating as well as an exciting coil, and that all of the coils together form a mechanically single winding similar to lap windings as they are often used in the field of induction motors. It is interesting to note that the armature reaction of a full-pitch armature winding is neutralized by a completely distributed winding of a half pitch. It is

obvious that by the use of a half pitch winding in the field, a large economy is obtained as compared with a full-pitch winding, because both windings exert exactly the same amount of magnetomotive force by the use of the same number of turns, but the length of the turns of the half pitch windings is far shorter than in the full pitch winding. From Fig. 2 may be seen that the teeth of the field are evenly distributed except that one tooth on each side of the commutating tooth is left out, thereby creating a wide neutral zone.

An examination of Fig. 2 reveals the fact that the construction provides for two commutating teeth. The compensating winding is made slightly stronger than the armature reaction and the difference in ampere turns sets up a commutating flux through the commutating teeth.

Experiments have shown that the fully distributed exciting winding has the advantage of producing a nearly sine wave flux distribution, resulting in a gradual building up of the voltage gradient on the commutator.

The slots as shown in Fig. 2 are open, making it possible to wind and insulate the coils outside of this machine. After the coils have been assembled, steel wedges are inserted closing the slot openings. The wide slots on each side of the commutating pole do not contain steel wedges since that would be undesirable as it would cause the commutating flux to leak sideways instead of penetrating the armature.

The most important feature of this new machine is illustrated in Fig. 2 and the advantage of this construction may be summarized as follows:

First: A mechanically simple single-coil winding is used, which winding is economical with respect to material, due to the use of a 50 per cent pitch.

Second: A single compensating winding is used both for the purpose of neutralizing the armature reaction and producing a commutating field.

Third: The exciting winding is fully distributed giving the advantage of being placed close to the armature, thus securing a minimum of leakage, and also giving a nearly sine wave flux distribution.

Fourth: Wide neutrals are provided so as to remove the exciting flux from the coils undergoing commutation.

The armature, as has already been stated, carries two independent windings, each being connected to a commutator. As the bottom winding naturally has more self induction than the top winding, it was found that if the compensating winding was adjusted to give black commutation for the top winding, the brushes on the commutator belonging to the bottom winding would spark. Vice versa, if the compensating winding were adjusted properly for the bottom winding, the top winding would spark. It is obvious that the bottom winding, which possesses the larger self induction, reverses more slowly than the top winding and it was found that this difficulty could be overcome by the use of thicker brushes for the bottom winding than for the

top winding. The brushes on the commutator connected to the bottom winding were about one-third thicker than the brushes belonging to the top winding.

In order to further illustrate the field winding, in Fig. 3 are shown the field coils developed in a plane. In Fig. 4 is shown the connection diagram of the machine, and as may be seen, a separate exciter is used in preference to self excitation. The reason for using a separate exciter is two-fold:

FIG. 3—INTERNAL FIELD CONNECTIONS FOR 12,000-VOLT, D-C. GENERATOR

First: It would be difficult to wind and insulate a shunt field for 6000 volts and above, which is the voltage on one commutator.

Second: At a sudden variation of the load, the tremendous induction of the shunt field would cause a discharge through the armature setting up disturbances and possibly making the machine flash over.

Tests have proved that this machine possesses ex-

FIG. 4—CONNECTION DIAGRAM FOR 12,000-VOLT, D-C. GENERATOR

cellent operating qualities. The commutation is perfect up to five times load, which load can be thrown on and off without causing any sparking or the slightest amount of flashing. The excitation can be thrown on and off without any resistance being inserted in the exciting winding. Instantaneous short circuits through the tubes, which have repeatedly occurred, do not disturb the machine in the least.

During the construction of the first sample machine, serious difficulties arose in the building of the commutators. The first commutators were constructed in accordance with standard practise, the commutator bars being clamped in place by mica cones, the cones being moulded from what is known as pasted mica. It was found that these mica cones would not withstand the required testing voltage, which was set as high as 40,000 volts.

This difficulty was finally overcome by a new method of building commutators, the construction of which is shown in Figs. 5 and 6. The idea originated from the construction of a special gear made by the General

FIG. 5—FABROIL COMMUTATOR FOR 12,000 VOLTS

FIG. 6—FABROIL COMMUTATOR FOR 10,000-VOLT, D-C. GENERATOR

Electric Co., called "the fabroil gear." The commutator segments are held together under heavy pressure between washers of cotton batting and in order to obtain high dielectric strength, washers of mica are interspersed between these cotton washers. The commutator is put up under a very heavy pressure, about 5 tons per square inch, amounting to a total pressure on the particular commutator under consideration of 120 tons. As cotton possesses the characteristic of resiliency under heavy pressure, the pressure is maintained at all times and the commutator, therefore, is tight under all conditions. Therefore, there need be no provisions made for tightening the commutator after it is once completed. This construction gives a three-fold advantage:

First: We obtain a large and clean creeping distance to ground.

Second: The multiplicity of mica washers provides an excellent insulation since these washers are placed in series with the voltage, a factor which is not obtainable by constructions heretofore employed in commutators.

Third: The commutator, being under a continuous

FIG. 7—TYPE C Y-70-15 KW., 12,000-VOLT, 1800 REV. PER MIN. GENERATOR

pressure, due to the resiliency of the cotton, needs no provisions for tightening after completion.

In order to give an understanding of the appearance of a finished machine, photographs of the disassembled parts, as well as the assembled machine, are shown in Figs. 7 and 8. This machine is rated 15 kw., 12,000 volts, 1750 rev. per min.

From the results obtained from tests, some interest-

FIG. 8—TYPE C Y-70-15 KW., 12,000-VOLT, 1800 REV. PER MIN. GENERATOR

ing observations may be made. The very fact that the volts between bars run as high as 90 volts, shows that the individual armature coils contain an unusually large number of turns, which means that the reactance voltage is considerable. Nevertheless, the commutation is perfect. As has already been stated, when conditions of operation are serious, a distributed compensating winding should be used, which statement is

fully vindicated by the results obtained in this machine. In machines with commutating poles in which no compensating winding is employed, the stability is imperfect due to the fact that the armature reaction is only compensated for along one single line. In machines with fully distributed compensating windings, the armature reaction is neutralized in every point and no disturbances occur due to shifting of the flux. Because of the completely distributed exciting winding, the leakage of this winding is limited to a much smaller amount than in machines where the exciting winding is massed together, and furthermore, the distribution of the voltage around the commutator is much better since this distribution of the winding gives a favorable distribution of the flux securing the particular advantage of a wide and stable neutral zone.

Since great successes have been obtained with generators of this type for wireless work, it is thought that this will open up new avenues for progress and it is for that purpose that this description has been given.

Discussion

P. L. Alger: The chief interest of Mr. Bergman's paper is in the commutation of the machine, that is, the chief theoretical interest. Mr. Bergman is building a machine for proper commutation. To get the commutation we must have low reactance and we must have a very definite commutating flux to make the voltage induced by the flux exactly overcome the voltage of the changing current. Unless a machine is very perfectly compensated, you cannot hold that flux just right because when the load changes, the armature reaction makes the neutral point shift; so the first thing is to obtain very perfect compensation. Mr. Bergman has done this. Another thing that helps commutation is his distributed field winding, as by this means he has a relatively gradual rise of flux on leaving the neutral, as compared with the salient pole winding.

Thus, by building a machine with perfect commutation he has made a machine which will stand anything almost in the way of speed or load variation without trouble and it appears to me that this scheme is also applicable to low-voltage continuous-current machines with similar advantage.

It seems to me the philosophy of the matter is that the machine with salient poles is one which has maximum space factor and maximum flux per pole, whereas Mr. Bergman's distributed winding machine is one which has a maximum fixity of wave form; that is, the flux is exactly placed by the winding instead of being left free to shift to and fro. I believe this idea of giving more weight to flux distribution than to space factor and total flux will grow in time and that all machines that are capable of compensation will ultimately change over to the distributed winding instead of the salient pole type.

H. Lemp: Mr. Bergman mentioned another form of producing unidirectional currents for high voltages, referring to kenotron or vacuum tubes, but he omitted to make any reference whatever to the mechanical synchronous rectifier. While I do not wish to put in a plea for myself, I would like to plead for a child

of my brain which has survived in the form of a mechanical rectifier for producing high-voltage unidirectional currents, and is particularly useful for X-ray work.

With the advent of the X-rays, there arose a demand for a continuous source of excitation of high voltage susceptible of furnishing large quantities of unidirectional currents; various forms were tried, and the Holtz influence machine which was at that time considered the most desirable source of excitation, was found ineffective on account of lack of sufficient energy behind it, particularly in wet weather, and it was then that the mechanical rectifier was developed by me in order to produce large quantities of these unidirectional currents unaffected by weather conditions and of sufficient high frequency to give a continuous non-flickering illumination, so necessary for fluoroscopic examinations.

This type of mechanical synchronous rectifier is now used, as is well known, by Cottrell in his method of precipitation of smoke and metallic vapors, and is still used exclusively for X-ray work where more than one hundred thousand volts are required. Below that voltage the hot cathode tube is sufficient to rectify its own supply.

I had recently the pleasure of seeing in Chicago at the factory of the Victor X-Ray Corporation, an improved mechanical rectifier in operation which supplied simultaneously energy to something like ten full-sized Coolidge X-ray tubes which represents a large amount of energy, particularly when one considers that 200,000 volts are used, which is substantially equivalent to sparks of from 12 in. to 14 in.

S. R. Bergman: I think Mr. Lemp's remarks on the mechanical rectifier are very interesting, but its use is limited to certain applications; for example, for X-ray work and for precipitation of smoke and metallic vapors.

The mechanical rectifier, however, for producing actual power does not seem very promising. It is very difficult to drive such a rectifier in exact synchronism, particularly when the power factor of the load changes. Since the mechanical rectifier not only changes the direction of the current, but also the wave form, particularly if we wish to derive a steady current, it is obvious that there exists a large differential current which causes sparking, which, particularly on short circuit, becomes so violent that it generally puts the rectifier out of business.

The mechanical rectifier generally gives rise to pulsations, in that respect, showing a similarity to a direct-current generator having two segments per pair of poles corresponding to a pulsation of 100 per cent. One of the objects of the machine which I described in my paper is to give as steady a current as possible. In a d-c. machine, the pulsations decrease with the number of segments per pole; for example, with 90 segments per pair of poles, the pulsations amount to 0.03 per cent. As a matter of fact, the pulsations due to the segmental arrangement of the commutator in a d-c. machine are generally smaller than the variation caused by the pulsation of the flux due to the variation of the reluctance of the magnetic circuit. It is a well-known fact that due to the presence of teeth in the armature, a certain amount of pulsation of reluctance takes place causing variation of the flux. Although, by choosing the number of teeth in the armature properly as compared with the number of teeth in the field, it is possible to limit this variation so as to make it unobjectionable. In a machine of the character which I describe, we manage to keep the pulsations down to 0.1 per cent. I believe it would be extremely difficult to make a mechanical rectifier having so small a variation.

The Axially Controlled Magnetron

A New Type of Magnetron, Controlled by Current Through the Filament

BY ALBERT W. HULL

General Electric Company

Review of the Subject.—In vacuum tubes with straight filaments of large diameter, it is found that the magnetic field of the heating current exercises a restraining effect on the escape of electrons, equivalent to the action of the grid in the pliotron, or the impressed magnetic field in the magnetron. This new valve principle may be utilized to control the output of the tube for practical purposes, such as changing high-voltage direct current into alternating

current; and leads to a very simple and efficient type of tube.

INTRODUCTION

IN a former number of this journal¹ a simple two-electrode tube was described in which the electron current between a straight cathode and a concentric cylindrical anode can be controlled by a magnetic field parallel to the axis of the tube. Such tubes are very easy to construct in comparison with three-electrode tubes; but the advantage so gained is partly offset by the requirement of an externally wound magnetic field coil.

The purpose of this paper is to show that in the case of large magnetrons such as are of interest for engineering applications, the magnetic field of the heating current which flows through the filament is sufficient for controlling the electron flow, so that the external magnetic field coil is unnecessary.

THEORY

Fig. 1 show a typical magnetron, consisting of a straight filament in the axis of a concentric cylindrical anode. The lines of magnetic force produced by the heating current are circles about the filament. Electrons passing from cathode to anode across these lines of force are deflected at right angles to the lines, as illustrated in Fig. 1B. The deflection is greater the larger the filament current, and with a sufficiently large filament current the electrons miss the anode entirely and return to the cathode (Fig. 1C).

Calculation shows that, with a given potential difference, E , between cathode and anode, the electrons should all reach the anode or fail to reach it, according as the current I through the cathode is greater or less than a critical value, given by the equation

$$E = 0.01882 I^2 \left(\log_{10} \frac{D}{d} \right)^2 \quad (1)$$

D, d = diameters of anode and cathode respectively.

I = current through cathode in amperes.

E = critical potential difference between anode and cathode, in volts.

The current I in Eq. 2 may be expressed in terms of the diameter of the cathode, for any given temperature.²

FIG. 1—SMALL MAGNETRON IN GLASS

- (a) Longitudinal cross-section through the filament showing paths of electrons with no filament current.
- (b) The same for weak filament current.
- (c) The same for strong filament current.

Thus for tungsten cathodes at 2500 deg. K. Eq. (2) becomes:

$$E = 0.000716 d^3_{\text{mils}} \left(\log_{10} \frac{D}{d} \right)^2 \quad \text{(tungsten cathode of dia. } d \text{ at 2500 deg. K. in axis of cyl. of dia. } D)$$

or

$$E = 44100 d^3_{\text{cm}} \left(\log_{10} \frac{D}{d} \right)^2 \quad (2)$$

For the general case of a tungsten cathode at any temperature near 2500 degrees absolute, the critical

2. Characteristics of tungsten filaments, Langmuir, Phys. Rev., 7, 302-30, 1916; G. E. Rev., Mar., 1916.

voltage may be expressed with sufficient approximation by the eq.:

$$E_{volts} = 44100 d^3_{cm} \left[\log_{10} \frac{D}{d} \right]^2 \left[1 + 0.00143 (T-2500) \right] \quad (3)$$

Eq. 3 shows that the critical voltage, that is, the voltage below which the magnetic field of the heating current is able to hold back the electrons, increases as the cube of the filament diameter, for the same temperature and relative size of electrodes. For example, in the "peanut" pliotron, UV-199, which has a filament of 0.0006 inches diameter, surrounded by a grid of approximately 0.06 in. diameter, operating at 1900 deg. K., the critical voltage is 0.0003 volts. For a 0.0085 in. filament, such as is used in the 50 watt pliotron UV-203A, the critical voltage (assuming the same ratio of

anode to cathode diameter) is $\left(\frac{85}{6}\right)^3$ or 2800 times

as great, viz. 0.84 volts³. Increasing the filament diameter to 0.085 inches would again increase the critical voltage 1000 fold, to 840 volts. Another ten fold increase of cathode diameter, with the same ratio of anode to cathode diameter (100 to 1), is impractical because of the size of the anode; but taking a ten to one ratio of anode to cathode diameter, a 0.85 inch diameter filament operating at 2500 deg. K. would have a critical voltage of 440,000.

The critical voltage increases less rapidly than the cube of the cathode diameter when the anode diameter is kept constant, instead of the ratio of anode to cathode diameter. A few examples, tabulated in Table I, will give an idea of the cut-off voltages for different sizes of filament heated by direct current, in a two-inch diameter anode.

TABLE I
CRITICAL VOLTAGES FOR TUNGSTEN FILAMENTS AT 2500° K

Diameter of Anode cm.	Diameter of Filament cm.	Critical Voltage volts
5.00	0.0025	0.0075
5.00	0.025	3.6
5.00	0.100	127.
5.00	0.250	1140.
5.00	1.00	21,600.
5.00	2.50	62,300.

It is seen that for all cathodes used in standard tubes at the present time, the effect of the magnetic field of the heating current is entirely negligible. For large cathodes, on the other hand, such as are needed for power tubes, the magnetic field of the heating current is able, even at the highest voltages used in engineering, to inhibit entirely the electron current between cathode and anode; i. e., to give the tube infinite resistance. It

3. Both of these values of critical voltage are meaningless, as they are scarcely larger than the average initial velocity of the electrons, and much smaller than the voltage drop in the filament.

is thus a factor that must be considered in the construction and operation of large tubes, both as a possible limitation and as a means of useful control, performing the function of the grid of the pliotron. Experimental tests of this method of controlling electron current, and possible applications of it, are described in the following pages.

EXPERIMENTAL TESTS

According to the theory outlined above, the electron current from a straight filament to a concentric cylindrical anode should be zero for all voltages below the critical value, given by Eq. 1; while for all voltages above this critical value the magnetic field should have no effect, i. e., the electron current should be limited only by the temperature of the filament or the mutual

FIG. 2—VOLT-AMPERE CHARACTERISTIC OF TUBE SHOWN IN FIG. 1

Filament diameter 100 mils, anode diameter 4 in.

repulsion of the electrons in the space (space charge limitation.)

Fig. 2 shows the currents observed, as a function of voltage, in a tube containing a 100 mil (0.25 cm.) diam. filament in the axis of a cylindrical anode 4 inches (10 cm.) in diam. by 12 inches long. Curve 1 shows the ordinary space-charge characteristic observed in the absence of magnetostriction. These values were obtained by opening the filament switch, and observing the plate current before the filament had time to cool. Immediately upon opening the filament switch the plate current rises to the value set by space-charge, remains constant for an instant, then falls rapidly as the filament cools to the point of temperature limitation. Curve 2 shows the currents observed when the heating current of 200 amperes was flowing through the fila-

ment. The characteristic predicted by theory is represented by the vertical straight line at 1930 volts (Curve 3).

FIG. 3—VARIATION OF PLATE CURRENT WITH FILAMENT CURRENT AT CONSTANT ANODE VOLTAGE

It is seen that the magnetic field of the filament current has a profound effect on the characteristic, reducing the plate current to essentially zero at all plate voltages

FIG. 4—VARIATION OF PLATE CURRENT WITH FILAMENT CURRENT AT CONSTANT ANODE VOLTAGE
Higher Voltage than in Fig 3.

below about 1400 volts. The fact that the transition from zero current to full space charge current is not abrupt, may be partly accounted for by the crooked-

ness of the filament, which was bowed about an inch out of center at its middle point; and partly by deflection of a small fraction of the electrons by collision with gas molecules. All the characteristics obtained show slight transition currents of this kind, but their magnitude is always small compared with the current under control.

Fig. 3 shows the variation of plate current with filament current at constant anode voltage for the same tube (filament 100 mils diameter, anode 4 inches diameter by twelve inches long. Curve 1 was taken with 800 volts on the anode, curve 2 with 1000 volts, and curve 3 with 1220 volts. The left hand, ascending branch is the same for all voltages, and depends only

FIG. 5—THREE FILMS SHOWING THE CONTROL OF PLATE CURRENT BY 60-CYCLE FILAMENT CURRENT IN A SMALL MAGNETRON, WITH CONSTANT ANODE VOLTAGES OF 250, 505, AND 1050 VOLTS DIRECT CURRENT

Record A — Plate current of rectangular form with the zero value at A.
Record A to 1 — Deflection, for calibration, given by a plate current of 1.4 amp. in film 1; 4.0 amp. film 2; and 6 amp. film 3.

Record B — 60-cycle filament current.

Note that the plate current flows only when the filament current is below a definite value.

on the temperature. It represents the temperature-limited saturation emission from the filament, and is given accurately by the equation.⁴

$$i = 60.2 T e^2 - \frac{52800}{T} \frac{\text{amperes}}{\text{cm}^2}$$

The right hand descending branches are due to magnetostriction. It is seen that for each constant anode voltage the electron current begins at a definite heating current (minimum temperature for emission) and increases rapidly with heating current up to a

4. Dushman, G. E. *Review*, 16, 153-60, Mar. 1923 and *Phys. Rev.*, Apr. 1923.

critical point. This critical point is the "critical filament current" given by Eq. 1. When the heating current is raised above this critical value, the electron emission falls rapidly to essentially zero because of the magnetic effect of the heating current.

Fig. 4 shows a similar series of characteristics with higher plate voltages and larger currents. At the highest filament current, 325 amperes, the filament is at 3300 deg. K., and is capable of emitting approximately 2000 amperes of electrons. The actual emission at 1600 volts is only 20 milliamperes.

Fig. 5 shows an oscillographic record of the plate current in the same tube when 60-cycle alternating current is used to heat the filament. In this case the filament temperature remains constant while the instantaneous value of the heating current changes, so that the full space-charge current flows during that part of each cycle in which the heating current is below the critical value, and no current during the part when the field is above the critical value.

The lower film (film 1) was taken with a constant potential of 250 volts on the anode. During the greater part of each cycle the filament current is above the critical value for 250 volts, and the plate current is zero, as it should be. When the filament current falls to the value 73 amperes, plate current begins and increases rapidly to the maximum value allowed by space charge. As soon as the filament current again reaches the same value of 73 amperes in the opposite direction, the plate current begins to fall, and drops rapidly to zero. The

FIG. 6—CONSTRUCTION OF HIGH-POWER MAGNETRON

plate current is thus interrupted twice each cycle, since both directions of filament current are alike in their magnetostrictive effect.

The second film was taken with 505 volts on the plate. The space current is larger and flows for a longer part of each cycle, beginning and ending when the filament current reaches the value 101 amperes. The critical value given by Eq. 2 is 102 amperes. The filament current in this test (184 amperes) was larger than that used for the first film, and the curve shows a slight distortion due to saturation in the filament transformer.

For the upper film (film III.) a plate voltage of 1050 was used, and a larger filament current (201 amperes). The filament current curve shows bad saturation distortion, so that the distance from the point where it crosses the axis to the point where it reaches its critical value is very different above and below the axis. In spite of this, the plate current begins and ends accurately at the critical filament current of 157 amperes, which agrees with the theoretical value of 149 amperes within the error of measurement.

The observed plate currents in each of these oscillographic tests are about 3 times as large as the value to be expected from the space charge law. The increase is due to reduction of space charge by gas ionization. It is notable that an amount of ionization sufficient to neutralize space charge to this extent does not noticeably affect the magnetic cut-off, showing that the magnetron is slightly less susceptible than the pliotron to the presence of gas.

3. A series of tests with much larger filaments has been carried out by Mr. J. H. Payne. Exact measurements are more difficult in this case, because of the inability of ordinary generating systems to deliver

FIG. 7—CONTROL OF PLATE CURRENT BY 60-CYCLE FILAMENT CURRENT IN A HIGH-POWER MAGNETRON. FILAMENT DIA. = 1 CM. ANODE DIA. = 4.6 CM.

Record A — Voltage between filament and anode (deflection downward)
Record B — Current from filament to concentric anode.
Record C — 60-cycle current in the filament.

Note that the current between filament and anode is zero except when the filament current is below a critical value.

intermittently the large amounts of power required, and the difficulty of getting rid of this power when delivered. For low voltages, up to 2000 volts, the tests are very satisfactory (oscillograms, Figs. 7 and 8). Electron currents up to 50 amperes are seen to be under perfect control by the magnetic field of the filament current; and the critical values of voltage and filament current agree well with those predicted by theory. At higher voltages only the low-current portion of the curves could be obtained with the generating system available (30 kv., 20 kv-a. transformer, with kenotron rectifiers and condensers). These oscillograms (Fig. 9) show suppression of the plate current when the magnetic field of the filament current is above the critical value, but give no idea of the magnitude of the plate current that would normally flow when the magnetic field is below the critical value.

The tube used for these tests is shown in Fig. 6. The anode is a copper tube 1 13/16 inches (4.60 cm.) in diameter by 30 in. (76 cm.) long, surrounded by a water jacket. The cathode is a tungsten rod 0.400 inches (1 cm.) in diameter, 22 inches (56 cm.) long. Upon each end of the cathode is tightly swaged a short bar of

molybdenum, which is threaded so that it can be screwed into the copper lead. A short section of glass at each end insulates the filament from the anode.

The results of these tests are shown in Figs. 7, 8 and 9. Fig. 7 shows a test at 1700 volts anode potential. This potential was furnished by a 20-kw., 3000-volt d-c. generator, with 50 μ f. across its terminals to stabilize the voltage during the sudden starting and stopping of

FIG. 8—SAME CONDITION AS FIG. 7 EXCEPT THE VOLTAGE AND CURRENT BETWEEN FILAMENT AND ANODE ARE LARGER

the current. In spite of this, the voltage dropped 25 per cent during each current pulse, and then rose gradually during the remainder of the cycle, as shown in curve A. Curve B shows the electron current that flowed from cathode to anode and thence in the plate circuit. It is seen that this current is completely suppressed except during the short fraction of each

FIG. 9—CONTROL OF PLATE CURRENT BY 60-CYCLE FILAMENT CURRENT IN HIGH-POWER MAGNETRON. FILAMENT DIA. = 0.87 CM., ANODE DIA. = 7.5 CM.

Record A — Plate voltage (deflection downward).
Record B — Plate current (deflection upward).
Record C — 60-cycle filament current.

cycle when the filament current is below a critical value. During these short periods, twice each cycle, it rises to 36 amperes, and then falls abruptly to zero as the filament current again reaches the critical value. The filament voltage, which is nearly in phase with the filament current, is shown in curve C.

Fig. 8 shows a similar test at 2100 volts. The anode current in this case rises to 45 amperes.

Fig. 9 shows a test at 8000 volts. The electron current (curve B) is limited by filament temperature to 1.7 amperes, and even with this small current the anode voltage (curve A) falls from 8000 to 3000 volts during the short fraction of each cycle when power is being drawn. The small residual current of $\frac{1}{4}$ ampere, due to gas and end leakage, shows prominently on the large scale of the oscillogram. It is entirely negligible however, compared with the normal useful current of 50 amperes which the tube can control. In this test the cathode was smaller, viz., 0.350 inches diameter, and the anode 3 inches diameter.

Preparations are being made for tests at higher voltage with larger amounts of power. A few tests already made at 20,000 and 30,000 volts, show that the magnetic control is effective at these voltages, but the currents available were too small for satisfactory oscillograms.

APPLICATIONS

The magnetron, like all high vacuum thermionic tubes, is a high resistance device, so that its use is limited to either small power or high voltage. The type of magnetron here described suffers the further re-

FIG. 10—CIRCUIT FOR CONVERSION OF DIRECT-CURRENT TO SINGLE-PHASE ALTERNATING CURRENT BY MEANS OF MAGNETRONS

striction that it is operable only with large diameter filaments, and hence is adapted only to high power applications. For these applications, however, it appears to be the simplest and most efficient tube that has yet been studied.

A single example will serve to illustrate the method of operation and the efficiency to be expected. The problem chosen is the conversion of high-voltage direct current into alternating current. Let the direct-current voltage be 100,000 and the alternating-current voltage anything that is desired. A tube is chosen similar to that shown in Fig. 5, having a cathode of 2.0 cm. (0.79 in.) in diameter by 1 meter long, and an anode 8.0 cm. (3.1 in.) in diameter. A current of 4400 amperes heats the filament to 2500 deg. K., at which temperature its electron emission is 170 amperes; and the magnetic field of this heating current is capable of making the magnetron a non-conductor at 200,000 volts.

For conversion to single-phase alternating current two of these tubes may be connected as shown in Fig. 10. Current passes from the positive d-c. terminals, through

a choke coil, to the middle point of the high-voltage winding of a transformer, whose terminals are connected to the anodes of the two magnetrons. The cathodes are connected to the negative d-c. terminal, and are heated by square-wave current of the frequency of the desired alternating current. This square-wave current may be obtained in a variety of ways. For example, it may be derived from a d-c. generator and commutator, giving the wave form shown in Fig. 11A; or from a quarter-phase alternator of proper design, giving the wave form shown in Fig. 11B; or it may be derived

FIG. 11A— WAVE-SHAPE AND PHASE OF FILAMENT CURRENTS WHEN D-C. GENERATOR IS USED

FIG. 11B— WAVE-SHAPE AND PHASE OF FILAMENT CURRENTS WHEN ALTERNATOR IS USED

partly from a d-c. generator and partly, by suitable coupling, from the alternating-current output, provided the output circuit contains a frequency-determining element, or is tied to a system of fixed frequency.

The operation is as follows: Current from the d-c. line flows through the choke and the transformer winding to the magnetron anodes, and then through one of the magnetrons—the one whose filament current is zero—to the negative d-c. terminal. If the load is adjusted for 100 amperes in the d-c. line, a voltage of 3000 volts will be required to carry this current through the tube, the remaining 97,000 volts being supported by the reactive drop in the transformer.

Just before the magnetron that has been carrying current becomes a non-conductor by the establishment

of filament current through it, the filament current in the other tube becomes zero and the load is transferred to it. The slight disturbance incident to this transfer is absorbed by the choke coil.

The total power converted by this pair of tubes is 10,000 kw. (100 amperes $\times$ 100,000 volts); and the efficiency, exclusive of transformer losses, is 96 per cent (150 kw. per tube dissipated at anode, 50 kw. in filament). The power used for control is that which heats the filament, and the total amount of power needed for this purpose, in case it is furnished by a separate generator, is 100 kw., or 1 per cent of the output. The calculated life of the filament, which is taken arbitrarily as the time necessary to reduce its diam. by 5 per cent by evaporation, is 60,000 hours, or approximately 7 years of continuous operation. The life will be shorter than this if there is appreciable disintegration of the filament due to bombardment with gas ions. The amount of this disintegration cannot be predicted from data at present available.

The simple single-phase conversion system just described gives square alternating-current waves. This is an advantage, if the alternating current, after being stepped down to the desired voltage, is to be again rectified and used as direct current. Sine waves of any required degree of purity may be obtained by the use of an appropriate number of these single-phase units, connected according to well known multiphase circuits. A system containing 6 single-phase units (12 tubes) would give an output of 60,000 kw. of fairly good wave-form, with an efficiency of 96 per cent.

It is seen that the power capacity of these tubes is ample for conversion purposes, and their efficiency, so far as can be predicted at present, compares favorably with that of other types of conversion apparatus. Unquestionably many problems remain yet to be solved before high-voltage operation of these tubes is practical; but there is no known obstacle or limitation in sight. It is hoped that actual conversion tests, as well as static characteristics, at high voltages, will soon be available.

I wish to acknowledge the very able assistance of Mr. F. R. Elder and Mr. E. F. Hennelly in carrying out these tests.

Discussion

For discussion of this paper see page 953.

In addition to the wrapped samples described above, a sample of the insulation of each set of three bars was made up in the form of a flat sheet 44.72 cm. square, effort being made by pressure and temperature to produce a uniform, compact, composite, sheet free from entrapped air. The purpose here was to make a comparative study of the wrapped and the flat insulation, having in mind the greater probability of air layers in the former.

For the electrical tests described below a tin foil electrode 22.32 cm. long, was applied to the central section of each bar. Each end of this electrode was flanked by a guard electrode 5.4 cm. wide, and separated from the central electrode by 0.16 cm. Each of the flat samples was provided with a central circular tin-foil electrode 15.24 cm. diameter, surrounded by a guard ring 2.54 cm. radial width; and on the opposite side an electrode of tinfoil of diameter equal that of the guard rings. The tinfoil was first coated on one side with shellac, dried, and then applied to the insulation with a hot iron. This resulted in a very intimate contact free from blisters or other evidence of entrapped air.

METHOD OF TEST

The purposes of the investigation were to determine, if possible, the values of voltage, or potential gradient, at which ionization begins, the increase in dielectric losses due to ionization, and their influence on the

FIG. 1—CONNECTIONS OF ELECTROSTATIC WATTMETER

structure and the life of the insulation. For detecting the beginning of ionization either direct visual observation, or some conductivity method as used in the corona voltmeter, is the most sensitive; but obviously neither can be used in the present case. Moreover owing to the wide variation in area and thickness of the entrapped air spaces it is probable that ionization begins at different values of voltage in different parts of the insulation, and so would show a gradual rather than a steep curve of rise by any method. Since the problem requires the measurement of the dielectric losses, it was decided to rely also on the loss measurements for indication of the beginnings of ionization. Ionization should cause more or less sharp breaks in both loss and power factor curves. There is required, therefore, a method of measuring relatively small amounts of power, say of the order of tenths of a watt, as found necessary in some cases, at low power factor, and at voltages in the range 1000 to 20,000 volts. Of the several available methods that have been used for this type of measurement, it was decided to use the quadrant electrometer in wattmeter connection, that is with voltage on the

needle, and the quadrant connections taken from the terminals of a relatively low resistance in series with the dielectric to be measured. In order to simplify the problem of the insulation of the needle, it was determined to use the method of applying to the needle known fractional values of the total voltage, by means of taps taken from the high-tension winding of the transformer. This method has been described and used by Miles Walker⁴, C. E. Skinner⁵, Rayner,⁶ Russell⁷, Orlich⁸ and others. The principal connections are shown in Fig. 1.

W is the quadrant electrometer with its needle connected, as desired, to several different points on the high-tension winding of the transformer. The quadrant terminals are connected through a reversing switch *S*₁ to the terminals of the non-inductive resistance *R*₁. One terminal of the transformer winding is connected to ground and the other through the non-inductive resistance *R*₂ to the central bar of the specimen under test, *A*. The central electrode *B* of the specimen is connected to ground through the resistance *R*₁. The guard electrodes *C C* are connected together and to ground through the resistance *R*₃. *I* is a Dolacelek quadrant electrometer which is connected through the reversing switch *S*₂ to the terminals of the non-inductive resistance *R*₁¹. This instrument serves to read the current to ground from the central electrode *B*. The current and watt readings are taken independently permitting the use of the same resistance for the different values *R*₁ and *R*₁¹. The resistance *R*₂ may be used for correcting the wattmeter reading for the error caused by the resistance *R*₁, or for the purposes of calibration, as described below. The resistance *R*₃ may be used for adjusting the difference of potential between the electrodes *B* and *C* to zero. However, in most of the observations, owing to the low values of potential drop over *R*₁, *R*₃ could be varied from zero over a wide range without influence on the wattmeter readings, and the electrodes *C* were usually connected directly to ground.

The wattmeter electrometer, especially constructed for this work, had cast brass quadrants of the usual cylindrical box type with an inside diameter of 6 in. (15.24 cm.) and a height of 1½ in. (3.81 cm.). They were mounted on hard rubber chairs with a clearance of 0.381 cm. to the base of the instrument. The needle was of 0.158 mm. sheet aluminum. The suspension was of phosphor bronze strip 20 cm. long. The needle system was insulated by a corrugated hard rubber bushing 5 cm. long and was tested to 2000 volts. During most of the experiments the maximum voltage on the needle did not exceed 1500 volts. Below the quadrants the needle carried mica damping vanes immersed in light oil. The whole instrument was enclosed in a metal case connected to ground and provided with a glass covered opening for taking readings, by means of a beam of light and ground glass scale at about one meter's distance. The resistances *R*₁, *R*₂ and *R*₃ were all placed in metal boxes connected

to ground. Transformer and test specimen were placed close together and the leads to the instruments were as short and as widely separated as possible, having in mind the importance of removing the needle terminal of the instrument from the electrostatic influence of the high-voltage connection. The transformer had a capacity of 3 kv-a. and a ratio of 100 to 25,000 volts. The high-tension winding was in twelve sections and points were brought out for the intervals 1/12, 1/6, 1/4 and 1/2 of the total winding. One end of the primary and one end of the secondary were connected together and to ground. The 5 kv-a., 110-volt, 60-cycle generator *G* has a surface wound armature and gives a smooth wave. It is driven by direct-con-

nected 7½ h. p., d-c. motor, which throughout the experiments was supplied from a large storage battery, insuring closely constant frequency at 60 cycles. The frequency could be read at all times by a direct-reading frequency meter showing differences of less than ¼ of a cycle. The test specimen *A* was placed on insulators in a deep metal trough connected to ground and careful tests made to insure the absence of electro-static influence of the high-tension winding on the electrode *B* and its connection to ground.

CALIBRATION OF INSTRUMENTS

The usual formula for the loss *W* as determined by the quadrant electrometer wattmeter is

$$W = N K \theta / R_1 + \frac{N - 2}{2} R_1 I^2 \quad (1)$$

in which N is the number of times the needle voltage is contained in the total voltage, θ the deflection of the instrument in centimeters of scale, R_1 the resistance in ohms between quadrants, I the current in R_1 , and K the constant of the instrument.

The constant K may be determined by measuring the power in a non-inductive circuit. The formula as given may be used with safety for all values of loss when the power factor is relatively high. The second right-hand term disappears for $N = 2$ and its computation for any value of N may be avoided⁹ by proper adjustment of the value of the resistance R_2 . A more convenient method, however, is to take two readings with different values of R_1 and to extrapolate for the value

of $\frac{N K \theta}{R_1}$, corresponding to $R_1 = 0$.

For low values of power and of power factor, such as usually occur in dielectrics of good insulating power, and such as are to be expected in the present work, the large value of R_1 necessary for a satisfactory reading, may introduce errors due to the passage of the quadrant charging current over R_1 , and a change in phase of the current in R_1 . The precise correction for this type of

TABLE III

K = Constant of Instrument

error involves a number of constants both of the instrument and of the sample under test, and does not appear to have been worked out in a readily available form. However, Orlich⁹ concludes that for ordinary frequencies this error is proportional to R_1 over a considerable range. Thus correction for the loss in R_1 , and for the quadrant charging current in R_1 , are both proportional to R_1 , and so may be corrected for by readings for two values of R_1 and extrapolation to the value for $R_1 = 0$. The test of the validity of this method is found in taking readings for three or more

values of R_1 ; if values of $\frac{\theta N K}{R_1}$ fall in a straight line

the method is reliable. This test and method have been followed in the present work. In calibrating and in all the loss measurements observations have been taken for two or more values of R_1 . For each value right and left-hand readings of the electrometer were also taken by reversal of the switch S_1 .

The wattmeter was first calibrated for unity power factor by comparison with the watt input to a non-inductive load, current being measured by the Dolacelek quadrant electrometer, (calibrated for volts, in terms of laboratory standards), and voltage by means of standard voltmeters on the low-tension side of the step-up transformers, whose ratios were checked with potential transformers. The load consisted of 1.5

megohms of fine manganin ribbon wound on mica cards, 6000 ohms each, recommended by the Bureau of Standards for pure reactance-free characteristics. This resistance was inserted at R_2 in Fig. 1, the insulated armature bar being omitted. Current and voltage

were read at I and E , and right and left deflections of W taken for each of two or more values of R_1 . This was done for values of N , 1, 2, 4, 6, and 12. The observations for $N = 1$ and $N = 12$ are given in Table II, and the summary of all the readings in the last division of Table III. The $I^2 R$ loss is computed and

equated to $\frac{\theta N K}{R_1}$ giving the value of K the constant

of the instrument. The frequency throughout was 60 cycles.

For calibration of the wattmeter for low values of loss at low power factor a 0.002 microfarad Moscicki condenser unit was used. These condensers are of Leyden jar type filled with, and immersed in oil, and with other features of design for preventing brush discharge from the edges of the inner and outer electrodes. The voltage rating was 15,000 volts. The condenser, in series with the variable resistance R_2 , was substituted for the sample bar, with the connections of Fig. 1. For each of three values of R_2 a series of observations was taken with different values of R_1 . Correcting each series by extrapolation to $R_1 = 0$, the successive

increments of $\frac{\theta N K}{R_1}$, together with the corresponding

losses in R_2 , as determined by the current measurement, will give the desired values of K . Table IV shows one

FIG. 2—CALIBRATION OF WATTMETER FOR LOW VALUES OF POWER FACTOR, $E = 30$, $N = 12$

set of observations with the resulting values of K . In

Fig. 2, $\frac{\theta N K}{R_1}$ is plotted as a function of R_1 , showing the

linear relation necessary for correcting the errors due to the resistance R_1 and to the capacities between the several elements of the instrument. These data also permit computations of the constants of the Moscicki unit. The approximate values are: capacity 0.002 microfarad, reactance at 60 cycles 1.33×10^6 ohms, effective resistance 1.04×10^4 ohms, loss at 7.5 kv., 0.25 watts, power factor 0.007.

No values of power factor as low as 0.007 were encountered in the tests, although values of loss lower than 0.25 watts were often met. A further check of the constant K was obtained by substituting one of the test bars for the Moscicki condenser in the foregoing method. The results were in all respects similar in character to those described and gave values of K shown in the second division of Table III. Throughout the tests the value for K has been taken as 166.

It appeared desirable to check the calibration of the wattmeter from time to time. For this purpose, in order to avoid the setting up anew each time, of the condenser and its auxiliaries, with the precautions for screening, one of the test bars was used as a secondary standard. This bar was immersed in compound, and after comparison with the original calibration, the reading of its loss and charging current at a definite value of voltage, at regular intervals, was used as a check of the constancy of the wattmeter. No variations were found during the course of the work.

CORRECTION FOR TEMPERATURE

The dielectric losses in insulation vary with the temperature. The law of this variation for one or two of the test bars was investigated and is discussed hereafter. However, since it is a difficult, if not impossible, matter to determine the temperature of the insulation, it was necessary to make the measurements at as nearly as possible constant temperature. In the experiments relating to the variations of dielectric loss among the various samples, this was accomplished by working at atmospheric temperature in a room comparatively free from temperature variation. Most of the observations were made at temperatures between 21 deg. cent. and 25 deg. cent. and in nearly every case the temperature variation for the observations on a single specimen was less than 1 deg. In this method therefore a small error is introduced in comparing actual values of losses of two specimens. The observations on individual specimens are free from appreciable temperature error, except perhaps at the very highest values of voltage. At high values of voltage in the case of nearly every specimen the loss is sufficiently high to cause an elevation of temperature during the time interval required for the taking of readings. The wattmeter was heavily damped and required two minutes to come to rest for any one reading. Taking right and left deflections for each of two or more values of the resistance R_1 therefore, requires a minimum of eight minutes for the making of one loss measurement. An additional two minutes is required for making the measurement of charging current, giving therefore a total of ten minutes for each reading, during which time voltage is applied to the specimen. In the upper range of voltage the loss during this interval is sufficient to increase the temperature and so make the loss readings higher than that pertaining to the initial condition of the specimen. In order to meet the error thus caused the following method was devised:

Beginning at atmospheric temperature and taking right and left deflections of the wattmeter at two-minute intervals, it was found that for the higher voltages the wattmeter readings increased linearly with the time over a considerable interval, 30 minutes in some cases, and less than this only in the cases of specimens having abnormally high loss and in the neighborhood of breakdown. This linear relation is doubtless due to the facts that the increase in loss is proportional to the temperature, and that the temperature rise is uniform with the time for a slow total rise, radiation being practically negligible. This linear relation of

FIG. 3—CORRECTION FOR TEMPERATURE RISE

loss and time makes it a simple matter to correct for the elevation of temperature during observations by means of the straight line diagram used for extrapolating the

value of $\frac{\theta N K}{R_1}$ to its value for $R_1 = 0$. By taking the

observation for the second value of R_1 immediately after the observation for the first value of R_1 , and by having these two values in the ratio 2 to 1, the temperature correction is automatically applied by the straight line passing through the two observations, making its

FIG. 4—INCREASE OF LOSS DUE TO TEMPERATURE RISE No. 44-75 KV., No. 49-12.5 KV.

intersection with the vertical axis $R_1 = 0$. The method is illustrated by the readings of Table V and the corresponding diagram of Fig. 3. A is the loss reading corresponding to $R_1 = 2000$ ohms, based on right and

left deflections requiring a total of four minutes from the application of voltage. B is the loss reading corresponding to $R_1 = 4000$ ohms based on right and left deflections and read eight minutes after the initial application of voltage. C is the loss reading corresponding to $R_1 = 2000$ ohms and taken four minutes after the reading B, or twelve minutes after the initial application of voltage. The length of the line AC therefore is the increase in loss due to the heating of the bar in an interval of eight minutes. Taking this value from that corresponding to the point B, we obtain the point E, which represents the true reading corresponding

FIG. 5

Bar No. 48 — Not Dried
Uncompressed x x x
Compressed o o o

to $R_1 = 4000$ ohms. Similarly, reducing the reading A by one-half the length of AC, we obtain the point D, or the true reading corresponding to $R_1 = 2000$ ohms. It will be seen that the geometry of the figure results in the intersection of the lines BA and ED in the same point on the vertical axis and this point gives the true

value of $\frac{\theta N K}{R_1}$ corrected for temperature resistance

loss in R_1 and also for quadrant charging current. The method obviously does not correct for absolute temperature differences, but only reduces the observations to that temperature obtaining when voltage is first applied. In those cases in which the loss was sufficiently high to cause an appreciable change in temperature during one observation it was not possible to take an observation at the next higher voltage until after the bar had cooled to the initial temperature.

In these cases twenty-four hours were allowed to elapse between successive observations on the same bar. Generally this temperature change due to dielectric loss was limited to the higher values of voltage, except in the cases of those bars containing little or no mica. Fig. 4 shows the increase in loss, at constant applied voltage, with time, in the case of bar No. 49 having large mica content, and bar No. 44 consisting of shellaced paper with no mica. It will be seen that at 7.5 kv. No. 44 shows a rapidly increasing loss which if continued would soon result in breakdown, while No. 49 at 12.5 kv. shows a practically linear increase of loss at a much lower rate and over a much longer time.

OBSERVATIONS

Figs. 5 and 6, plotted from the readings of Table VI show the dielectric loss, charging current, and power factor as functions of the voltage applied to the insu-

point at which corona begins. In Fig. 6 the voltage loss curves are plotted on logarithmic coordinates. The relation, when so plotted, between voltage and loss is obviously linear, indicating that the loss increases as a simple power of the voltage. However, the slope of the linear relation changes in the neighborhood of 3 kv. Later on it will be seen that this break is much more pronounced in other samples.

Early in the tests it was noticed that some of the bars developed the sound of internal sparking, or ionization, as the voltage was raised, thus giving direct evidence of the presence of internal ionization. The effect of compressing these bars was studied and it was found that very substantial reductions in the losses resulted. This method was used for a study of the amounts of internal ionization in the various bars and the results of this study are given in a later paragraph. In Figs. 5 and 6 it will be noticed that there are two sets

lation of bar No. 48. This insulation consisted entirely of mica folium except for two layers of shellaced paper on the outside. The insulation was applied to the bar by the rolling-ironing process under temperature and pressure, resulting in a structure as compact and as free from entrapped air as possible. It was expected, in this method of investigation, that the beginning of internal ionization, or corona, would be indicated by a break in either the power factor or loss curves. It will be noted from Fig. 5 that the power factor curves show no such break. The charging current, however, shows a slight departure from the straight line relation, but not in sufficient amount to use it as an indication of the

of points corresponding to the uncompressed and compressed states of the insulation. The reduction in loss, as a result of compression, is scarcely noticeable in the case of bar 48, showing that the corona loss in this bar is very small. This is also indicated by the slight change in the slope of the logarithmic curve in passing from the voltage range in which corona loss is practically absent, into the upper range where it is present.

Figs. 7, 8, 9 and 10 give similar curves for bars No. 50 and No. 34. Each of them has approximately 75 per cent of micarta folium the additional 25 per cent

being treated cloth in the case of No. 50, and shellaced paper in the case of No. 34. Figs. 7 and 8 for No. 50 give two sets of curves corresponding to the uncom-

pressed and compressed states of the insulation. It will be noted that below 4 kilovolts the loss is lower in air layers have the effect of lowering the potential gradient in the insulation and thus lowering its loss. Above the ionization voltage, however, the loss is high, due to the ionization. On compression the potential gradient in the insulation is increased, resulting in an increase of dielectric loss below 4 kilovolts, while above that value, owing to the decrease in thickness of the

FIG. 9
Bar No. 34
Low corona loss

pressed and compressed states of the insulation. It will be noted that below 4 kilovolts the loss is lower in

air layers, the loss due to ionization is decreased. The slope of the loss curves in logarithmic coordinates indicates that below the ionization point in both the compressed and uncompressed states the loss increases almost exactly as the square of the voltage, while above the ionization point the increase is as the 2.67

the uncompressed than in the compressed state, but higher for the upper ranges of voltage. This is obviously due to the fact that when uncompressed the

power of the voltage. On compression bar No. 34 shows practically no change of dielectric properties. The logarithmic curve, however, shows a slight change

in slope in the neighborhood of 3 kilovolts, indicating the presence of a slight ionization loss above that value.

Figs. 11 and 12 show the results on bars No. 43 and No. 59. The former is made up entirely of shellaced paper and the latter entirely of treated cloth, there being no mica in either. These bars are conspicuous for the very high values of their dielectric losses. However, they apparently have relatively very low internal ionization, as indicated by the slight change of slope in the logarithmic curves. It will be noticed that in the case of No. 43 the slope of the logarithmic curve above 4 kilovolts is changing rapidly. In this region the internal loss is so high that the temperature of the insulation, and therefore the loss, are increasing rapidly; in fact this bar broke down at 7.5 kilovolts at the end of six minutes. The slope of the logarithmic curves below 4 kilovolts indicates that the loss increases almost exactly as the square of the voltage.

FIG. 13—LOSSES BARS No. 33, 46.

Before compression x x x
After compression o o o

The break in the logarithmic loss curves in the neighborhood of 3 or 4 kilovolts and the effect of compression on the internal losses are also well shown in Fig. 13, giving observations on bar No. 33, which has full mica folium content. The observations of Fig. 13 were made after the bar had been subjected continuously for seven months to a temperature of 125 deg. cent. and also to 10,000 volts for 16 out of every 24 hours. The result of this treatment was that the bar was thoroughly dried out, its losses reduced to very low values, but that the insulation had expanded so that the thickness was considerably increased and the air layers obviously also increased in thickness. The logarithmic curves show again the change in the grad-

ient in the neighborhood of 3 or 4 kilovolts, the very steep slope of the curve before compression, the increase of loss occasioned by compression for low voltages, and its decrease for high voltages. The slope of the curves below the ionization point indicates an

FIG. 14—DIELECTRIC LOSSES AT 25 DEG. CENT.

increase of loss with the voltage gradient as the square of the voltage. This case, however, must be accepted with some reserve, owing to the extremely low values of

FIG. 15—DIELECTRIC LOSSES AT 25 DEG. CENT.

loss and the probable error in the wattmeter reading. The total loss being measured here is of the order 0.003 watts at 0.03 power factor, requiring abnormally large values of the resistance R_1 . The uncertainties thus introduced are indicated by the irregular location of the plotted points in Fig. 13.

LOSS DUE TO INTERNAL IONIZATION

It is suggested from the foregoing that the dielectric losses in the various types of insulation studied, all of them having the thickness of standard 6600-volt insulation, vary approximately as the square of the

side electrodes, or by the temperature or sharp increase of the loss curve, indicating that the sample was approaching breakdown. No two observations on the same bar were made in one day, this being done to insure a minimum of error due to difference in tempera-

FIG. 16—DIELECTRIC LOSS AT 25 DEG. CENT.

voltage up to the neighborhood of 3 or 4 kilovolts and that beyond this value the losses vary as some higher power of the voltage.

The presence of internal sound at higher values of voltage, and the effect of compression of the sample in reducing the losses, and also the sound, are strong indications that this increase in loss at higher voltage

FIG. 17—DIELECTRIC LOSSES AT 25 DEG. CENT.

is due to internal ionization. In further study therefore of this question, loss readings were taken on the whole series of bars at several different values of voltage from 5 kilovolts upwards to values limited either by sparkover between the central conductor and the out-

FIG. 18—DIELECTRIC LOSSES AT 25 DEG. CENT.

ture. All observations were made at room temperatures varying from 25 deg. to 28 deg. cent., and all were corrected to the lower temperature from a series of observations on one bar taken at various values of temperature. It should be noted, that the variation of loss with temperature is different in different bars

FIG. 19—LOSSES, POWER FACTOR, CHARGING CURVE

and that the whole question of temperature variation is apparently dependent upon the condition and life of the insulation. However, in the condition in which the present measurements were made, losses increased

uniformly with the temperature, and as the range of variation was small, it is certain that no serious error is introduced here on this account.

The results of the measurements are given in Figs. 14, 15, 16, 17 and 18, in which watts per inch of length of bar are plotted as functions of the voltage in logarithmic coordinates.

FIG. 20—LOSSES, POWER FACTOR, CHARGING CURVE

mic coordinates. Figs. 19 and 20 give corresponding values of the power factor and charging current plotted in rectilinear coordinates.

Commenting on Figs. 14 to 20, we may note as follows:

The three similar bars of a group in nearly every case show a wide variation in the absolute magnitude of the loss. This variation, however, maintains itself throughout the range of voltage, the curves remaining parallel. We shall see later on, in connection with the experiments on compression of insulation, that a part of this variation, at least, is due to a corresponding difference in the magnitude of the loss due to internal ionization.

Taking the average values in the various sets, the losses are in general higher the less the mica content of the insulation. The relation, however, seems to follow no regular law. The curves for these average values for the set B-3 are given in Fig. 21. The extreme difference in loss is between group 46-47-48 and group 43-44-45, the ratio of the losses being 1 : 10.

With the exception of one group, the losses are higher for the bars containing treated cloth than for those containing shellaced paper. The exception is the group in which there is no mica, and in this case the shellaced paper shows a considerably higher loss (bars 43-44-45). The difference in the methods of assembling the two types of insulation, and subsequent experiments on the influence of compression, seem to indicate that the

higher losses in the bars containing treated cloth are due to less compact structure and therefore higher ionization losses. This does not explain the higher losses of the samples made up entirely of shellaced paper. However, neither of these groups contains any mica, the absolute values of the losses are much higher, and it appears probable that the predominating component of the loss in these cases is not internal ionization, but the normal dielectric loss pertaining to the lower values of voltage. It may be noted in passing that the accurate increase of the loss as the square of the voltage, as indicated in Fig. 12, suggests that the

dielectric losses in the absence of mica are due entirely to the conductivity of insulation, that is, the losses are of the I^2R character.

The logarithmic curves are apparently all straight lines and moreover these lines all have very nearly the same slope, indicating a loss increasing approximately

FIG. 21—AVERAGE LOSSES BY GROUPS

as about the 2.3 power of the voltage. Exceptions to these statements are found in the cases of bars 40 and 42. These bars, however, are believed to have been defective, as they heated rapidly at higher voltages, and, in fact, punctured at 15 and 17.5 kilovolts respectively. Also, by noting the points of the lines pertaining to

the 46-60, or treated cloth group, there is, in several cases, a suggestion that the rate of increase of loss falls off slightly at the higher values of voltage. This tendency, if a true effect, is apparently absent in the other group. It appears probable from these experiments therefore that the losses due to internal ionization increase as some power of the voltage higher than the second, and that this loss, combining with a normal dielectric loss curve varying as the square of the voltage, yields the steeper loss curve of the higher ranges. It is probable also that the absolute values of the losses due to ionization depend upon the thickness and volume of the internal air spaces. This factor probably contributes more than any other to the wide separation of the loss lines of the several similar samples of the same group.

The drooping power-factor curves pertaining to the treated cloth bars shown in Fig. 20, are due to this slight falling off of the values of loss at the higher voltages in conjunction with a continually increasing charging current.

In considering all of the foregoing, it should be remembered that the various samples were all in a green state; that is, they had not been subjected to any drying process other than that of standing perhaps six or eight weeks after the original rolling and pressing. However, the absolute values of the initial losses, as determined for measurements on three bars, did not differ greatly from those obtaining after a long heat run. During the process of heating, the losses increased to high values and then decreased again, as will be shown in a later section of this paper.

THE INFLUENCE OF COMPRESSION ON THE DIELECTRIC LOSS OF ARMATURE INSULATION

In a number of the bars in which the losses increased markedly above 4 kilovolts, it was noticed that at about this value of voltage there also began a sound indicating internal discharge. This sound increased with the voltage and a rough compression of the bar resulted immediately in a lowering of the volume of this sound. A complete series of tests was therefore made on the whole series of bars. All of these tests were made at 7.5 kilovolts, 60 cycles. Observations were made first with the bar under no compression, then with the bar tightly compressed by means of two 1/32 in. steel plates 8 in. long and of the exact width of the bar, placed on opposite sides of the sample, and clamped tight by means of 15 set screws uniformly placed in a specially constructed wrought iron clamp. Measurements were made in each case immediately before and after compressing and in a number of instances after standing 24, 48 and 72 hours respectively. The charging current was measured in each case. No measurement of the degree of compression was attempted, but the amount was approximately the same case. A few tests were also made at extreme of compression and in several cases after removal

of the compression to note the recovery. All of the observations were corrected for temperature changes. The results of the tests are given in the following Tables VII and VIII, in which the values of loss are given in total watts for 8 in. length of bar.

corners of the armature bar would to some extent have the effect of causing the flat sides to spring outward, causing further increase of the thickness of entrapped

air layers. Provision was therefore made for testing the various types of insulation when assembled in flat sheets rather than when wrapped on armature bars. One sheet of this character, corresponding to each group of three armature bars, was prepared. The same materials were included in each case and the assembled sheet was compressed to the same thickness as that of the bar insulation, and allowed to dry.

These sheets were provided with electrodes of tin-foil, coated with shellac, dried and melted into the permanent contact with the sample by ironing. The upper electrode was of circular form, 6 in. in diameter, surrounded by a guard ring of 1 in. radial width and a radial separation from the inner electrode of 1/16 in. The lower electrode was 8½ in. in diameter. Provision was made for compressing the samples. Measurements were made before and after compression, as in the case of the armature bars. Table IX gives the

in 43-45 seems to be purely that due to conductivity. In this group the reduction of loss by compression is somewhat higher than in others of the paper group.

In the treated cloth group the maximum reduction is 37.5 per cent and all treated cloth and mica bars, with one exception, show a reduction greater than 27 per cent, with a somewhat general indication of less reduction in loss for less mica content. Bars 58-60, all treated cloth, no mica, show less losses than the all-paper bars and the relatively low reduction on compression of from 3.5 per cent to 14 per cent. Here again it is suggested that the principal loss in these bars is due to conductivity and that the loss due to internal ionization is relatively unimportant. This is probably due to the absence of mica and the close adhesion between layers of treated cloth.

Considered in groups, the least reduction in loss occurs in bars 31-33 and 46-48, both having standard mica folium insulation, wrapped and compressed under temperature. No. 33 stands out with a considerable reduction in loss under compression. A further study of this bar is described hereafter.

In each group the greatest percentage reduction of loss is shown by the bar having the highest initial value of loss.

Tests at extreme values of compression show only a very slight further increase of loss over those given in the tables. Tests on relieving the compression show an immediate recovery of about one-half the total reduction of loss. No tests of further recovery with lapse of time were made. The further reduction of loss under compression after standing 24 hours or longer is in general relatively small.

The charging current is invariably increased by compression, in spite of the decrease in loss. This is obviously explained by an increase of capacity due to the elimination or lessening of the thickness of the air layers. Due to the same cause, the loss is decreased, in spite of the increased voltage gradient in the body of the insulation.

The experiments on the sheet form of the insulation all show the presence of entrapped air, causing increase in dielectric loss. The losses per square inch are lower than those of the corresponding armature insulation but of the same order of magnitude, (*e. g.* sheet No. 11, 0.0114, bar No. 33, 0.018). The decrease of loss under mechanical compression is generally less than in the armature bars, indicating some influence of the bending of mica in increasing internal ionization loss. The influence of prolonging compression is to still further reduce the loss, and of the removal of pressure a recovery of the loss to approximately the original value.

In view of the foregoing, it appears certain that all of the types of armature insulation measured have in them a greater or less proportion of loss due to internal electric discharge, or ionization based on the following facts:

result of tests carried out in all respects in exactly the same way as those pertaining to the bars.

The following conclusions seem to be warranted from the above results:

All bars show a diminution of loss with increasing mechanical compression except bar 41, which shows a small increase.

The amount of decrease for the bars made up of shellaced paper and mica folium is in all cases less than in those made up of varnished cloth and mica.

For the paper bars, all except 43, 44 and 45 have a relatively small initial loss and the per cent amount of decrease is about that of the standard bars 31-33 and 46-48. Bars 43-45, no mica and all paper, have extremely high initial losses, at once indicating the importance of mica; for example, there is a tenfold increase in loss between No. 41 and No. 43. As suggested elsewhere, the law of the variation of loss with the voltage

(a) Bars having the highest losses always give a sound of internal discharge which is more or less reduced by compression.

(b) The reduction of loss on compression is greatest for the highest losses, indicating also that variations in the values of loss in a single group are to some extent due to the ionization losses.

(c) Bars with no mica show the least reduction in losses.

(d) The charging current is always increased by compression, in spite of the corresponding decrease in loss.

Mica therefore has the effect of reducing the losses in paper and treated cloth insulation by as much as the ratio of 10:1. It also tends to increase the losses due to internal ionization. However, this increase of ionization losses is reduced to a small, if not negligible, amount by the method of wrapping and pressing under temperature, used in bars 31-33 and 46-48.

INFLUENCE OF SUSTAINED HIGH TEMPERATURE AND VOLTAGE ON THE INTERNAL LOSSES

As has already been pointed out, none of the bars under observation has been subjected to any special drying out process. The variations in loss, with comparatively small differences in temperature, are attributable to this condition. It was realized that the sustained voltage and high temperature obtaining in operating machinery might well introduce modifications of the values and conclusions described above. Provision was therefore made for a sustained run at high voltage and high temperature on three typical bars. For this purpose a special Fries constant temperature oven was obtained and equipped with insulating bushings, for 20,000 volts, and also for the necessary connections to the central electrodes and guard ring electrodes of three armature bars, as already described. These were assembled on insulating stands and in a grounded metal screen inside of the oven. Some trouble was encountered at the higher voltages at various stages of the work at atmospheric temperature, with brush discharges over the surface of the insulation between the guard ring electrodes and the exposed ends of the armature bar. Realizing that at higher temperatures this trouble would be greatly increased, the bars, before placing in the oven, were dipped in a special compound obtained through the courtesy of the Standard Underground Cable Co., this compound being still stiff at a temperature of 150 deg. cent.

After assembly as above, measurements were taken of dielectric loss, charging current, and insulation resistance, every one or two days, over a period of six and a half months.

The bars selected for this purpose were two of the standard mica folium bars, namely No. 33, for high internal loss, and No. 46, for low internal loss, and bar

No. 49. At first the third bar was No. 58, containing no mica and having high internal loss. Within a few days, however, this bar broke down under only a moderate elevation in temperature, doubtless due to the cumulative influence of its internal losses in still further increasing its temperature. There was therefore substituted, as a third bar, bar No. 49, having less mica than the others and also having relatively an extremely high internal loss.

The results of this series of tests can be best seen by the curves in Fig. 22. Starting December 5th, the losses were measured at atmospheric temperature and the oven was then set for 80 deg. cent. It was operated at this temperature until early in January, when it was necessary to repair a contact point of the electric temperature control, which necessitated opening the oven for a brief period, during which the temperature dropped to 25 deg. cent. It was then set for 111 deg. cent., at which value it operated until January 24th. For the remaining 4½ months the temperature was maintained at 127 deg. cent. During the entire run 10,000 volts was applied to all three of the central conductors, with grounded outer electrodes, for 16 out of every 24 hours. The temperature, however, was never interrupted. The loss measurements were made as described above, and the power factor computed from the values of loss and charging current. The insulation resistance was measured, using a primary battery of 215 volts, a Weston galvanometer having a sensitivity of 10^{-9} amperes per division, checking calibration at every series of readings. The insulation resistance, however, particularly in the later stages, was so high that the galvanometer deflections were of the order of only 2 or 3 millimeters. Consequently the values of insulation resistance vary considerably. The general trend of the curves, however, is probably reliable.

The tremendous increase in internal losses on the first application of temperature should be noted. They reached 10 or 12 times their initial values. Within two or three days, however, they began to decrease sharply in the process of drying out and the decrease continues steadily with continued application of temperature. The brief reduction to 25 deg. cent. showed an immediate influence of reduction of loss and each succeeding increase in temperature was accompanied by a temporary increase of loss, followed by a further decrease as the process of drying continued.

It is especially interesting to consider the influence of the internal losses on the position of the complete loss curves. In the beginning No. 33 of standard mica folium insulation showed, by the compression tests, an internal loss relatively high in its own group. Throughout the tests this bar maintains its position of having the highest loss.

Bar No. 46 showed the smallest reduction of loss under compression, indicating a minimum of ionization loss. No. 49, on the other hand, showed a high internal ionization loss. Notwithstanding the fact that the

initial loss of No. 46 was considerably higher than that of No. 49, about one-quarter of the way through the run No. 46 falls below No. 49, which latter bar shows a slowly increasing loss approximating to that of No. 33 at the end of the run. Thus No. 33 and No. 49, both having relatively high internal ionization loss, show a slow but steady increase in loss under sustained temperature and voltage. No. 46, on the other hand, having very low internal ionization loss, reached a minimum value at 127 deg. cent., and held it throughout the run. These properties of the loss curves are followed in general by the curves for power factor, that is, the power factors of Nos. 33 and 49 are gradually increasing, while that of No. 46 holds to a constant value. The curves for insulation resistance are not so

definite, for while No. 49 seems to hold at a low value, Nos. 33 and 46 appear to be increasing, the former at a higher rate. A possible explanation of this fact is the continued expansion of the sides of No. 33, giving higher losses, and at the same time increasing insulation resistance.

The run was terminated by a failure of one of the control circuits, but the curves show quite clearly that the influence of sustained temperature and voltage on the insulation of armature bars having internal ionization losses is to still further increase those losses, with the suggestion therefore of a tendency toward the shortening of their life. On the other hand, in a tightly wrapped bar having low internal loss, there is no indication during this 6½ months run at 125 deg. and at

FIG. 22—WATTS LOSS AT SUSTAINED HIGH TEMPERATURE AND HIGH VOLTAGE

about 50 per cent excess voltage, of any increase of loss or tendency to a shortening of life.

On opening the oven it was found that the insulation on the bars had expanded considerably on the sides. It is noteworthy, however, that this expansion was limited to the region covered by the outer electrodes. Since this is the only region where the full voltage gradient occurs in the insulation, it appears that the internal ionization is the most important factor in the expansion or spreading of the insulation. The losses in these bars were not especially high, and there is nothing to suggest that the temperature under the electrodes was any higher than that in the remainder of the insulation; the temperature of the oven was uniformly maintained within 1 or 2 deg. In practise

this expansion of the sides of the insulation would be limited to small amounts, by the sides of the slot.

During the process of cooling the oven after interruption and by a few measurements taken subsequently, the loss temperature curves on these bars, shown in Fig. 23, were taken. They are of interest as showing that in the neighborhood of 127 deg. the losses for all three of these bars tend to increase rapidly.

The variation of the loss with voltage on these three bars, after removal from the oven and at atmospheric temperature, was also studied and the results for bar 33 are given in Fig. 13. Another curve in Fig. 13 gives the result of compressing this bar. It is seen again that the effect of compression is to increase the losses at the lower values of voltage, decreasing them in the upper

range. The influence of the expansion under temperature and voltage is also indicated in the curves of Fig. 24, which show the great increase in the slope of logarithmic loss-voltage lines after the heat run. Before drying out, the exponents of the voltage represented by these lines were 2.43, 2.16 and 2.3 for the three bars 33, 46 and 49, and after the six months' run these exponents were 3.95, 4.38 and 3.95 respectively. Thus the internal ionization loss is greatly increased after the long heat run, due to the expansion

FIG. 23—DIELECTRIC LOSS—TEMPERATURE

of the unrestrained flat sides of the insulation. At the same time the relative positions of the curves before and after heating indicate that the losses of other type have been lowered by the process of drying out.

The tests were made in the laboratory of Electrical Engineering, The Johns Hopkins University, at the request and with the support of the Westinghouse Electric and Manufacturing Company. During the course of the work much assistance was rendered by Messrs. N. Inouye and W. C. Ball to whom grateful acknowledgment is extended.

CONCLUSIONS

We may draw the following conclusions from the foregoing:

1. The dielectric losses in wrapped insulation increase as the square of the voltage in the lower range. In the 6600-volt insulation, on which the tests were made, this simple relation extends to 3 or 4 kilovolts, corresponding to an average potential gradient of about 16,000 volts per cm. In cases of bars having a large proportion of mica, particularly if dried out, and expanded by temperature, there is some evidence that the exponent of the voltage may fall below 2.

2. Above 4 kv. the loss also increases directly as power of the voltage, higher, however, than 2. For the most tightly wrapped mica folium bars the exponent may be as low as 2.15. For bars high in mica, dried and expanded under temperature it reaches 4.4. The values for the whole series of bars in the undried state lie between 2.15 and 2.6 with an average value about 2.3.

3. The increase in loss above 4 kv. is due to gaseous ionization in entrapped air spaces. This is shown by the

simultaneous beginnings of internal sound and loss increase, and the reduction of each by compression of the insulation. Further, complete voltage—loss curves for the uncompressed and compressed states show an increase of loss below 4 kv. and a decrease at higher voltages following compression. Notwithstanding the decrease of loss, in the higher range the charging current is at the same time increased.

4. The internal air spaces are increased to some extent by the bowing of the mica on bending, but more particularly by loose wrapping and expansion of the insulation under temperature. Bars wrapped under temperature and pressure show the lowest ionization loss but the run of the bars in each group of three is not uniform, occasional samples showing high ionization loss.

5. The *total* dielectric losses, in mica folium and paper insulation in the undried state, increase with decreasing mica content. Reducing the mica content by 75 per cent and substituting shellaced paper approximately doubles the loss. Omission of the final 25 per cent of mica folium increases the original loss 10 times. The loss in an all paper bar is probably in large measure of the nature of conductivity. The results suggest that the principal function of mica is in the reduction of the conductivity of the insulation and in withstanding the

FIG. 24—DIELECTRIC LOSSES
Before drying o o o o
After drying x x x x

action of internal ionization. Bars in which treated cloth is substituted for mica show great increase in loss, resulting in internal temperature rise and ultimate breakdown. The breakdown of all types of insulation investigated, including those containing large proportions of mica, does not occur suddenly, but is the result of large increase of loss, and consequent temperature elevation.

6. The loss in well wrapped mica folium insulation of 6600-volt rating, is, at 6600 volts conductor to

ground, about 0.0017 watts per sq. cm. (0.02 watts per cu. cm.). Of this probably not more than 10 per cent is due to internal ionization. On the other hand bars of the same type and prepared by the same process may show losses 10 per cent to 40 per cent higher than the above figures due to internal air spaces and ionization.

7. Wrapped insulation prepared in factory processes, shows at first rapid increase of loss under increase of temperature; this is followed, under sustained temperature, by a slow decrease to values considerably below those at start. The initial increase of loss may be 10 to 12 times the starting value. The consequent internal temperature rise, if voltage is applied during this period, may lead to a further cumulative increase of loss resulting in breakdown.

8. The life of well wrapped mica folium insulation is not seriously affected by internal ionization. On the other hand imperfectly wrapped bars may appear in

factory processes and in these there results a slow increase of loss and power factor. In two bars studied, under voltage and temperature continuously applied, this increase was about 10 per cent in three (3) months.

The Effect of Transient Voltages on Dielectrics—III

(An Investigation with very High Lightning Voltages.)

F. W. PEEK, Jr.

Member, A. I. E. E.

General Electric Company, Pittsfield, Mass.

Review of the Subject.—During a thunder storm lightning voltages that reach the transmission line appear across insulators, transformers and other apparatus at the extremely rapid rate of millions of volts per second. With this rapid rate of application the voltage may reach a very high value in a microsecond (millionth of a second). Hence, since there is always a delay or lag in the breakdown of insulation, quite peculiar effects result from these voltages. For instance, some remarkable phenomena that take place are: Much higher lightning voltages are usually required to jump a given distance than voltages at normal operating frequency; conductors at normal frequency voltages are often good insulators for lightning voltages; water may be punctured like oil; the wet and dry spark-over voltage of insulators are equal; the lightning discharge has a decidedly explosive effect, etc. In addition to the characteristics just mentioned, a study has also been made of the change in voltage and shape of a lightning wave as it travels over a transmission line at the velocity of light.

In order that a laboratory study may be of a practical as well as a theoretical interest, it is necessary to be able to reproduce lightning voltages in the laboratory on a large scale and of known characteristics. This investigation was started some years ago

with a 200-kv. generator. The generator has been added to from time to time until now, 2,000,000 volts are available and single lightning strokes can be obtained that increase at the rate of 50 million million volts per second. The power is of the order of millions of kilowatts. It is believed that this generator closely approximates voltage and other conditions that usually occur on transmission lines. The lightning voltages used in this investigation were far in excess of any heretofore produced in a laboratory. This impulse generator discharge must not be confused with that produced by an oscillator. The lightning generator, unlike the oscillator, discharges with a loud sharp report or crack.

The photographic study shows the lightning spark-over of insulator strings that are of such a length as rarely to spark-over in practise even in bad lightning country. The photographs of the flashes show all the characteristics of lightning such as a zig-zag path, side flashes, etc.

The study of the travel of the lightning wave on transmission lines is of interest. It indicates for instance, a certain protective effect of corona and shows that under certain conditions inductance coils may increase the lightning voltage four fold. Certain phases of the ground wire have also been studied.

FORMER INVESTIGATION—THE LIGHTNING GENERATOR

THE first paper of this series, published in 1915, described a generator for producing lightning impulses of a predetermined shape and voltage.¹

The maximum voltage of this generator was about 200 kv. Quite complete data were given at that time on the time lag and lightning spark-over voltages of various gaps, line insulators, etc. Data were also given on the lightning breakdown voltage of oil, air and solid insulation, corona produced by lightning, etc. It was found convenient to term the ratio of the lightning spark-over voltage to the continuously applied or 60-cycle voltage the "impulse ratio." This term has since come into general use.

The second paper dealt more particularly with lightning arrester gaps.²

The voltage and capacity of the impulse generator has been increased from time to time as higher exciting voltages have become available. During the past year the voltage has been increased to about two million maximum, while the power may be millions of kilowatts. Two million volts is higher than most lightning voltages that are induced on transmission lines. Tests can now be made in the laboratory at voltages and energy approximating operating conditions. It seems desirable, therefore, to report progress at this time.

Presented at the Annual Convention of the A. I. E. E., Swampscott, Mass., June 26-29, 1923.

The methods of making the tests and predetermining the characteristics of the impulse have already been adequately described in the first paper of this series. For convenience, a very brief description will be given

FIG. 1—IMPULSE GENERATOR CIRCUIT

here. The circuit is as shown in Fig. 1A. The gap G is set at some desired voltage. The transformer voltage is increased until discharge occurs. At that instant the condenser C is charged up to a voltage corresponding to the gap setting. A dynamic arc forms at G and holds. This acts as a switch and the condenser discharges through the known inductance L

and resistance R . The circuit that produces the impulse is shown in Fig. 1B or is, in effect, that shown in Fig. 1c. The condenser discharging through the known resistance and inductance causes a transient current that can be readily calculated. This current

added at will. In fact, it is planned to increase the number of plates to one thousand.

The capacity per plate is 0.0112 microfarads; per cell, 0.00112 microfarads. The cells are readily arranged in multiple and series combinations as required. Three cells in series on each side operate satisfactorily at a million and a half volts maximum to ground. In the "set-up" shown, a series of tests were made up to 1500 kv. max. The energy available for the discharge is proportional to $\frac{E^2 C}{2}$. The inductance L is that formed by the

rectangular circuit. The resistance R is a water tube of 5000 ohms. This particular arrangement gives the wave shown in Fig. 3.

FIG. 2—2,000,000 VOLT IMPULSE OR LIGHTNING GENERATOR

produces a transient voltage drop across R . This is the impulse voltage used in the test.

The lightning generator in its present form in the "High-Voltage Engineering Laboratory" at Pittsfield is shown in Fig. 2. The condenser C of Fig. 1 is shown supported on post insulators. It will be noted that C

Note that successive strokes do not follow the same path.

NEEDLE GAPS—DISCHARGE HAS ZIG-ZAG PATH AND CHARACTERISTIC SIDE FLASHES OF LIGHTNING—SAME LAWS FOLLOWED AS AT LOWER VOLTAGES

Fig. 4 shows a discharge of 1500 kv. max. between points. This type of discharge must not be confused with the high-frequency discharge produced by an oscillator. This discharge takes place with a loud explosive report. It will be noted that the general appearance of the spark resembles a lightning flash. In addition to the "zig-zag" path a close examination of Fig. 5 will show characteristic side flashes. In Fig. 6 three discharges are produced on the same plate. It will be noted that no two occur in the same place. The lightning spark-over curve for needles is given in

Fig. 7. Confirming data given in the previously mentioned papers the impulse ratio is high for points.

SPHERES—SAME LAWS FOLLOWED AS AT LOWER VOLTAGES. SERIES RESISTANCE INTRODUCES TIME LAG

Figs. 8 and 9 show the discharge between spheres. The great thickness of the spark (over 3 in. in diameter)

gap. It takes time to charge the capacity of the sphere through the high resistance.

This is illustrated by the following data:

Applied lightning voltage kv. (max.)	Series resistance ohms	12.5 cm. spheres gap cm. setting	60-cycle spark-over kv. (max.)
106	0	3.95	106
106	2,500	3.60	98.5
106	5,000	3.30	92.0
106	10,000	2.80	80.0
106	20,000	2.30	66.0
106	30,000	2.05	59.1

Constant lightning voltages were applied to the sphere and series resistance. As the series resistance was increased it was necessary to reduce the gap as indicated in order to obtain spark-over with the same applied impulse. The effect of the series resistance

shows the large current (approximately 10,000 amperes) in this discharge. In measuring the maximum lightning voltage with sphere gaps it is important to have no appreciable series resistance. Series resistance will give the sphere the characteristic of the needle

FIG. 10—DRY 60-CYCLE SPARK-OVER OF A SHIELDED STRING OF INSULATORS
Arc clears the string

increases with increasing wave front. This arrangement may be used, therefore, to indicate the duration and wave front of a transient.

LINE INSULATORS—EFFECT OF 1,200,000 VOLT LIGHTNING STROKE—LIGHTNING DOES NOT FOLLOW DRIP DURING RAIN ON SHIELDED STRING

Previous tests showed that the wet and dry lightning spark-over voltages of insulators were equal. Tests made at the higher voltages further confirm these data. These tests are, however, particularly important from the practical standpoint since they give the lightning spark-over characteristics of very long strings of insulators. Laboratory tests have been made at higher lightning voltages than usually occur on operating lines. Fig. 10 shows the characteristic dry 60-cycle arc-over on a shielded string; the corresponding lightning spark-over is shown in Fig. 11. Fig. 12 is of great practical

importance. It shows that the lightning spark-over clears the string during a very heavy storm. The great display is due to the illumination of the drops. The drops appear stationary in space because the photograph was taken by the light of the spark lasting

FIG. 11—1,200,000-VOLT LIGHTNING SPARK-OVER OF A SHIELDED STRING OF INSULATORS—DRY
Spark clears the string

less than a millionth of a second. It was found that the wet and dry lightning spark-over voltages were not reduced by the shield. Fig. 13 shows a non-shielded string struck by lightning.

A few years ago the author's attention was called to

FIG. 12—1,200,000-VOLT LIGHTNING SPARK-OVER OF A SHIELDED STRING OF INSULATORS

During a heavy rain. Note rain drops illuminated by the flash. The illumination differs from that in Fig. 11. The spark clears the string.

some suspension insulator units of the cemented type that had been punctured through the head, apparently the result of a direct stroke. In these insulators, not only was the porcelain in the head shattered, but the

metal cap had the appearance of having been punctured by a bullet shot through from the inside. Recently, in puncturing a glass plate in the laboratory a heavy foil coating was punctured in the same manner. This seems to be due to an "explosion" between the insulation and the foil. The foil is shown in Fig. 14.

As in the case of spheres, if a resistance is placed in series with an insulator the lightning voltage necessary to cause spark-over is greatly increased. The following insulator spark-over data are given as an example.

FIG. 13—1,200,000-VOLT LIGHTNING SPARK-OVER OF A NON-SHIELDED STRING OF INSULATORS—DRY

FIG. 14—METAL "PUNCTURED" BY LIGHTNING

LIGHTNING SPARK-OVER VOLTAGE—INSULATOR IN SERIES WITH RESISTANCE

Series resistance ohms	60-cycle spark-over voltage kv. (Max.)	Lightning spark-over voltage kv. (Max.)
0	119.0	127.0
5,000	119.0	190.0
10,000	119.0	235.0
20,000	119.0	320.0
30,000	119.0	420.0
50,000	119.0	600.0

The resistance has the effect of increasing the time lag. In these tests the gap (insulator) was kept constant and the impulse spark-over voltage measured with increasing resistance. In the sphere gap tests above, the impulse was kept constant and the gap varied.

Incidentally, these tests show how useless a high-resistance arrester is.

PROPAGATION OF LIGHTNING ON TRANSMISSION LINES DECREASE IN VOLTAGE DUE TO CORONA AND OTHER LOSSES. CHOKE COILS CAUSE DANGEROUS VOLTAGES—GROUND WIRE—REFLECTIONS

A study is being made of the propagation of lightning on transmission lines. It is possible at this time to report only the preliminary study which seems to be of considerable practical interest. In these preliminary tests an impulse with a front equivalent to that of a 5,600,000 cycle sine wave was applied to a short transmission line. The length of the front of this wave from zero to maximum was approximately 36 feet (12 meters). The maximum length of line used was made up of two parallel wires each 280 feet (85 meters) long and spaced 3 ft. (0.92 meters) apart. The diameter of the wire was 0.04 in. (0.102 cm.). The object of the small wire was to cause a high corona loss, and thus get the attenuation effects of a much longer line. Corona produced by these transients could readily be seen and the eye could differentiate between the positive and negative wire.

The general connections used in studying wave propagation are shown in Fig. 15. The data will be found in Table I. Fig. 15 shows the arrangement for test 3 of Table I. The impulse was applied to the line and the voltage measured at the start, in the center of the line,

FIG. 15—GENERAL CONNECTIONS USED IN STUDYING PROPAGATION ON TRANSMISSION LINES

Figures give voltage as measured by spheres, impulse ratio and voltage as measured by needles.

and at the end. Both needles and spheres were used to measure the voltage. The sphere measures the correct maximum voltage, while the needle always indicates a lower voltage. The steeper the wave the lower the voltage that is indicated by the needle. The ratio of the sphere and needle voltages, or the impulse ratio, is thus a measure of the steepness of the wave. The higher the ratio the greater the steepness. Referring to Fig. 15, test 3, a 133-kv. impulse was applied.

The needle gap indicated 56 kv. or an impulse ratio of 2.4. At the center of the line the maximum voltage of the wave was reduced 18 per cent while the wave front was flattened out as shown by the impulse ratio of 1.7. It is interesting that the needle gap indicated a higher voltage in the center than at the start. If the voltage decreased at the above rate it would have a value of 80 kv. at the end. Actually, approximately

INDUCTANCE AT END OF LINE
SHUNTED BY RESISTANCE

double this value was measured; in striking the end the voltage doubled in value as would be expected. The wave front was also steepened at the open end as shown by the impulse ratio.

In test 4, the line was short-circuited at the far end, while in test 5 the far end was closed by a resistance approximately equal to the surge impedance. In both cases, the voltage and impulse ratio at the start and in the center of the line were approximately the same as for the open line.

Of great practical interest is test 7, shown diagrammatically in Fig. 16 where inductance coils were placed at the end of the line. In this case the wave almost doubled up on reaching the start of the reactor. At the far side of the reactor a very high voltage appeared. This voltage, 238 kv. was almost double the impulse applied to the line and probably three times the voltage that reached the start of the reactor. Under these conditions the reactor would be dangerous. By shunting the reactor by a resistance, test 9, Fig. 17, the voltage was greatly reduced. A greater reduction in voltage is found when the far end is shunted by a capacity.

Tests made by applying the impulse between one wire and the ground are given in Table II. A comparison of tests 12 and 13 is of interest. Test 13 is similar to test 12 except that the wave was split at the start

applying the voltage very high stress can be obtained across conductors without appreciable heating. Certain conductors can thus be subjected to the same voltage stresses as insulations. By means of the impulse generator it was found possible to puncture water.

In this test the voltage of the impulse applied to the water was increased until disruptive discharge or spark

there was no heating. Applied in the usual way over a few seconds not 1 per cent of these voltages would be possible without causing the water to boil out.

The results of the tests are given in Table III and plotted in Figs. 18 and 19. The spark-over voltages for the same electrodes with the globe filled with air were also measured and are given on the curves. It will be noted that the disruptive strength of water is much greater than that of air.

FIG. 18—DISRUPTIVE STRENGTH OF WATER BETWEEN 2.54 CM. BRASS SPHERES

FIG. 19—DISRUPTIVE STRENGTH OF WATER BETWEEN 60-DEGREE POINTS

took place. The water was actually "punctured." The appearance of the spark was very much like a disruptive discharge in air or oil and was quite violent. Tests were made with both point and sphere electrodes. It was possible to cause voltages as high as 165 kv. as 1.50 cm. (0.6 in.) of water. Since the time of cation was about one micro-second (10^{-6} seconds)

TABLE III
TRANSIENT DISRUPTIVE STRENGTH OF WATER
2.54 cm. Spheres

Gap cm.	Impulse kv. (Max.) water	Impulse kv. (Max.) air	Ratio
0.1	49.5	3.5	14.1

1.0	56.5	25.0	2.25
2.0	72.0	35.3	2.15
3.0	92.0	41.0	2.25
4.0	113.0	46.5	2.42
5.0	134.0	51.5	2.61
6.0	156.0	56.5	2.76
Resistance 40,000 ohms			

NOTE. Tests made with single half cycle of a 500-kilocycle wave. This wave was, therefore, not as steep as waves used in some of the other tests.

The results of this test are in agreement with the tests above which showed the wet and dry spark-over voltages of insulators to be equal. The test also shows that "insulation" that is not good or is, in fact, a conductor at operating voltages may be very good insulation at lightning voltages. This again emphasizes the importance of low-resistance lightning arresters.

CONCLUSIONS

Lightning voltages are now available in the laboratory which exceed those usually induced on transmission lines. This conclusion is based on the fact that insulator strings of the length flashed over in this investigation rarely spark-over in practise due to lightning. An investigation on lines in Colorado also showed that lightning voltages in excess of 400 kv. were rarely induced on lines. This, of course, is not a direct measure of the voltage of the lightning bolt. The lightning voltages used in the investigation were far in excess of any heretofore produced in a laboratory.

The lightning spark-over of various gaps follow the same laws at these extremely high voltages as at the lower voltages.

It usually takes a higher lightning voltage to "jump" a given gap than a low-frequency voltage. When it is considered that two million volts bridge only a few feet, the voltage of the lightning bolt from cloud to cloud or cloud to ground must be exceedingly high.

A photographic study shows that the laboratory

lightning has the characteristic zig-zag path and side flashes of cloud lightning. The discharge also takes place with an explosive report.

The lightning spark-over of insulators is not greatly affected by rain or weather conditions. On a shielded string of insulators the spark may be made to clear in both fair and rainy weather. The lightning spark-over voltage is not reduced by the shield.

Certain materials that are conductors of moderate resistance at normal frequency voltages may be good insulators for lightning voltages. Tests in this direction indicate at once how useless a high-resistance lightning arrester is.

In measuring lightning voltages resistance must not be used in series with the sphere gap. Resistances so placed give the sphere gap all of the time lag characteristics of the needle gap and the spark-over voltage varies with the wave front.

The investigation of the change in characteristics of

lightning waves as they travel along a transmission line shows a decrease in voltage and flattening of the wave front due to corona and other losses. The waves tend to double up or increase on striking an open line or an inductance. An inductance may be a real source of danger. Under certain conditions the voltage on the far side of an inductance may be increased to three or four times the voltage that reaches the inductance. In general, inductance to be safe should be shunted by resistance.

With these high lightning voltages and currents it is possible to investigate the protective value of ground wires and also of lightning rods. This investigation is under way.

I acknowledge the assistance of Mr. W. L. Lloyd in conducting the laboratory work.

Discussion

For discussion of this paper see page 953.

Two Photographic Methods of Studying High-Voltage Discharges

BY KARL B. McEACHRON

Member, A. I. E. E.

Lightning Arrester Eng. Dept., General Electric Co., Pittsfield, Mass.
Formerly Research Assoc., Purdue University.

Review of the Subject.—This paper presents some of the results of two methods of drawing out the alternating-current corona discharge along a time axis.

The first method consists in photographing, with the usual camera, the discharge from a needle point revolved by the alternator which is the source of supply for the high-voltage transformer. The needle is revolved inside a porcelain tube whose outside surface is made conducting and grounded.

The second method makes use of a special camera using mirrors revolved synchronously by the alternator itself. This camera is equipped with a shutter so arranged that photographs of sparks may be taken using one sweep of one of the mirrors.

Photographs have been taken showing the discharge between needles, both with and without a solid dielectric placed midway between the points.

When drawn out along the time axis certain characteristics of corona discharges may be seen, even when the discharge is extremely

weak for the exposure may be continued for any length of time with a reoccurring phenomenon.

A few photographs giving same conception of the different discharges under varying conditions are given.

INTRODUCTION

FOR several years the Engineering Experiment Station at Purdue University¹ has been investigating the problem of the fixation of atmospheric nitrogen using various forms of discharge at high voltage.² During the progress of this investigation, the need for further knowledge concerning the mechanism of these discharges became increasingly apparent.

It has been shown that the chemical effects produced by these discharges are erratic,³ this being particularly

so when using the corona or so-called "silent discharge." The nature of the gas and even the solid dielectric in the electric field seems to play an important part in determining the nature of the discharge. As a rule, engineers have been more interested in the prevention of corona than in its production, which involves a viewpoint somewhat different from that of the author.

Many investigators have been concerned with the discharge from the static machine or the induction coil, through gases under varying conditions.⁴ Farwell⁵ used a number of direct-current generators in series and

studied the characteristics of the corona using different diameters of wires inside concentric tubes. Much important work has been done in recent years in connection with the alternating-current corona discharge by Peek, Whitehead, Ryan, and others.

The present investigation of electric discharges in air deals with two methods which are somewhat different from any other known to the author. These two methods will be described separately.

PART I

Method Using the Revolving Electrode

APPARATUS EMPLOYED

If a needle point is revolved synchronously with the particular alternator which produces the potential for corona discharge, the successive discharges of each alternation of the potential will appear to the eye as stationary in space and discharges which are scarcely visible to the eye may be photographed if the exposure is made sufficiently long.

The apparatus for producing the corona is shown in

FIG. 1—REVOLVING ELECTRODES (SLIGHTLY WITHDRAWN) AND PORCELAIN TUBE USED IN MAKING PHOTOGRAPHS OF CORONA

- a.—Wooden shaft extension of alternator
- b.—Chuck and discharging needle point
- c.—Grounded tinfoil covering of porcelain tube
- d.—Insulating disk to prevent arc over the end of the porcelain tube.

Fig. 1. The wooden shaft shown at the left of the photograph is connected to an extension of the shaft of an 8-pole, surface wound, alternator rated at 10-kv-a., 110/1100 volts, 133 cycles. This alternator at frequencies below 60 cycles produced a voltage wave which departed considerably from the true sine wave. The unfortunate effect of this irregular form of wave was to render the photographs of discharges somewhat difficult to analyze. This machine was, however, the only one available. The alternator was connected to a 50-kv-a., air-cooled transformer capable of producing 100 kv. from line to ground or 200 kv. between lines.

The wooden shaft extension of the main shaft of the alternator carries at its outer end an adjustable chuck in which is fastened a No. 14 iron wire bent at right angles to the shaft in the form shown in Fig. 1. The

of the wire was carefully pointed and polished. When revolved, the needle point traces a circle 1.78

inches (4.52 cm.) in diameter. The plane of this revolving point was made to coincide with the plane of the end of a porcelain tube which was 3 inches (7.62 cm.) inside diameter and 4 inches (10.15 cm.) outside diameter and several feet in length. Part of the outside of this porcelain tube was covered with tinfoil which was grounded. The nearest approach of this foil to the plane of the revolving needle was one inch (2.54 cm.). Precautions were taken to limit the form of discharge to either glow or spark. To prevent a discharge from taking place directly from the needle point to the tinfoil, a pressboard collar was sealed over the edge of the tinfoil in the manner shown in the photograph (Fig. 1). Sealing wax was used to close the space between the disk and tube.

A connection was made from the high-voltage terminal of the transformer to the revolving needle by the use of a wire looped loosely around the chuck which held the needle.

When the voltage was raised sufficiently high, eight discharges on the circumference of the circle traced by the needle point could be plainly seen. These corresponded to the eight poles on the alternator, being alternately positive and negative. All of the photographs shown in the paper were taken from the rear of the tube. By shortening the porcelain tube to about 12 in. (30.5 cm.) in length, it was possible to take the pictures full size.

The photographs were all taken in a dark room, the exposure being 60 minutes. Standard plates made by the Eastman Company were used for the photographs.

The frequency was varied by changing the speed of the driving motor, and in most cases its value was determined from the alternator speed.

A preliminary test to determine the polarity of the discharge was made in a very simple manner. With full field excitation, the generator shaft was revolved slowly by hand while note was made of the position of the shaft that gave positive and negative deflection on a 750-volt permanent-magnet type of voltmeter which was connected between the needle point and the ground.

RESULTS OF TESTS

Successive photographs were taken at four frequencies: 15, 30, 60 and 120 cycles. At each frequency three successive voltages were applied: 5, 8.5 and 15 kv. However, only photographs of discharges at 60 and 120 cycles are shown here (Fig. 2).

The voltage impressed on the needle point by the transformer was determined by the readings of a tertiary coil which had been previously calibrated against a standard 25-cm. sphere gap. A calibration curve was taken for 30, 60 and 120 cycles and the results for the three were found to be identical.

The difference between the positive and negative discharge was recorded on the photographs. When the needle was positive it showed more or less brush dis-

charge in a radial direction. When the needle point was negative the tiny glow at its point traced on the photographic plate the arc of a circle. With the aid of a stroboscope, Peek⁶ has obtained photographs of the positive and negative discharges which show the general characteristic observed here, namely the positive brush discharge and the negative point discharge.

When the needle was positive a dark space between the brush and the point discharge in the radial direction on the photograph could be plainly seen in Fig. 2

FIG. 2

at 8.5 kv., 120 cycles. Similar dark spaces were found at the lower frequencies.

At 15 kv. the discharge at 15 cycles (not reproduced here) was about as strong as that at 120 cycles, but the 30-cycle discharge showed no brush at all. At 8 kv. and 60 cycles there was no brush discharge recorded. The reason for this anomaly was not apparent.

It is interesting to note that in Fig. 2 the positive brush apparently forms in the air before the needle point itself shows any glow. This effect is due, partially at least, to the natural spreading out of the brush in a cylindrical form and also, perhaps, to the motion of the needle.

PART II

Method Using the Revolving Mirror

The preliminary study using the revolving point showed clearly some of the interesting characteristics of the corona discharge, but a method of observation in which the needle point did not move would be advantageous in some ways. As a substitute for the revolving electrode the attention naturally turned to the use of a camera employing revolving mirrors driven synchronously.

*The Camera and Revolving Mirrors.** The essential parts of the camera are shown in the diagrammatical sketch (Fig. 3).

*The success of this camera is largely due to the skillful work of Messrs. George, Pugh, and Maupin, all of Purdue University.

Four "first-surface" mirrors are mounted as indicated at *M* and driven by the gear *G* mounted on the same shaft as the mirrors. Gear *G* is driven by pinion *P*, the ratio being 8 to 1. The light from the discharge to be photographed passes through the glass lens *L* and is reflected from the mirror surface *M* to the surface *F* on which a sensitized film has been placed. The surface *F* was constructed of heavy celluloid, supported on wooden side pieces shaped to such a curvature that a sharp image is obtained with any angle of the shaft carrying the four mirrors.

The camera was mounted on a stout tripod with braced legs to prevent vibration, and a considerable weight was hung underneath to increase its stability. One end of the pinion shaft was provided with a universal joint coupling, thus, not only allowing a positive drive, but also preventing the mechanical vibration of the alternator from being communicated to the camera. The camera was provided with magazines for the film, and spring clamps for holding the film taut and in position.

In order to obtain photographs of sparks where only one exposure of the film was desired, use was made of a shutter operated by a contact arrangement mounted on the mirror shaft.

FIG. 3—SKETCH OF CORONA CAMERA

On one of the curved wooden surfaces supporting the film, a pin was placed in such a manner that the position of the film could always be determined, since the pin passed through a hole previously punched through the edge of the film.

All photographs were made either at night, or in a light-tight room which was later found desirable to build around the apparatus. To prevent the possibility of fogging the film, the duplex paper provided by the film manufacturers was kept over the film. In

addition to this, the camera was always covered with a black cloth when in use.

The water-cooled glass dielectric which was used for most of the tests is shown in Fig. 4. Two plates of double weight window glass approximately 0.118 in. (3 mm.) in thickness were sealed to wooden spacing pieces with a special insulating compound. The total thickness of the dielectric was 0.695 in. (1.765 cm.) including the space occupied by the cooling medium. Cooling water from the city supply was circulated at a rather slow rate,—a glass tube 5 ft. (1.5 m.) in length and 0.39 in. (1 cm.) in diameter being used to convey the water to the dielectric. The level of the water was kept constant by means of the overflow pipe which discharged the water in a discontinuous stream. This arrangement, in effect, grounded the water between the two glass plates through a high resistance.

The needles used were made of steel rod 0.127 in. (0.323 cm.) in diameter, and were adjustable. They were carefully pointed and polished. Considerable care was taken to get the points accurately in line and perpendicular to the dielectric surfaces.

FIG. 4—WATER-COOLED GLASS DIELECTRIC SET PERPENDICULAR TO THE ELECTRIC FIELD

The secondary terminals of the high-tension transformer whose primary was excited by the 8-pole alternator, were connected by the use of bus bars directly to the needle points. No resistance of any kind was placed between the points and the transformer. The resistance of the transformer secondary was 33,390 ohms, and the inductance by short-circuit test was 1920 henries. The middle of the high-tension winding was grounded as were also the alternator and the metal parts of the camera.

RESULTS OF TESTS

It was found by trial that a film exposure of 45 minutes was necessary to secure a satisfactory image of the corona discharge at low potentials, and this length of exposure was therefore used with all of the corona photographs regardless of the intensity of the discharge.

Data on the following points were obtained: Effect of changing the potential, frequency, spacing of electrodes, dielectric material and electrode shape.

For many of the corona photographs the voltage was raised to a point so near the sparking potential that

occasionally a spark would pass. From the appearance of such sparks on the developed film, it was concluded to make some investigation of sparks. On account of the high resistance and reactance of the transformer, such tests could be easily made without the possibility of an arc following.

In Fig. 5 may be seen the discharge as it appears to the eye. This was taken with the pinion driving the

FIG. 5—DISCHARGE BETWEEN POINTS AS IT APPEARS TO THE EYE

Taken with the camera mirrors stationary. The potential is 113 kv. at 60 cycles. (The edges of the glass dielectric are plainly outlined by the parallel reflections appearing as bright lines.)

mirror shaft disconnected from the alternator, the mirrors thus being stationary. The discharge seems to consist of two parts, the neck or stem and the brush which extends to the glass dielectric. This characteristic form has been noted by others, and some very good photographs were obtained by Peek,⁷ whose only dielectric was air. Thus to the eye the discharge

FIG. 6—CORONA DISCHARGE AT 11 KV., 60 CYCLES, DRAWN OUT ALONG A TIME AXIS BY THE USE OF THE SYNCHRONOUSLY DRIVEN ROTATING MIRROR CAMERA. 16 CM. SPACING

appears essentially the same whether the solid dielectric is present or not.

When these discharges are drawn out along a time axis at right angles some additional features can be seen. The stroboscopic method, as used by Peek showed plainly the difference between the positive and the negative discharges, but did not show how they vary with time. Fig. 6 shows the discharge at 60 cycles

and Fig. 7 at 120 cycles, the voltage in each being kept as high as possible without sparking.

As in the photographs showing the discharge with the revolving point, the negative appears as a line, which is the trace of a concentrated glow on the needle point, while the positive discharge is accompanied by the characteristic brush extending from the needle points to the surface of the glass dielectric (Figs. 6 and 7). At all frequencies studied, the negative discharge seems to take place throughout the entire 180 degrees. This condition was made use of in determining the location of the position of the degree scale, for it was possible, on the film, to erect a perpendicular at the end of the negative on one needle to the beginning of the negative on the other. The degree marking was drawn on a separate film, and by the use of the punch marks, which determined the location of the film on the camera, the degree marks could be located in the same position for each frequency.

The positive discharge shows a distinct dark space between the end of the neck and the brush. The shape is somewhat different at the different frequencies, the

FIG. 7—CORONA DISCHARGE AT 104 KV., 120 CYCLES. 15 CM. SPACING

change being most marked at 120 cycles (Fig. 7) where there is evidence of a double dark space. On both films there is a point discharge from the needle point before the neck forms and the brush appears. With each frequency this point discharge continues a short time after the neck has disappeared. Oscillograms of the current flow between a wire and a concentric cylinder taken by Bennett⁸ show the presence of a slight flow of current previous to the point of "copious ionization." It should also be noticed that the discharge is not symmetrical with respect to the mid-points—90 and 270 degrees.

The negative discharge is much the same for each frequency and shows in each case a stronger discharge during the time that the positive neck exists.

In studying these photographs, it is important to remember that there is considerable overlapping of the brush discharge since it has appreciable width.

EFFECT OF ELECTRODE SHAPE

With a brass sphere 24 mm. in diameter substituted for the lower needle, and with a spacing of 15 cm.,

photographs were taken showing the discharge at different frequencies. The discharge from the needle point is not appreciably changed by the substitution of the sphere for the lower point. The discharge from the sphere itself seen in the lower half of Fig. 8 is interesting. The negative is no longer a point discharge but extends out some distance. A brush appears at the beginning and at the end of each negative discharge from the sphere, the first brush with a dark space and the second without one. This effect is very plain on

FIG. 8—SHOWING THE DISCHARGE BETWEEN A NEEDLE (UPPER) AND A SMALL SPHERE (LOWER ELECTRODE) AT 96 KV. AND 60 CYCLES. 15 CM. SPACING

the film but may be lost in reproduction. The positive has no dark space and shows no point discharge. The neck forms abruptly and ceases in the same manner. Both the positive and the negative discharge are shorter in degrees than with needle points.

It should be mentioned in connection with these tests with the sphere and needle that the discharge from the sphere looks very different from that of the needle, consisting of much coarser streamers and tend-

FIG. 9—DISCHARGE WITH AIR DIELECTRIC ONLY. 43 KV., 120 CYCLES. 15 CM. SPACING

ing more toward the condition of sparks than is the case with needles.

TESTS WITH AIR DIELECTRIC ONLY

With the glass dielectric removed it was only with difficulty that photographs of corona could be obtained, for the spark point is close to the corona point with this spacing. Photographs were taken at 30, 60 and 120 cycles. Fig. 9 shows the discharge at 120 cycles. The positive brush has extended clear across to the

negative. The positive dark space is plainly seen in this photograph. The positive brush starts at the same time the glow begins on the positive point. The brush extending to the negative does not form until the 90 degree point has been reached.

PHOTOGRAPHS OF SPARKS

Quite a large number of photographs of sparks were taken. The characteristics seen in Fig. 10, which represents only one sweep of one mirror, are observed at all of the different frequencies studied. When using the glass or a bakelite dielectric, the sparks from the positive needle point are straight for a short distance out from the point and then become quite crooked, deviating considerably from a straight line connecting the needle points. On the other hand, the negative in many cases passes in a straight bold path to a point close to the dielectric, where it jumps to one side before reaching the dielectric.

It should be noticed that the negative spark widens out at the same average distance from the needle point that the positive begins to deviate from a straight line. This distance at 60 cycles is about 17 mm.

FIG. 10—PHOTOGRAPH OF SPARKS: STEEL POINTS, 15 CM. SPACING GLASS DIELECTRIC, SINGLE EXPOSURE, 116 KV., 60 CYCLES

Sparks from a small sphere (2.4 cm. dia.) are nearly as straight when the sphere is positive as when it is negative.

SPECIAL TESTS

Placing an air condenser in series with one of the needle points allowed a much larger discharge without the formation of sparks. The dark spaces, although present, are considerably modified in appearance.

A photograph was taken without a solid dielectric with one of the needles turned through 90 degrees about the point as a center. Sparks from the end of this needle follow the direction of its axis for a short distance.

When a grounded plate was placed in the cooling water, it was found that it was not possible to produce any appreciable corona discharge without the formation of sparks, (15 cm. spacing). This calls attention to the fact that with a dielectric between two needles, the dielectric will not be at ground potential if a discharge is taking place, but will have a potential closer to the positive than to the negative point. This effect is quite appreciable for with grounded cooling water, only 68 kv. is required to produce sparks, while 115 kv. is

necessary when the ground plate is removed. This has an important bearing in several applications; for instance, in an ozonizer, the maximum discharge will be obtained when the dielectric is not in contact with either electrode.

When a bakelite dielectric was substituted for the glass, the general form of the discharge was unchanged, but differences in detail were noted particularly in connection with the shape of the dark space.

A peculiar discharge when the needle is negative is found to have occurred with many of the photographs taken with the corona camera. A luminous point formed back along the needle a distance of about 1 cm. from the point. This point discharge moves in toward the point as the cycle progresses, the total movement being three or four mm. The clearness of the image on the films shows that this movement occurs synchronously when the needle is negative. This has occurred with both needles even after having been re-polished. When photographing a wire, Whitehead⁹ found a spiraling effect which may be of the same nature.

SUMMARY

Two methods which show the variation of the discharge with time have been developed. In the first method, the discharging point is moved synchronously with the alternating current.

The second method, by the use of synchronously revolved mirrors, draws out the discharge along a straight time axis.

It has been found by the use of these two methods that a region exists, between the positive brush and the brilliant discharge from the end of the needle, which does not affect the photographic plate.

It has also been found that the appearance of the positive discharge is considerably modified by changes in circuit conditions.

Sparks from needle points to a solid dielectric are found to possess definite characteristics depending on whether the needle point is positive or negative.

CONCLUSION

A large number of photographs under many different conditions have been taken, using the methods described in this paper. It is hoped that these may soon be published in a Bulletin of the Engineering Experiment Station.

Much additional information should be obtained using quartz lenses and studying the discharge with different gases and at varying pressures. This work is being continued at Purdue University with the idea of learning more about the mechanism of this discharge.

The author wishes to express his appreciation to his associates in conducting this work, especially to R. H. George, Research Assistant, and E. Pugh, Instructor; both of Purdue University. To Dr. Anderegg, and to Prof. C. F. Harding under whose general direction the work was done, thanks are due.

Discussion

**THE AXIALLY CONTROLLED MAGNETRON (HULL),
GASEOUS IONIZATION IN BUILT-UP INSULATION
(WHITEHEAD),
EFFECT OF TRANSIENT VOLTAGES ON DIELECTRICS
—III (PEEK), and
TWO PHOTOGRAPHIC METHODS OF STUDYING
HIGH-VOLTAGE DISCHARGES (McEACHRON),**

SWAMPSCOTT, MASS., JUNE 29, 1923

F. B. Jewett: I wish to touch upon a point which Mr. Peek has referred to in his concluding remarks and call attention to the curious phenomena which have been observed from time to time in connection with these very high energy transients, which sometimes occur in connection with lightning discharges.

Very frequently in examining pieces of rubber covered wire, such as that used in ordinary telephone work for connecting up subscribers' instruments, pieces of wire through which heavy current discharges have passed, the most curious things have been noticed. In the first place you frequently find long lengths of this insulated wire where the wire itself has not only been completely disintegrated, but where casual observation indicates that the metal of the wire has almost completely disappeared without any visible indication of the rubber coating having been seriously ruptured. There are ruptures, of course, and that has given rise to suggestions such as Mr. Peek has just made as to what curious things might be produced by these enormous mechanical forces which must be for a very short instant of time developed in the wire itself. With the apparatus which Mr. Peek has had in hand and similar apparatus, I rather expect that in the next few years we will learn a great many things about matters which in the past have been more or less the subject of speculation.

For instance, if the metal of the wires were not copper—were now a pure metal, but an alloy—would these enormous forces applied at a time when the metal was in a molten state, or near a molten state, produce extreme examples of those processes which have been developed for producing very high grade alloys from relatively low grade material?

I just mention that as a matter of curiosity because there are obviously a lot of things that we want to know about, which may or can take place under the conditions of these enormous energies dissipated in a very small space of time.

H. Goodwin: There has long been a feeling among practical men that wood arms have some value in connection with the insulation of high-voltage lines, that is, from 11,000 to 66,000 volts. In general, technical men have scoffed at the idea of the wood having any real value as insulation for these voltages. Further, it has been considered that when these arms are wet

their resistance is very much reduced, and any insulating value they might have when dry is entirely eliminated. Have your tests gone far enough to show that there may be some insulating value in the wet wood cross-arm in series with the insulators when subjected to a high-voltage steep front wave? Some of your data would seem to indicate that the wood arm may have considerable value, but we appreciate how very unsafe it is to draw sweeping deductions from special tests.

What you have developed on the increase of voltage due to the use of choke coils is of very great interest and confirms claims made by others.

C. J. Fechheimer: I think perhaps that the causes of insulation failure in large high-voltage generators may be attributed to three sources, the first being too high temperature, which may cause the insulation to char and to chafe. This is well known. We have had a great deal of discussion in the Institute on that subject.

The second is mechanical failure which may arise from various causes; with long core machines there is possibility of electrical failure from alternate expansion and contraction, due to changes in temperature. That has not been discussed, so far as I know, at any of our meetings.

The third is the possibility of failure from corona, either external to the insulation or internal.

With regard to the second source, I may say that at the Westinghouse Company we are conducting a large number of tests to determine how serious may be the danger of failure from alternate expansion and contraction and we hope that within the course of a year or less we shall be able to present before this Society the results of our investigation. At present, I would rather not speak of that as it does not pertain to the subject.

On the subject of the possibilities of failure from corona that Dr. Whitehead's covers, there are two or three points to which I want to call attention.

I think the principal conclusion which one may reach is that the danger from failure in well insulated coils having a large percentage of mica is extremely small. Those who have been skeptical in this regard may now feel quite safe that their machines will not fail. I know that some years ago when mica was not used to the extent that it is today, treated cloth or paper were the chief constituents of the insulation; the insulation failed undoubtedly from internal corona or possibly external corona.

Even when coils are insulated with mica we have found that after they were in service for a number of years, the insulation on the outside—which is usually paper for mechanical protection—was pitted. But immediately after removing the external layer of paper, where the mica appears it was found there was no pitting whatsoever; the mica was in as good condition as when it was placed upon the coil. In other words, for ordinary service up to, say, around 15,000 volts, there is practically no danger from breakdown due to corona.

That is one conclusion which one might infer from the paper, but the other conclusion is that the corona loss with mica insulation is very much less than with fibrous material. In other words, we have eliminated danger from breakdown when mica insulation is employed, by two means; we have first reduced the internal corona loss, and then we have, since we use mica, practically eliminated any further danger of breakdown because mica will successfully withstand corona discharge for indefinite periods.

J. F. Peters: Mr. Peek's paper indeed is very interesting in showing us the behavior of very high-voltage circuits and the apparatus described in the paper undoubtedly will be of very great value in obtaining data for high-voltage engineering. I feel, however, that some of the conclusions drawn from the tests have been made rather loosely.

For instance, in the second column of the third page, where

the author is discussing the impulse ratio of sphere gaps with various series resistances he states, "The effect of the series resistance increases with increasing wave front. This arrangement may be used, therefore, to indicate the duration and wave front of transients."

It has been very definitely proven that the delay of a sphere gap with series resistance is due to the time required to charge up the spheres as a condenser through the series resistance. That being the case, the delay is fixed almost entirely by the duration of the surge and is practically independent of the wave front. The wave front and duration to a very limited extent are proportional, but the duration can be varied over a very wide range without materially affecting the wave front.

For instance, taking the curve shown in Fig. 3 and the constants there given, the equation of that curve is

$$E_0 (\epsilon^{-0.152t} - \epsilon^{-0.173t})$$

where ϵ is the base of naperian log and t is time in microseconds. " ϵ to the minus 173, t fixes the wave front almost entirely while the other factor " ϵ to the minus 0.152 t —fixes the time or tail of the wave."

If the capacitance there used were double and R and L remained the same, then the exponent fixing the wave front would be 173.1 as compared with 173, whereas the exponent fixing the length or time of the surge would be 0.075 instead of 0.152. In other words, the duration is practically doubled, where the wave front is not modified or is modified very slightly.

That being the case, it is obvious that the impulse ratio would be different for the conditions with a larger condenser than it is for the small condenser. So that the spark gap for the given resistance really gives wave front only for some particular quantity of charge.

In connection with the author's investigation of strings of insulators in series with resistances shown on the fourth page, which have characteristics similar to the needle gap, the author states at the top of the first column on the fifth page: "Incidentally these tests show how useless a high-resistance arrester is."

Although I entirely agree with the author on the ineffectiveness of a high-resistance lightning arrester—it is not clear how these tests prove the point. In the first place, a resistance type arrester as usually constructed consists of combinations of resistance and spark gaps in series and has characteristics similar to those shown on the third page, and for moderate resistances the impulse ratio would not be serious. My belief in the ineffectiveness of the high-resistance type arrester is not due to its large impulse ratio but is due to its limitation of current that it will drain from the system when it does function.

Referring to Mr. Peek's conclusion, his last conclusion in the first column of the eighth page is: "In measuring lightning voltages resistance must not be used in series with sphere gap. Resistances so placed give the sphere gap all of the time lag characteristics of the needle gap and the spark-over voltage varies with the wave front."

Whether a resistance in series with a spark gap is at all objectionable or not depends on the relative value of that resistance as compared to the capacitance of the spheres. A certain amount of resistance may be desirable. We all know that if a voltage is abruptly applied to an inductance and capacitance in series where the circuit is not critically damped, the voltage on that condenser will overshoot. A sphere gap with no series resistance is just such a circuit.

The author shows by some of his tests that an inductance located at the open end of a line gives a large increase in voltage due to reflections, and in connection with those tests he finds that by shunting these inductances by resistances, the reflections are very much reduced, and he concludes that "In general, inductances to be safe should be shunted by resistances."

The usual installation of inductance (reactances) is not at the open end of lines. The only inductances that have a legitimate

right to be located at the open end of a line are those used in connection with lightning arresters, and when used in connection with lightning arresters, the better reflector they are the more effective will be the lightning arrester.

R. H. Marvin: I was particularly struck by Mr. Peek's experiments with regard to resistance in series with the sphere gap.

It is, I think, generally recognized that wooden construction is of great value in reducing lightning disturbances. I think the general feeling has been—I know my own has been—that its value in this case was not so much in preventing flashover, as in preventing a dangerous arc from following, or hastening the extinguishing of the arc after its occurrence. It would appear from these experiments that we have a still further action in actually preventing the flashover of the insulator and so reducing the number of disturbances. Of course, it is true also that we may have this action in limiting the current after the arc has started.

It is also interesting in this connection to consider the effect of ground resistance. We all know that the resistance of the earth varies widely with the amount of moisture in the ground, and it seems entirely possible that even with metal construction the resistance of the earth may have some effect in determining flashovers from lightning voltages.

J. Slepian: The phenomenon of time-lag in the electrical breakdown of dielectrics has been rightly attributed to the necessity of a certain energy input for converting the dielectric from the insulating to the conducting state. Since electrical energy input is determined by the product of potential, current and time, we see that in all cases time is necessary for breakdown.

The sphere gap in air is known to be extremely fast in its breakdown, and for most purposes may be considered instantaneous. However, we must not forget that actually a finite time is required, and when, as Mr. Peek does in his paper, we are considering things happening in 10^{-8} seconds, we must inquire whether the sphere gap is sufficiently "instantaneous" for its time of breakdown to be negligible I shall show that to bring a sphere-gap into a highly conducting state something of the order of a micro-second is necessary. This being the case, the calculated steep front of the wave shape shown in Fig. 3 of the paper has no actual significance. The gap G of Fig. 1 does not break down fast enough for the voltage on the resistor R to build up at the rate indicated in Fig. 3.

The theory of conduction in gases is now in a highly developed state, and we may make calculations in this field with great confidence in the order of magnitude. I shall now calculate the time of breakdown of the gap G .

To begin, what energy is necessary to make the gap conducting? Before this can be answered we must state more precisely the degree of conductivity the gap is to attain. I assume that in Fig. 3 a four cm. gap was used which breaks down at about 100,000 volts. With a resistance of 5000 ohms, this will give 20 amperes after complete breakdown. Since in calculating the curve of Fig. 3 the volts taken by the gap are assumed negligible against the 100,000 volts, I shall assume that 1000 volts are taken by the gap when carrying the 20 amperes. This defines the degree of conductivity attained by the gap.

The current in the gap is carried by ions, that is, positively and negatively charged particles into which formerly neutral molecules of the air have been broken. The negative ions will be electrons which have a very much greater velocity than the positive ions. Hence, practically all the current will be carried by the negative ions.

Since the current will be given by the product of the charge per cm. of gap carried by the electrons and the velocity with which the electrons move, if we know the velocity, we can determine the charge. Referring to Townsend, "Electricity in Gases" p. 180, we find that the velocity for a gradient of 250 volts per cm. is about 700,000 cm. per sec. This gives

$\frac{20}{700,000} = 2.9 \times 10^{-5}$ coulombs per cm. or for the whole 4 cm.

of gap 11.1×10^{-5} coulombs as the charge carried by the electrons.

Now, to separate an electron from a neutral molecule requires a certain amount of energy. This energy has been fairly accurately determined, and is commonly expressed as the voltage, called the ionizing potential, through which an electron must fall to attain this energy. The ionizing potential for air is about 15 volts. Hence the energy necessary to produce the 11.1×10^{-5} coulombs of electrons in the gap is $15 \times 11.1 \times 10^{-5} = 1.67 \times 10^{-3}$ joules. This is about 1/12 of the energy which leaves the condenser in the first two hundredths of a micro-second, as shown in Fig. 3.

Now although 1.67×10^{-3} joules is the energy necessary to produce the assumed degree of conductivity of the gap, this is not a measure of the total energy which must be put into the gap, for the larger part of this energy goes into producing heat, and only a small part into producing ionization. To get an idea of the relative proportion, we must consider the mechanism of ionization in more detail. An electron will ionize a molecule if it collides with it after having fallen freely through fifteen volts of potential. Now with the largest mean gradient in the gap, namely, with the initial 100,000 volts acting on 4 cm., or a mean gradient of 25,000 volts per cm., this means that the electron

will have to fall freely through a distance of $\frac{15}{25,000}$ or 60×10^{-5}

cm. But the mean free path of an electron in air is only about 5.7×10^{-5} cm. Hence very, very few electrons will fall freely through the necessary 60×10^{-5} cm. Practically all of them will collide with molecules before they have fallen through this distance and give up their energy as heat instead of as ionization. The actual proportion which will produce ionization may be determined by the formula given in Townsend, "Electricity in Gases," pp. 292 - 293. This gives, on substituting,

$$e \frac{60 \times 10^{-5}}{5.7 \times 10^{-5}} = 10^{4.6}$$

Thus an electron will collide with molecules $10^{4.6}$ times with an energy corresponding to a fall through the mean free path, for each time it collides with a molecule with energy sufficient to ionize, corresponding to a fall through the distance 60×10^{-5} cm. We conclude then that

$5.7 \times 10^{4.6} = 4 \times 10^3$ times as much energy will go into heat, as goes into ionization. If this proportion were kept up, $4 \times 10^3 \times 1.67 \times 10^{-3} = 6.68$ joules would have to be put into the gap to produce the desired ionization, and at 10 amperes, 100,000 volts, this would require, 6.68×10^{-6} seconds.

However, after some ionization is produced conditions become more favorable for further ionization, since portions of the gap become charged and cause the electrostatic field in the gap to be distorted, the gradient being increased near the electrodes, and reduced at the center of the gap. In the stronger fields a larger part of the energy spent will go into ionization, so that the total energy which must be put into the gap will be reduced. This does not help out very much on the time of breakdown, however, as the ions which are produced in the stronger portions of the field must move into the weaker portions before full conductivity can be obtained. Now, for a gradient as high as 25,000 volts per cm. the velocity of the electron will be nearly 10^8 cm. per sec., but the velocity of the positive ion is very much less, so that time of the order of micro seconds must elapse before the ions move from the strong field, where they are generated rapidly, to the weak field.

More convincing, perhaps, than the above calculations, are actual experiments. A. Leontiewa, in *Physikalische Zeitschrift*, Jan. 15, 1922, p. 33, describes experiments which show a

lag in the breakdown of sphere gaps distinctly greater than 10^{-8} seconds. In these experiments however, breakdown meant merely a luminous discharge, and a discharge of only a micro-ampere may be luminous. To attain conductivity sufficient to discharge amperes, as in commercial lightning arresters, or as in the gap *G* of Mr. Peek's tests will require considerably longer times.

This brings us now to the matter of spark gaps for measuring transient voltages. Since the current necessary to produce a luminous discharge is so small, a measuring spark gap does not need to develop the high degree of conductivity assumed above, and its time lag is much shorter, of the order of 10^{-8} seconds. This may be considered as instantaneous when the gap is used for measuring surges initiated by discharge gaps in the laboratory, or lightning strokes or insulator flashovers in the field, which require 10^{-6} sec. or more to develop their full conductivity.

Mr. Peek states that for most accurate work, no resistance should be used in series with measuring spark gap. I do not agree with him there in general as the leads to the spark gap necessarily have inductance, and as is well known, if a voltage is suddenly applied and maintained on an inductance in series with a condenser, the voltage on the condenser will rise to nearly twice the applied voltage. A somewhat similar question would be as to what is the best value of damping to put in the movement of an ordinary voltmeter to read accurately voltages which are suddenly applied and held on for only a brief time. If there is no damping at all, the movement will come most rapidly to the proper position, but it will not stop there. It will overshoot, and momentarily indicate too high values. The amount by which it overshoots will depend on the rate at which the applied voltage builds up. If the applied voltage builds up in a time small compared to the natural period of the movement, it will overshoot to twice the correct displacement. If the applied voltage builds up in a time large compared to the natural period of the movement, the overshooting will be negligible.

If too much damping is used, the movement will be sluggish, and will not reach the proper deflection during the time of application of the voltage.

To reach the proper deflection most rapidly and without overshooting, the movement should be critically damped.

Similarly, for a measuring spark gap it is best to use that value of series resistance which will critically damp the oscillations attendant upon charging the capacitance of the sphere gap through the inductance of the leads. When, as was most likely in Mr. Peek's circuits, the time of building up of the voltage is long compared to the natural period of the measuring sphere-gap oscillations, not much error will result in omitting this series resistance, but in other cases the error may be considerable. It is not unusual in the laboratory to find an undamped measuring gap indicating higher voltages than the gap initiating the impulse.

H. J. Ryan: In the high-voltage field, generally speaking, breakdowns of solid, liquid, or gaseous dielectrics are due to many factors, and often in very complicated relations. Exact knowledge of all circumstances is, therefore, of the highest importance. Systematic work under definite conditions is rapidly erecting a sufficiently complete understanding of high-voltage phenomena to assist greatly in placing causes of accidents of a high-voltage character in practice.

There is a duty imposed upon those who undertake to profit by these papers. They should remember in connection with Mr. Peek's paper what has been said therein regarding the conditions involving the time element. Where the time in action is so short, as was always the case in those studies, the results show that the discharges through the air require extraordinary voltages, having impulse ratios of about two, and values of 20 kilovolts, effective, per inch in air at common densities. On the other hand, the oscillator that delivers 120, 60,000-cycle

wave trains per second produces discharges through air at ordinary densities with impulse ratios that begin at 1.5 for short distances, say *one foot*, and diminish with ever increasing rapidity to 0.67 at *eight feet*. In these circumstances the logarithm of the discharge distance is found to be proportional to the discharge voltage. The logarithms of numbers grow very slowly. The discharge lengths grow very rapidly, therefore, with voltages.

Finally, when we came to that type of discharge that is established through air with high voltages at continuous high frequencies, wherein some of the ionization that is established holds over from voltage crest to crest, the nature of this action is further developed and amplified. In comparatively short discharges the voltage per inch required to break down an air column may fall to the low value of 1.5 or 1 kilovolt. In these circumstances I am convinced that the value of voltage in relation to increase of discharge distances will continue to fall. If one keeps up the action, increases the distance, follows it up with the requisite amount of voltage to accomplish breakdown, I am convinced that the value of voltage per inch of gap will fall below one kilovolt—a ratio of voltages from one extreme of circumstances to the other of 20 to 1, or more.

It is important, therefore, for those who study these papers and their discussions, to remember the conditions their authors carefully specified, under which they obtained their results.

D. D. Clarke: My own great interest in Mr. Peek's paper lies, perhaps, in the new tool that his work has given us in studying what happens on a transmission line and on distribution lines during lightning storms. Those of us who have been more or less responsible at times for keeping lines going, and the people of widely distributed towns in service during lightning weather, very greatly appreciate any move toward solving the peculiar problem of stopping the trouble.

There are several things in a lightning stroke as indicated on the line which are not entirely new to the operating man, but which might be divided into a few classes of phenomena. There is (1) the spit-over, which is not due to a direct stroke, but over which the power current may flow with destructive results.

There is (2), the direct stroke which may melt conductors and drop the lines.

And there is (3), the burning of poles by the power current which may drop the line.

Lines are classified in general as wood pole lines and metal supported lines. Outdoor substations are of course metal supported. The great interest in this paper, to me, comes particularly in the wood pole line construction. Occasionally on such work we find that the poles are split. In the three weeks preceding my attendance at this meeting, we had three distinct cases of such split poles. These are always accompanied by more or less splintering of the arm from the pin of one or more insulators, to the brace, showing that a very steep wave front has existed. Again, the poles in these three cases were distinctly split, but in no case dropping the line. In one of these cases not only one pole was split but four successive poles showed splinters.

The splitting of poles is dangerous to the operation of the line because it is liable to drop the line. It seems very probable that continued investigation with this new tool—the impulse generator—will lead to a solution of this problem and at the same time allow us to retain the very important added flashover value of the line as a whole due to the wood construction.

On a low-frequency oscillator we have demonstrated repeatedly that the wood, whether wet or dry, has a very distinct advantage in increasing flashover voltages of pole-line construction.

The flashover value of three or four feet of wood is so high as to make comparatively negligible the flashover value of the insulator itself. After the insulator flashover is over, the wood—efficient resistance ordinarily to put out any ensuing arc.

this paper strikes home to the operating man in pro-

tecting his substations. The substation is protected ordinarily by a lightning arrester from destructive insulation failure either due to flashover or puncture of transformer coils. The great problem with the operating engineer is to apply the lightning arrester so as to give it a chance to perform its function at all times.

The performance of lightning to date has been a very mysterious quantity. The man has quite a problem on his hands whose duty it is to investigate failure during a lightning storm in a substation which has been equipped with the most complete protective apparatus that modern science has put on the commercial market. He finds that the lightning arrester is set at a reasonable value, that the ground resistances are as low as they can be made on isolated construction—and yet it fails.

I feel that the experiments as indicated in Mr. Peek's paper have lent a way to solving to best advantage that problem.

D. M. Simons: I have been particularly interested in Dr. Whitehead's method of measurement, apart from the results which he has obtained. I do not think that the quadrant electrometer or electrostatic wattmeter has had sufficient recognition, and I would like to say a few words about this method of measuring dielectric losses.

A great many people seemed to have obtained an impression that the electrometer is a very fragile and delicate instrument. We have had one in service for 10 years without an accident and without even changing its suspension, and have found it a very valuable and rugged instrument.

Dr. Whitehead says that some of the errors in the electrometer such as that due to the charging current between the needle and the quadrant and others have not yet been worked out. We have done a lot of work on this subject and I hope that we can soon present some of this matter in definite equation form, which may help to add to the utility of the instrument.

We have been able to measure dielectric losses of an extremely low value, down to milliwatts, at high voltages and at very low power factors and to check our results very thoroughly. I merely want to add these remarks to emphasize what I believe is the very great importance and value of this method of measuring extremely low dielectric losses.

C. F. Harding: Mr. McEachron's paper will be recognized, I think, as confirmatory evidence of the nature of the corona discharge, particularly at the positive and negative electrodes respectively, which was presented some years ago by Mr. Peek and others. It might be well to emphasize the fact, however, that the two methods outlined in this paper provide opportunity for additional study of the variation of such corona throughout the cycle, with respect to time.

Also, it might be well to point out that in both of these cases the corona under investigation is simply that portion which affects the eye or the photographic film. Some recent investigations seem to indicate that corona formation may seriously affect insulation and produce the higher oxides of nitrogen, which in connection with moisture cause insulation to deteriorate, even though that corona does not affect the photographic plate or is not visual. That is particularly true in other portions of the spectrum than the ultra-violet, since the latter may be studied by means of quartz lenses.

Referring briefly to the next to the last paragraph on the second page of his paper, Mr. McEachron states that "At 15 kv. the discharge at 15 cycles (not reproduced here) was about as strong as that at 120 cycles, but the 30-cycle discharge showed no brush at all. At 8 kv. and 60 cycles there was no brush discharge recorded."

It may be that at certain voltages we have critical frequencies at which this corona effect takes place which may, at those frequencies, cause serious deterioration of insulation.

I wish to emphasize also the fact that there were a number of rather important developments brought out by Mr. McEachron in this work that will be published in a bulletin of the Engineering

ably is not feasible at the temperatures and conditions prevailing in an armature winding.

H. S. Warren: These very interesting tests which Mr. Peek has described have suggested to me the possibility of employing his equipment in a field somewhat outside its intended range. I refer to the efficacy of lightning rods for the protection of buildings against lightning.

The subject of protecting buildings—particularly farm property and buildings containing oils and explosives—has received considerable attention but has not been given the intensive scientific study which it deserves. In consequence, while the lightning rod is fairly well established in the opinion of those who actually provide such installations, there is room for legitimate doubt as to the necessity and sufficiency of the methods now commonly employed. This doubt is due to a realization that the whole subject of protecting buildings against lightning rests on an inadequate foundation because of the lack of exact knowledge of the physical principles underlying lightning phenomena.

That this should be so is not surprising in view of the difficulties presented by a scientific investigation of the subject. To conduct in the field such an investigation, comprehensive enough to lead to conclusive results, is a most formidable undertaking.

I wish, therefore, to suggest for Mr. Peek's consideration the possibility of utilizing his apparatus to make laboratory tests in the endeavor to throw some light on the behavior of lightning discharges in the vicinity of buildings with and without different types of protective equipment.

In making this suggestion, I am not unmindful that lightning produced in the laboratory is small in comparison with the maximum voltages encountered in atmospheric electricity. Such tests could not presumably be conducted on a full-scale basis and any attempt to simulate by models practical conditions of exposure is fraught with uncertainties. Great care would have to be exercised in interpreting any results obtained in that way. However, the need of scientific data on the protection of buildings is so great that I am moved to raise the question. I hope Mr. Peek will take it up and see if something cannot be done which will be useful in that application.

F. W. Peek, Jr.: Messrs. Goodwin and Clarke are quite right in that wooden poles even when wet add materially to the line insulation for lightning voltages.

Referring to Mr. Peters' discussion, the table on page 625 gives the effect of various values of resistance in series with the sphere for a given wave. Obviously the effect will vary with the capacity of the sphere. The "instantaneous" voltage can only be measured when there is no series resistance or when it has a very moderate value. I have sometimes used a moderate value of resistance to suppress local oscillations. Generally this is not necessary. The duration of the transient is readily determined by measuring both the "instantaneous" voltage and the voltage with a high known resistance in series with the sphere. A small

known inductance in series with the circuit shunted with a sphere gap offers a means of determining the wave front.

A lightning arrester with high impulse ratio or high series resistance is undesirable. The high series resistance has the effect of reducing the discharge capacity and also of increasing the impulse ratio.

The tests with the inductance coils show, I believe, that an inductance without shunt resistance may be dangerous.

Mr. Slepian's calculations are very interesting, I have made similar calculations. The difficulty in this, before the calculations are started certain assumptions must be made. While the calculations may be correct, there may be some doubt as to the assumptions upon which they are based. However, such work is often of great help in the final solution of a problem.

I naturally do not claim the accuracy for these measurements as that which could be obtained by leisurely reading the voltage with a meter in a d-c. circuit. Nevertheless I believe the accuracy is fair considering the difficulties.

Professor Ryan's word of caution is timely.

Dr. Jewett's observations add to the many peculiar phenomena caused by lightning voltages. I have observed that when voltages from the lightning generator are applied to a wooden post, it is blown apart violently. Examination of the two parts show a tiny hole lengthwise through the post where the wood has entirely disappeared. The wood has apparently been turned into a gas and tremendous pressures are thus produced. This effect is readily obtained on kiln dried wood.

Answering Mr. Warren's question, I am engaged at present in an investigation to try and determine the value of the lightning rod.

K. B. McEachron: There has been considerable comment among those who discussed Mr. Peek's paper concerning the explosive effect which appeared in the pieces of wood, poles and so forth. I don't wish to attempt any explanation, but I do want to call your attention to something which may help to explain it.

In J. J. Thompson's book on the "Conduction of Electricity Through Gases," which was published quite a good many years ago, there will be found a description of some experiments on the pressure developed in the electric spark. I remember being much surprised when I found that pressures as high as 600 atmospheres could be expected from the electric spark.

When it is remembered that in those experiments the spark was very small compared to the sparks with which Mr. Peek is working, or the sparks which we get in lightning discharge, it is clear that mechanical pressures may be produced which are sufficient to account, at least in part, for the stresses set up when the wood or other material is torn apart.

The reason why sparks produce oxides of nitro much better than the more gentle corona discharge, may be due to the explosive effect, combined with the difficulty of breaking up the nitrogen molecule.

Mechanical Electrical Construction of Modern Power Transmission Lines.—Insulators for High-Voltage Lines

BY C. B. CARLSON and W. R. BATTEY

Associate, A. I. E. E.

Both of the Southern California Edison Co.

Review of the Subject.—The paper deals with the investigations for economics followed by the design assumptions based on the economical findings; the limitations required by electrical clearances; the testing of the structures; the design assumptions of the cable

attachments; the unusual requirements of loading for attaching cable to structures; the extensions required by nature of country traversed; and the erection problems.

* * * * *

IN handling the subject assigned, a complete description of the problems encountered in the design of the 220-kv. transmission line from the Laguna Bell Substation to Eagle Rock Substation of the Southern California Edison Co. will form the subject matter for this discussion.

The design was started following a request from a committee assigned to investigate the electrical features of a line of this voltage. The questionnaire outlined investigation on the use of the following five sizes of conductors:

605,000	circular	mill	steel	reinforced	aluminum	cable
1,000,000	"	"	"	"	"	"
1,500,000	"	"	"	"	"	"

Copper cables of equal conductivity to the last two sizes.

There were several clearances to ground assigned for investigation together with a strict adherence to the

FULL SIZE TOWER TEST

recently adopted order of the Railroad Commission regulating high-voltage transmission lines.

The first preliminary study eliminated from consideration the majority of the materials and limitations and further study was requested on the use of the following:

Cable—666,600-circular mill steel-reinforced aluminum, made up of 7 strands of extra high strength

Presented at the Pacific Coast Convention of the A. I. E. E., Del Monte, Cal., October 2-5, 1923.

steel and 54 strands of aluminum having the following characteristics:

Diameter—1 inch

Ultimate tension—23,430 lb.

Elastic limit—16,180 lb.

Area—0.59 Square inches

Weight—0.86 lb. per lineal foot

Further, a single ground wire running over the top of the towers, was desired to provide the grounding for the line.

Having now fixed on the cable, a complete set of assumptions was made on which to base an economical study of height of tower and span.

The calculations showed that with present-day costs and the assumed tensions that a span between 1150 and 1300 ft. would give the most economical line.

Shortly before the need of ordering steel for the supporting structures, the Southern California Edison Co. needed a large quantity of steel for extending the height of the towers of their present 150,000-volt transmission line to meet the conditions of the new legislation regarding ground clearances. It was found that by considering the higher stresses permissible by the use of high-elastic-limit steel as manufactured by a Pacific Coast manufacturer that a saving could be made, so the towers for the 220-kv. lines were designed on the basis of this steel and other conditions of design which were as follows:

Wind on Line—8 lb. per square foot on projected area of wire

Footings—Earth with frustum of cone at 30 deg. for uplift resistance. Bearing according to soil.

Full-sized tests were made at the steel company's testing frames as shown on accompanying photograph marked "Full Size Tower Test." The results of these tests, with the exception of a few minor details of connection, justified the design and were considered representative of the conditions of actual loading in the field under broken wire and maximum tension conditions with the required factor of safety. illustration of the standard tower is included herewith showing the framing systems.

Extensions were also then designed to meet conditions of country through which the line had to pass. These extensions were made vertical from the same footing spreads as the tower itself, thereby making the setting of stubs uniform throughout. Sidehill extensions both parallel and normal to the line were made, as considerable of the line traverses a mountainous country. Special footing extensions were made to take care of side slopes where sufficient resistance-to-uplift was not obtainable.

The committee having the features of the design of this line in hand required a factor of safety of 3 in the strength of the attachments of the cable to the towers. Due to limitations of clearances this required the hardware to be made of cast steel. The entire

requirements for hardware were designed and tested for loads three times the maximum tension.

A complete assembly of both the suspension and dead end strings is shown on plates marked "Assembly of Insulator String for Anchor Tower" and "Assembly of Insulators for Standard Tower." It is to be noted that to develop, on a factor of 3, the tension in the insulators that a special type of high-strength disks and pin connections was necessary.

The towers, except those in rather inaccessible places, which were assembled piece by piece, were erected by assembling the tower on the ground in two parts dividing the face normal to the line and bolting with loose bolts each leg to the footing studs. Then by means of two gin poles set aside the footings and a winch set on a truck and operated by its motor, the

two halves were raised and connection made at the center gusset plates. The bridge of the tower was then hoisted in place.

The line stringing was also done by the use of the motor-operated winch and brought to tension by use of the sag method.

The unusual features in transmission line design such as the stringing tension, the spans, and the high voltages, made many difficult problems, but as the line is just now in process of erection, the complete justification for the assumptions cannot be completely told.

Discussion

For discussion of this paper see page 966.

Special Features in the Design of Transmission Tower Lines as Imposed by Electrical Conditions

BY W. DREYER

Asst. Engineer, Division of Civil Engineering, Pacific Gas & Electric Company, San Francisco, California

Review of the Subject.—This paper is confined to the factors which affect the structural and mechanical phases of transmission line design. These are divided into two groups as follows:

1. Factors affecting design of tower.
2. Features involving location of towers.

The writer has in general refrained from commenting on the various items listed. Exceptions are made, however, in certain features which in his opinion deserve particular emphasis. Briefly, these are:

1. The consideration of an "economical stringing stress" as described under "Factors affecting Strength of Tower."

2. The description of transpositions.

3. Features involving location of towers.

Views and diagrams are used to describe the transpositions and a table giving data on the standard towers for the 110-kv. and 220-kv. transmission lines of the Pacific Gas and Electric Company is also included.

THE title assigned to this paper, namely "Special Features in the Design of Transmission Tower Lines as Imposed by Electrical Conditions," will, if strictly interpreted, cover a field somewhat broader than the scope of the writer's knowledge, which is confined strictly to the structural and mechanical side of the transmission problem. The paper will, therefore, be limited to those features which affect either the design of the supporting structures, or the location of these structures in the field.

The writer will attempt to enumerate all of the factors, giving a brief description of the more important points and describing how the problems are handled in the transmission lines of the Pacific Gas and Electric Company. The features of greatest interest,—transpositions,—are described by illustration. A table is also included which gives data on the standard towers for the 110-kv. and 220-kv. transmission lines of the company.

FACTORS AFFECTING DESIGN OF TOWER

The factors which affect the design of the standard line towers may be divided into two groups, one affecting the shape and the other the strength of the supporting structure. These factors are briefly enumerated below:

(a) Factors Affecting Shape of Tower:

1. Type of tower—single vs. double circuit.
2. Permissible distance between phases.
3. Permissible distance between circuits.
4. Length and allowable transverse deflection of insulator string.

5. Sag of wire inside tower.

An allowance for sag inside of the tower based on a 20-deg. angle of pull will usually be sufficient for obtaining proper clearance between the wire and the members of the tower.

6. Minimum clearance between conductor and members of tower.

This clearance should be maintained, using a length

Presented at the Pacific Coast Convention of the A. I. E. E., Del Monte, Cal., October 2-5, 1923.

from point of support equal to the length of the insulator plus the sag inside of the tower, this length being swung at the angle of maximum transverse deflection. This investigation will, particularly for single-circuit towers of the flat top type practically establish the shape of the transverse framing of the structure.

(b) Factors Affecting Strength of Tower:

1. Size and maximum stress of conductor.

The size of the wire on trunk transmission lines is usually selected to best suit electrical conditions. The maximum stress in the wire can, however, be controlled by the tension at which the wire is strung.

The usual practise in tower line construction is to string the conductor so that it will be stressed nearly to its elastic limit when under maximum loading. The writer believes that following this practise blindly will give neither the most economical nor the most satisfactory transmission line. Investigations have been made by our company to determine the conductor stress which would result in the lowest cost for supporting structures, consideration being given to both the towers and their foundations. This investigation showed that a maximum tension of 17,000 lb. per sq. inch for copper 250,000 cir. mil to 500,000 cir. mil in size resulted in the lowest cost of completed line. The use of this tension instead of 27,000 lb. per sq. in., resulted in a saving of about 20 per cent in the cost of towers and foundations. For the Pit River 220-kv. line this represents a saving of nearly \$1200 per mile. In addition, this tension, which is only about 60 per cent of the elastic limit of medium drawn copper, greatly reduces the load on dead-end insulator strings, consequently reduces the number of dead-end insulator failures, and therefore gives a more satisfactory line.

2. Standard Span.

The standard span is determined by economic considerations and for steel towers on concrete foundations, greatest economy will result with spans 800 to 1200 ft. in length.

3. Type of Tower.

(a) *Double-Circuit vs. Single-Circuit.* It is customary to consider more broken wires for double-circuit than

for single-circuit towers. It is our practise to assume three broken wires on standard double circuit towers, all wires being on one side of the tower. This case will usually occur when the top wire breaks and drops across the two lower wires. Two wires are assumed broken with standard single-circuit towers.

(b) *Standard, Anchor and Dead-End Towers.* Dead-end towers are designed to resist all wires broken at maximum stress in the conductor. This would occur under the condition of heaviest loading and with dead-end insulator strings.

For standard towers (designed for two or three wires broken) and for anchor towers (designed for all wires broken) no dead-end construction is permitted, the insulator string being suspended vertically. In this case when a wire breaks the insulator strings swing into the catenary, increase its length and therefore greatly reduce the tension in the span adjacent to the break. For our standard 110-kv. double-circuit lines the resultant stress is 78 per cent and for the 220-kv. double-circuit line, it is 66 per cent of the maximum conductor stress.

All towers of the Pacific Gas and Electric Company are tested to 50 per cent overload.

(c) *Transposition Structures.*

FIG. 1—110,000-VOLT TRANSPPOSITION TOWER

1. *110-Kv. Transmission Lines.* Transpositions on the 110-kv. lines are of the conventional "Dead-end and jumper" type, where the transposing is done on a tower. Our standard 110-kv., double-circuit transposition tower is shown as Fig. 1. The only additions to the standard tower are extensions to the upper and lower arms.

2. *220-Kv. Transmission Lines.* Transpositions on the 220-kv. Pit River line are of the "rolling type," that is, the wires are transposed without dead-ends or jumpers.

The double-circuit transposition structure, as shown in Fig. 2, consists of two standard line towers the cages of which are connected by two latticed bridges. A

FIG. 2—220,000-VOLT DOUBLE-CIRCUIT TRANSPPOSITION TOWER

diagrammatic plan showing the transposition scheme is shown on Fig. 3. It will be noted that the crossing wire of each circuit is pulled out of the vertical plane to an insulator suspended from the bridge, and that the transposition is completed in two spans.

The single-circuit transposition, shown diagrammatically on Fig. 4, requires three spans for completion. This was done to bring the crossing points of the wires on the towers rather than at the center of the span. The intermediate towers are standard line towers with an extension above them, and with a portion of the cross-arm removed. In order to reduce the side deflection of the insulators to a minimum, the intermediate towers are offset as shown on the plan. This results in the wires crossing in straight lines, with the insulators on the intermediate towers hanging vertically. Fig. 5 shows one of the completed transpositions; it will be noted that there is no deflection of the insulators except on the end towers, which is unavoidable.

FIG. 3

FIG. 4

FEATURES INVOLVING LOCATION OF TOWERS

(a) Stagger or Offset of Towers on Twin Lines.

Where twin tower lines traverse country that is not flat, it is impossible to set the structures directly opposite each other. The amount of offset that will be

permitted should be based on maintaining a minimum clearance between adjacent wires equal to the distance between phases on the flat-top, single-circuit towers. The horizontal projection of the catenary as deflected by wind, furnishes the basis for the determination of allowable stagger.

(b) *Ratio of Horizontal and Vertical Loads to Limit Deflection of Insulator.*

In designing the towers, clearances are investigated under the assumption that the insulators are permitted to swing transversely to the line at some angle (usually between 30 deg. and 45 deg.) from the vertical. In locating the towers in rough country it is necessary to see that this maximum angle of deflection is not

to nothing. In this case the insulator would probably deflect toward the tower beyond the allowable angle, and would create a situation which would ultimately cause an interruption to service. Where this situation exists, there are three remedies available, one to extend the tower in order to increase the amount of vertical loading, and if this cannot be economically done, to resort to either a tie-down or a dead-end.

On the 220-kv. Pit River tower line it was considered highly desirable to reduce the number of dead-end strings, it being felt that these points offered the greatest opportunity for trouble, which would mean cutting out of service a line carrying in excess of 200,000 kilowatts. As tie-down strings were also considered undesirable the only alternative to dead-ending was to extend the tower to increase the vertical loading at doubtful points. The additional cost of the extension to the tower was always largely offset by the value of the insulators saved (about \$110 per dead-end string). With the single-circuit towers of this line, the saving in insulators alone would provide over two tons of steel in the extension. At other points the elimination of dead-ends permitted the use of the standard line tower (Type SA) instead of the anchor tower (Type SC) with an actual saving of money.

As a result of this investigation, and by the liberal use of tower extensions, the Pit River line, some 200 miles long, contains one tower which has dead-end insulator strings to take care of the irregularity of the profile. There are only 21 points on the line where dead-end strings are required, 2 of these being the terminal points, 18 at horizontal angles and one because of the profile of the ground.

FIG. 5—220,000-VOLT SINGLE-CIRCUIT TRANSPOSITION TOWER

exceeded, for if it should be, clearances become impaired and there is danger of arcing from the line to the tower.

A typical illustration of a doubtful location is one where one tower is placed in a depression with the adjacent towers on high ground. The horizontal wind load on the intermediate tower is unaffected by the profile, while the vertical load may be reduced almost

Discussion

MECHANICAL ELECTRICAL CONSTRUCTION OF MODERN POWER TRANSMISSION LINES—INSULATORS FOR HIGH-VOLTAGE LINES¹

(CARLSON AND BATTEY),

SPECIAL FEATURES IN THE DESIGN OF TRANSMISSION TOWER LINES AS IMPOSED BY ELECTRICAL CONDITIONS² (DREYER),

DEL MONTE, CAL., OCTOBER 3, 1923.

E. V. Pannell: Mr. Dreyer, on the fourth page of his paper, makes particular reference to the matter of excessive swinging of insulator strings where the vertical loading disappears. On the subject of dangerous swing of insulators where the horizontal load is unbalanced, the facts seem to show that the tie-down string is somewhat unsatisfactory, but Mr. Dreyer makes no mention of the possibility of using weights and I would like to know whether he has made any experiments in this respect. The use of a weight in place of a tie-down string has the advantages that a vertical component is provided at the same time the flexible characteristics of the line are not impaired and the arrangement would seem to be inherently superior to imposing dead-end stresses on a point which is not designed as a dead-end. In several installations in this country weights are being used instead of tie-downs and I also know of work in Japan where weights have superseded tie-downs with greater satisfaction. It is necessary, of course, that clearances shall not be impaired but if this condition is satisfied I believe weights will be found the most satisfactory device.

H. Michener: On the Big Creek lines, consideration was given to the use of weights instead of tie-downs; it was finally decided that it took too many tons of cast iron. The tie-down strings on the Big Creek lines have given no more trouble than any other strings on the line, so we do not feel that they are a great hazard.

R. J. C. Wood: It seems to me that we may go too far in trying to eliminate the dead-end strings. We would like to get away without any of them largely on account of the cost, but it is a fact that on the Big Creek lines we have had less trouble on the dead-end strings than on any of the others. I think the exact record is two cases of trouble on dead-end strings in the whole operation of the line.

M. Hillebrand: I would like to ask Mr. Wood to amplify that last statement.

The reason for the elimination of dead-end strings, to my mind, holds as much today, possibly not just as much, but the fundamental reasons are the same as they always have been. That is, that the mechanical load on the dead-end string is higher than elsewhere. This tends to cracking and exists to a greater extent in the dead-end insulator than on the suspension strings. It is in order to reduce the cracking of the insulators that it has been so often recommended to eliminate dead-end strings wherever possible.

Now, the troubles that Mr. Wood refers to, unless I am mistaken, are in the nature of flashovers through the air and around the insulator. On the other hand, I believe it is true that their records show that their insulator failures on dead-ends have been at much higher rates than those on the suspension string. Is that true, Mr. Wood?

R. J. C. Wood: Yes, it is higher.

Mr. Hillebrand: I would like to ask Mr. Dreyer just what is derived from the use of a lower string tension. That is, was it

due to a lighter tower, resulting from a lower design in order to maintain a minimum clearance?

C. B. Carlson: On the point of tension, it might be added that the span, as we have made it in our line, is considerably larger than those heretofore used. This might bring that point back again to a higher tension rather than lower tension. That is, with a greatly increased span maintaining all the time a factor of thirty feet from the ground as a constant, the calculations might revert back to an advantage towards a little higher tension insofar as that is concerned.

W. Dreyer: Answering Mr. Hillebrand's question as to how the lower tension affects the tower design, the towers become lighter and the footings become lighter, almost in direct relation to the movement of the loading. The product of the loads on the tower times their distance from the ground, approximately gives the law of variation in the weight of the towers. Thirty feet of the height of the towers is put in to take care of minimum ground clearance. Seven feet more is necessary to take care of the length of suspension insulators on 220-kv. lines, giving a total height of thirty-seven feet which is necessary without any consideration of conductor stress.

In order to show how the problem would work out on a line of 220-kv. potential using 500,000 cm. copper and insulators seven-ft. long, the following table comparing maximum stresses of 27,000 and 17,000 lbs. per sq. inch respectively.

Stress—Lbs. per Sq. Inch			Sag. at Min. Stress	Height to Low Wire
Max.	Min.	Broken Wire (Allowing for insulator)		
27,000	19,700	15,000	16 ft.	53 ft.
17,000	13,000	11,200	24 "	61 "

Using the above table as a basis, the following table shows the relation between heights to center of application of leads and overturning moments for both single and double-circuit towers.

Max. Stress	Single-Circuit Towers				Double-Circuit Towers			
	Height to Center of Load	Ratio of Height	Ratio of Load	Ratio of Moment	Height to Center of Load	Ratio of Height	Ratio of Load	Ratio of Moment
27,000#0"	53	1.00	1.00	1.00	68	1.00	1.00	1.00
17,000#0"	61	1.15	0.75	0.86	76	1.12	0.75	0.84

The ratio of moment, which is nearly in proportion to the ratio of weight of towers and size of footings, shows a saving of 14 per cent for the single-circuit and 16 per cent for the double-circuit towers. This analysis is only approximate, but it indicates the existence of a point of economy for the stress in the conductor.

Regarding the affect of torsional stresses the square tower is not materially affected in weight, the torsional stresses being taken care of almost entirely by the web members.

Regarding the use of weights to prevent excessive swinging of insulator, as suggested by Mr. Pannell, we have given consideration to such an expedient. The objection was the additional electrical clearances required, which would either make it necessary to use special towers with greater clearances for the particular cases involved, or else design all towers with excessive clearance, which would be uneconomical.

110-Kv. Transmission Line for Oak Grove Development of Portland Railway, Light and Power Company

BY H. R. WAKEMAN and W. H. LINES

Member, A. I. E. E.

Both of the Portland Railway & Light Co.

Review of the Subject.—This paper covers the design of the 110-kv. transmission line to transmit energy from the new Oak Grove development of the Portland Railway, Light and Power Company to the city of Portland, Oregon, a distance of 5.4 miles.

The company now has three hydroelectric developments aggregating 52,000 kw. supplied from the same general watershed from which energy is transmitted to Portland over five 60-kv. circuits, only one of which is on steel towers. The problem was to design a transmission line to most economically handle the three 30,000-kv-a. units as installed at the new development and to tie in with the existing transmission system. The following factors were considered in determining the design:

1. Transmission voltage
2. Conductor capacity
3. Maximum conductor tension
4. Assumed maximum mechanical loading conditions
5. Type of supporting structures

Consideration was also given to the physical characteristics of the country through which the line must be built. For 14.8 miles the line will be located in the United States Government Forest Reserve, which is very heavily timbered, and accordingly cost of clearing will be very high, averaging \$15,000 a mile, even after credit for merchantable timber is allowed. This fact, outside of other considerations, required a minimum number of circuits. To reduce clearing costs as much as possible, the line was located along the river gorge necessitating 55 angles, a few as great as 60 deg., and 28 river crossing spans, varying from 400 to 1800 feet.

After considering various types of supporting structures, three

types of double circuit, heavy rigid steel towers were decided upon as follows:

Type A towers, to be used on tangents up to 800-foot spans, also on curves up to 10 deg., the spans not exceeding 500 feet; suspension insulators to be used.

Type B towers, to be used on tangents up to 1700-foot spans, also on curves from 8 to 30 deg., the spans not exceeding 800 feet for the larger curves; suspension insulators to be used.

Type C towers, to be used at dead-ends and curves over 30 deg.

Towers are designed for 250,000 cir. mil. copper conductors, and maximum loading conditions of one-half inch of ice and eight pounds per square foot wind pressure at 0 deg. fahr. were assumed. Each type of tower was designed to withstand the maximum loading conditions plus 50 per cent without exceeding the elastic limit of the steel, and the towers were subjected to an actual field test. Special steel having an elastic limit of 45,000 pounds per square inch and a minimum elongation of 22 per cent was used in the towers.

In order to reduce the number of insulators and deadened positions, use was made of brackets pivoted to the cross arms so that they would be free to swing in the line but rigid across the line.

12-inch brackets are provided for the Type A towers on 8 deg. curves and 24-inch brackets on Type B towers with 30 deg. curves so as to maintain a three-foot clearance between the conductor and steel on that side of the tower where the conductors pull the insulator strings up and toward the cage. The use of these brackets reduced the total cost of the insulators and hardware fully 25 per cent.

Tables are included giving resultant simultaneous loading and weights and dimensions for each type of tower.

THIS paper is one of several dealing with the review of the problems encountered in the design and construction of the high-tension tower lines completed during the past two years. The Portland Railway, Light and Power Company has not constructed any lines of importance in this class during the period in question, but has recently completed the design and started field work on a transmission circuit of considerable capacity to serve its new Oak Grove development. This project is situated on the Clackamas River, a tributary of the Willamette, about 5.4 miles from the city of Portland. The ultimate capacity of 90,000 kv-a. will be provided by three units of 30,000 kv-a. each, the first of which is scheduled for completion in September, 1924, the others to follow as the system load requires.

At the present time the company has three hydroelectric developments, aggregating 52,000 kw. in capacity, fed from the same general watershed, two of which are located on the Clackamas River, 19 and 22 miles respectively below the Oak Grove development, and one on the Bull Run River, a tributary of the Columbia. Transmission from these plants is

supplied by five circuits at 60 kv. grounded neutral, only one of which is on steel towers. Four of these circuits converge at Lents Junction on the outskirts of the city proper.

Briefly the problem was to design the most economical transmission system to handle the successive units of the Oak Grove development and to tie in with the physical and electrical characteristics of the present lines. This involved the consideration and proper economic selection of the following major variables:

1. Transmission voltage.
2. Conductor capacity.
3. Maximum conductor tension.
4. Assumed maximum mechanical loading conditions.
5. Type of supporting structures.

Naturally all of these variables are intimately related and in addition are effected by the physical conditions obtaining along the line. To arrive at the proper economic solution due consideration was given all the physical conditions and all possible combinations of the five major variables mentioned above.

The first step was a reconnaissance and a preliminary location of the line in the field. Then a party was organized and a sufficient topography taken to enable

the selection of the best profile. The data thus obtained brought out the following physical facts affecting the design:

The total length from generating station to Lents Junction, where it is proposed to tie with existing 60-kv. circuits, is 45 miles. Of this distance 14.8 miles is in U. S. Government forest reserve and very heavily timbered. In order to secure a right-of-way from the Forest Service, the company was forced to agree to several somewhat stringent regulations as to the methods to be used in felling timber and clearing up, and these requirements, plus the price paid for stumpage, will result in an average cost of about \$15,000 per mile to clear and clean up a 400-foot strip through the reserve, even after proper credits are allowed for merchantable timber, which it is proposed to market. In order to avoid as much as possible all this excessive cost, the line was located along the river gorge, which, in turn, required many horizontal angles and river crossings. In addition, it became apparent that a minimum number of circuits should be adopted in order to avoid excessive clearing costs. In the upper 19 miles of the line, namely, from the generating station to Faraday, at which point existing transmission circuits start, there are 55 angles, a few of which are as great as 60 deg., 28 river crossings with spans varying from 400 to 1800 feet, and numerous grades, some over 75 per cent.

TRANSMISSION VOLTAGE AND CAPACITY

It was determined, after proper consideration of the above physical facts, that for the ultimate development of 90,000 kv-a. two circuits each of 250,000 circular mil hard-drawn, stranded copper, at 110 kv. grounded neutral, were respectively the economic number, size and voltage to employ.

MAXIMUM CONDUCTOR TENSION

This was a problem to which considerable study was given. The limitations imposed by the mechanical strength of available insulators and hardware were a considerable factor in the decision to use 4000 pounds maximum conductor tension, equivalent to a stress of 20,000 per square inch or one-third of the ultimate strength of the conductors in this line.

ASSUMED MAXIMUM LOADING CONDITIONS

After an investigation of the possible sleet, snow and wind conditions in the country traversed by this line, it was determined to use class B loading, namely, a maximum conductor tension equivalent to the load of the conductors plus one-half inch of ice and 8 pounds per square foot wind pressure on the ice-coated conductors at temperature of 0 deg. fahr.

TYPE OF SUPPORTING STRUCTURES

Before a decision was reached on this point, there were placed on the profile, to scale and by means of properly constructed sag templates, four types of

supporting structures designed for the assumed loading conditions and appropriate for the physical topography of the country. Thomas sag curves were used in computing the relations between stress and sag under various loading conditions. It was found that the maximum sag occurred on the line under summer loading conditions, at a temperature of 120 deg. fahr. The following are the four types of supporting structures which were considered:

1. Single wooden poles, average spans 300 feet, single-circuit capacity.
2. Double wooden poles (H frames), average spans 450 feet, single-circuit capacity.
3. Light steel towers (combination of flexible frames and anchor towers), average spans 500 feet, double-circuit capacity.
4. Heavy rigid towers, average spans 700 feet, double-circuit capacity.

Detailed estimates of material and labor were then prepared for each of the four types and these resulted in favor of the fourth, namely, heavy rigid towers, average spans 700 feet.

A brief consideration of the following points will perhaps explain this result:

The cost, coupled with the possibility of failure of modern high-voltage insulators and hardware, tended to force the adoption of longer spans and thus fewer insulators. In the case of wooden poles, the item of hole digging for poles and guy stubs, mostly in rock, was considerable. Guying costs to reinforce pole strength at the many horizontal and vertical angles in the line were excessive. River crossing and other spans of greater than the average length required the adoption of special and expensive structures to provide the required strength. The difficulty of placing material along the line was also a considerable factor in making the estimates high, particularly with the wooden pole structures with their attendant extra weight per mile of line.

From a study of the loading conditions imposed on the towers by the varying span lengths and the horizontal and vertical curves, it was decided to provide three types of towers to meet all these loading conditions, as follows:

Type A Towers. To be used on tangents up to 800-ft. spans, also on curves up to 10 deg. with spans not exceeding 500 feet; suspension insulators to be used.

Type B Towers. To be used on tangents up to 1700-foot spans, also on curves from 8 deg. to 30 deg. with spans not exceeding 800 feet for the larger curves; suspension insulators to be used.

Type C Towers. To be used at dead-ends and curves over 30 deg.

The towers were designed to withstand maximum loading conditions embraced in each of the above classes, plus 50 per cent as an assumed margin of safety, without exceeding the elastic limit of the steel. In Types A and B, where suspension insulators are

used, consideration was given the fact that with a broken conductor on one side of the tower the insulator string will swing into the line, increasing the sag, and thus reducing the conductor tension and tower loading. At all horizontal angles the towers will be set to bisect the line angle.

Following is a summary of the resultant simultaneous loading assumed for each type of structure and applied at points of insulator support:

Loading Conditions	Type A	Type B	Type C
Number of conductors assumed broken.....	3	6	6
Maximum horizontal curve.....	10 deg.	30 deg.	60 deg.
Maximum span length when combined with curve.....	500	800	800
Vertical load—dead weights of conductor.....	6 at 1,800#	6 at 1,200#	6 at 1,200#
Horizontal load in line component of conductor tension.....	3 at 4,000	6 at 3,500	6 at 5,200
Horizontal load across line component of conductor tension + wind on cond.....	6 at 1,400	6 at 2,200	6 at 3,700
Horizontal load across line wind on tower.....	1 at 1,600	1 at 1,600	1 at 1,600
	32,800#	43,000#	62,000#

The type A tower on tangents will accommodate spans to 800 feet.
The type B tower on tangents will accommodate spans to 2400 feet.

The design of the towers was also checked for maximum possible torsional load, namely, with three conductors broken on one side of the cage.

Special steel having a guaranteed elastic limit of 45,000 pounds per square inch and a minimum elongation of 22 per cent was used in the towers. Actual tests of samples taken from the tower stock showed yield points from 48,000 to 53,000 pounds per square inch.

As a positive check on the design, each type of tower was subjected to an actual field test, and all of them withstood the prescribed loads without permanent deflection of any member. We are reliably informed that these towers are the lightest ever built for equivalent loading conditions, which fact can be explained in part by accurate design and in part by the use of high elastic limit steel. The following tabulation of comparative dimensions and weights may be of interest:

In order to eliminate any possibilities of the conductors at different elevations swinging together when a lower conductor drops a heavy ice load before the one above, the middle conductors were offset two feet beyond the top and bottom ones.

Steel footings were decided upon on account of the difficulty and expense of handling and mixing concrete along the line. The footings are designed to resist maximum uplift 10 per cent greater than that occasioned by the assumed test loading conditions.

The towers are designed to permit hillside and square extensions at 5, 10, 15 and 20-foot intervals and any combinations of these. Some idea of the nature of the country can be had when notice is taken of the

	Type A	Type B	Type C
Cage.....	4 ft.-6 in.	4 ft.-6 in.	4 ft.-6 in.
Length of crossarm, cage to insulator support.....	7 ft.-0 in. & 9 ft.-0 in.	7 ft.-3 in. & 9 ft.-3 in.	7 ft.-3 in. & 9 ft.-3 in.
Horizontal separation of conductor at supports.....	18 ft.-6 in. & 22 ft.-6 in.	18 ft.-9 in. & 22 ft.-9 in.	18 ft.-9 in. & 22 ft.-9 in.
Vertical separation of conductor at supports.....	10 ft.	10 ft.	10 ft.
Height of lowest arm above ground.....	48 ft.	48 ft.	45 ft.
Overall height above ground....	72 ft.	72 ft.	69 ft.
Weight of tower exclusive of extension and footings.....	4325 #	5355 #	5635 #
Weight of footings (all steel)....	550 #	1820 #	2780 #
Depth of footings in ground....	7 ft.-6 in.	6 ft.-6 in.	7 ft.-6 in.
Area of footing at bottom.....	3 ft. x 3 ft.	4 ft.-8 in. x 4 ft.-8 in.	5 ft.-6 in. x 5 ft.-6 in.

fact that approximately 70 per cent of all the towers in this line are provided with an extension of some sort.

A maximum clearance, conductor to steel, of 3 ft. 0 in. was specified for all possible positions of the conductor.

An interesting detail in connection with this line was the decision to employ a string of insulators in suspension position on horizontal curves up to 30 deg. In order to maintain the specified clearance of 3 ft. conductor to crossarm, it became necessary to drop the point of insulator support 12 in. on Type A towers (8 deg. curve) and 24 in. on Type B towers (30 deg. curve) below the crossarm on that side of the cage where the conductor pulls the insulator string up and toward the cage. This was accomplished by the use of brackets attached and pivoted to the crossarms so that they would be free to swing in the line but rigid across the line. The use of this device saved fully 25 per cent of the total cost of insulators and hardware and further reduced the number of actual dead-end positions, always a possible source of insulator failure, to a minimum.

Insulators are attached to crossarms by means of forged steel hooks with an elastic limit of 6000 pounds. It was thought best to limit the strength of this connecting member so that if any load greater than the assumed came on the conductors, the connection would fail rather than the tower.

The two transmission circuits above described were designed to transmit the ultimate development of Oak Grove, 90,000 kv-a., at 110 kv., a distance of 45 miles to Lents Junction where it is planned to tie them through auto-transformers on to a 60-kv. switching bus. The existing 60-kv. circuits from other hydroelectric plants will tie on to the same bus. Two synchronous condensers of 15,000 kv-a., each supplied by tertiary windings from the auto-transformers, are planned at this point for power factor correction and voltage regulation of all incoming lines.

Transmission Line Construction in Crossing Mountain Ranges

BY M. T. CRAWFORD

Fellow, A. I. E. E.
Superintendent Distribution, Puget Sound Power and Light Company

Review of the Subject.—In crossing mountain ranges with a recent transmission line in the Pacific Northwest severe climatic conditions were encountered. Snow lies from ten to thirty feet deep, wind attains high velocities and the temperature ranges between wide limits. A strongly built steel tower line successfully met these conditions. At one point however, a somewhat unusual formation of frozen fog was found to successively build up and drop off of wires and towers producing stresses greater than it would have been reasonable to design a line to withstand, and as a result failures occurred.

Conditions in the extreme loading area are outlined and the assumption made that the most severe stresses were largely of an intermittent nature. The subsequent modifications in the con-

struction are discussed, which were designed to more efficiently stress the materials under intermittent strains, providing an increased flexibility by the substitution of suspension for strain forms of wire support.

Where line construction fails from excessive dead loading a stronger design throughout is no doubt the proper remedy. If however this loading is only excessive in one span at a time it may be relieved by longitudinal flexibility. While not submitting the principle of the elimination of strain forms as universally applicable in transmission line construction, it is hoped that this paper will elicit a discussion from authorities on the subject that will define its range of application.

* * * * *

AMONG recent extensions of the Puget Sound Power and Light Company is a 120-mile 110-kv. transmission line from the White River generating station to Wenatchee. This line was built up the Green River valley, over the Cascade Range near Stampede Pass at about 4000 feet elevation, down through the Yakima River valley and over the Wenatchee Range at an elevation of nearly 6000 feet, and down into the Columbia River valley to the City of Wenatchee. The engineering features of

with conductors pulled to a tension which would stress the wire to its elastic limit of 4250 lb. at 0 deg. fahr., 8 lb. wind pressure and one-half inch of ice coating.

FIG. 1—LIGHT FROST FORMATION EARLY IN THE WINTER ON TOWER No. S25

this line were worked out with admirable care and skill, and the construction embodies exceptional mechanical sturdiness throughout.

On account of the heavy snows and inaccessibility of sections of the line over the two mountain ranges, additional mechanical strength was provided where the elevation exceeded 3000 feet. Type S. A. 55-foot steel towers were used for line supports, 4/0 B. & S. hard-drawn seven-strand copper cables for conductors, with O. B. No. 25620 cap and pin-type insulators, six-unit strings in suspension and seven-unit strings in strain. Spans were normally from 400 to 700 feet,

FIG. 2—HEAVY FROZEN FOG FORMATION LATER IN WINTER, TOWER No. S23

Presented at the Pacific Coast Convention of the A. I. E. E., Del Monte, Cal., October 2-5, 1923.

Although the Wenatchee Range crossing was at a higher elevation, the climatic and topographic conditions over the Cascade Range were much more severe from the standpoint of line operation. The summit of this range marks a radical change in climatic conditions, from the moderate temperatures and damp winters of the Puget Sound area to the wider range in temperature and dry climate of Eastern Washington. In crossing the Cascade Range at Stampede Pass, it was necessary to locate the line at a bare exposed

at from 5 to 10 lb. per cubic foot. Observations were taken from time to time during the first winter and advice sought from officials of the Weather Bureau. The indications were that the conditions bringing about this formation are apt to recur a number of times per year, but usually within a limited area, as the contact with cold air soon turns the fog clouds into snow. This formation has been found to occur

FIG. 3—HEAVY FROZEN FOG FORMATION LATER IN WINTER, Tower No. S23

point, where the summit was clearly defined. It was found that at times during the fall and winter months a heavy frost formation builds up on exposed surfaces near this summit, due to the wind carrying moisture-laden clouds of fog up from lower elevations, which freezes as it strikes the cold surfaces, building out rapidly toward the wind. Formations up to a maximum of about two feet in thickness in one direction were observed. As soon as the weight of the frosty mass becomes great enough it falls off and the building-up process starts again. The weight was estimated

FIG. 4—HEAVY FROZEN FOG FORMATION LATER IN WINTER, Tower No. S26

along only about one mile of line near the summit, from observations made so far. The photographs were obtained after the atmosphere cleared and the formation had dropped off of the wires.

One break occurred in the line during the first winter, which is considered too many for trunk line operation by an organization that has high standards of service. A careful study was therefore made of all the factors

FIG. 5—CLOSE-UP OF FORMATION ON Tower No. S26

involved in order to plan reinforcement work. As shown in the photographs and profile, the south wire was pulled in two in the second span east of the summit, but no insulator strings failed on this wire, although the wire slipped through the clamp at the next dead end east of the break. The other two wires were not broken, but three insulator strings pulled in two and one clamp slipped at the dead end points adjoining. It should be especially noted that there were several suspension towers in between these failures, but no

evidences of insulator damage or wire slipping were found at suspension points. Two of the insulator failures were of a character typical of the failure of cap and pin-type insulators under extreme tension, the porcelain parting well up under the cap with a fracture at right angles to the tensile stress. The third failure was in the lip of the cap casting. The wire failure was typical of a tensile break, six of the strands being drawn out to a reduced diameter before parting. The seventh strand had a brazed lap joint at this point which was put in at the time of manufacture and apparently parted somewhat more easily than the other strands. The effect of this was probably

would not have equalled this ultimate strength with the largest formation that evidence could be found of adhering to the wires. This formation builds out almost horizontally toward the wind from the con-

FIG. 6—LINE DAMAGE, TOWER No. S26, LOOKING NORTHEAST SHOWING BROKEN WIRE

to reduce the strength of the cable at this point a few per cent, which accounts for the wire parting and not the insulators on this conductor.

The towers were not damaged by the frost formation. Later in the winter heavy snow falls packed down to a depth of eight to ten feet, very hard on top. The spring melting underneath and the settling of this packed crust damaged the tower members badly in places near the ground and sheared off bolts.

The ultimate strength of this conductor is about 8500 lb. and of some of the insulator disks probably slightly less. Approximate computations indicate that a quiescent dead load on the wires in these spans

FIG. 7—LINE DAMAGE, SUMMIT ANGLE, TOWER No. S25, LOOKING NORTH

FIG. 8—LINE DAMAGE, TOWER No. S22, LOOKING NORTHWEST

ductor, forming in a narrow elliptical cross-section up to about 3 by 8 inches before dropping off, weighing possibly one and one-half to two pounds per lineal foot. It is believed that the building up and falling

off of the heavy frost formation on the conductors resulted in intermittent strains and jerks of a very severe character near dead end points which exceeded the strength of the wire, and that where the insulator strings failed or clamps slipped at dead end points, this tension was relieved thereby, but where the insulators held rigidly the conductor was broken. It should be noted that the damage along the two wires that stayed up through the winter was such as to virtually convert the construction to a suspension form through the loaded area.

In the heavily timbered Puget Sound region it has been found expedient to build some less important lines with only a narrow swath cut through the timber, the tall firs towering above the wires on each side. Branches and sometimes entire trees will often be blown across the line, producing a suddenly applied extreme loading. Many years of experience with this sort of trouble has shown that the most flexible types

FIG. 9—LINE DAMAGE, TOWER No. S21, LOOKING NORTHWEST

of line construction are the least damaged. For example, one 110-kv. line of this class is built on a single wood pole line with light crossarms and suspension construction with few dead ends. Trees and branches will often fall on the wires without breaking them, although they may be carried to the ground. The tension is relieved by pulling slack out of spans some distance on each side, with possibly a few broken crossarms. On lines where wires are rigidly held the damage is much more severe.

Conclusions reached involved a redesign of certain features of the construction through the exceptional loading area, to provide:

1. A reduction in working tension on insulator strings which will safeguard against failure, as well as improve the electrical reliability.

2. A flexibility in wire supporting mechanism to allow some longitudinal movement of wires at all supports, which will permit the easing off of temporary over stresses from one span into adjoining spans.

3. Additional strength in tower members near the base.

It is believed that the substitution of the suspension form of support for all dead ends has taken care of the first two requirements. The insulator string under suspension conditions carries only the resultant of the

respective wire stresses in each direction, and the dead end loading is largely shifted from porcelain to copper, reducing insulator tensions without increasing the number of insulators on the line. The suspension unit installed in places of former strain construction

FIG. 11

Straight Strain Tower No. S22, with one wire changed to suspension form and two yet to be changed.

was made up of two strings of insulators in parallel with strain yokes at each end, which reduced the tension duty in the porcelain by half. This yoked double string unit was installed to hang approximately in vertical suspension, and the wire so pulled as to

give normally equal tensions on each side. At such times as abnormal loads come on one side these suspension units will swing out into the position of strain units. The necessary spacing out was provided at tower fastening and wire clamp to allow this with proper clearances.

Computations indicate that a slight increase in the length of arc resulting from this swinging out of suspension units makes a very material increase in sag and corresponding reduction in tension. Under extremely unbalanced conditions the conductor might

be prevented by the installation of additional pieces of heavier angle stock alongside existing members, with the corner of the angle facing upwards to form a roof effect and provide a cutting edge to break the snow.

If still more severe winters are encountered in the future which this construction will not withstand, a stronger conductor with more insulator strings yoked in parallel and possibly additional towers may be needed, but the principles of mechanical design are submitted as obtaining the best balance in the stressing of materials under such extreme loading conditions.

FIG. 12—TRANSMISSION LINE CROSSING CASCADE RANGE, NEAR STAMPEDE PASS
Showing details of damage by heavy frost formation.

even sag down until it touched the snow in the center of the span. This movement is restricted, however, by the amount of sag that can be pulled out of the several adjoining spans in each direction, and an equilibrium is usually reached after a slight movement which equalizes tensions. This action is very common on lines of suspension construction with wet snow alternately sticking and falling off of wire spans, resulting in short circuits where vertical wire arrangements are used.

In replacing strain forms with suspension forms on long steep slopes where it is desired to have wire stresses unequal on each side of towers, it would be necessary to install additional tie down strings on the up-hill side, offsetting the point of clamping the suspension and tie down strings to wire several feet. This provides for necessary clearances, and gives some longitudinal flexibility. Had there been any sharp line angles in this section, the flexible construction could have been provided by installing additional towers so as to make a round turn with short spans, the suspension strings swinging out nearly horizontal. This form of corner construction has been successfully used on suspension insulator lines along county roads and railroads where the right of way turns on a wide radius. It involves the use of bracket supports side insulator strings to obtain clearances.

Discussion

110-Kv. TRANSMISSION LINE FOR OAK GROVE DEVELOPMENT OF PORTLAND RAILWAY, LIGHT AND POWER COMPANY¹

(WAKEMAN AND LINES),

TRANSMISSION LINE CONSTRUCTION IN CROSSING MOUNTAIN RANGES² (CRAWFORD),

DEL MONTE, CAL., OCTOBER 3, 1923.

R. J. C. Wood: We have encountered some little trouble in crossing mountain ranges in snow countries, supposedly due to the loss of the snow or sleet load from a span and the conductor coming in contact with the one above it. On the double-circuit steel tower line, in question, the conductors are offset a foot and a half from the vertical plane of the one above it. We have had considerable discussion as to just what happens to cause these conductors to come together. One theory being that the sleet falls off the one span and still remaining on the adjacent span, the lighter span is pulled up into the one above it.

Another theory is that the sleet falls off a portion only of a long span and that gives it a deformed shape sufficient to permit the two conductors to come together.

The third theory is that when the sleet falls off it sets up waves of sufficient amplitude to produce contact.

It will be interesting to know if anybody else has made observations on this subject and can give us information on just what happens when the sleet falls off.

J. P. Jollyman: We do not cross any high ranges at high altitudes or any locations subject to extremely severe climatic conditions.

We have had some sleet trouble. It has been generally thought, though not actually observed, that the sag in the conductors is greatly interfered with by the inequality in the loading of sleet.

It is now believed that the conductors load up uniformly and when the sleet starts to melt the trouble begins.

We had one interesting report where sleet accumulation on spans was found to slide to the lower part of the span and pile up in very great weight at the bottom of the span. We had one or two cases of trouble which indicated that such an event had happened. The only precaution that has been taken in country known to be subject to sleet is to employ the horizontal configuration, or to employ the displaced conductor arrangements of the vertical circuit. It has been our experience thus far in points not subject to very heavy loading, that a 20-foot vertical displacement seems to be free from trouble, whereas, a 10-foot is not. In a configuration using three conductors normally spaced ten feet apart vertically, the center conductor is displaced either outward or inward two or three feet and thus far it has been satisfactory.

R. J. C. Wood: Referring to the 20-foot vertical spacing, what length of span is that?

J. P. Jollyman: We would not ordinarily regard the horizontal displacement as effective in spans of, over 500 or 600 feet. Where we have longer spans, and where we have any idea that sleet conditions will occur, we would feel it necessary to change from a vertical to a horizontal configuration, to be entirely safe from the difficulties attending on the unloading of sleet.

W. S. Jennens: Sleet does not occur on our lines on the plateau or high points in the Rocky Mountain district, in which our system is located, but mostly in the low hills adjacent to the Bear River and at those points where the cold air from the other side of the hills strikes the moisture-laden air. The condition known as sleet by most of us, is not in the form of solid ice, but chiefly in a compact form of frost. Sometimes, of course, we have damp or extremely wet snow which, in falling from the conductors, gives us the same condition as you gentlemen know as "sleet-jump." Fortunately the condition prevails mostly in short sections of the line and if the condition can be discovered in time, lines mostly concerned are taken out of service long enough to permit the maintenance crews to dislodge the wet snow by jarring the conductors. From the observation of these crews, we have concluded that there is no definite way in which the conductors act when the sleet jumps before the snow actually falls. We will find adjacent spans having entirely different appearances, one being loaded with snow, the conductors will sag down and the other span without snow, the conductors will be stretched tight and consequently rise. If, therefore, no equal loading of the conductors in the same span prevails, it will readily be seen that the conductors will come in contact with one another without the sleet having jumped. On the other hand, when the sleet does not let go through any unbalance of adjacent spans, conductors may rise in accordance with their previous loaded condition, and come in contact with each other in the third or even in the fourth span, particularly if the latter be below on a hillside where the tendency of the conductor is to run down towards the bottom of the slope. In some cases there will be a wave motion of the conductors, as pointed out by Mr. Wood, due to snow falling in one span and its jarring effect communicated to the conductors of other spans. The result of change of tension in the various contiguous spans causes the wave of the conductor to run along the line and if two or more conductors do not act similarly, they will come in contact with each other. Where they are out of step, so far as the wave motion is concerned, it is evident that on 130-kv. line that contact made thus will quickly burn the conductor through. We find that the conductors burn chiefly in the center of the span.

Each year's condition has become worse and worse, and during the past summer we have off-set the center conductor of each circuit arranged in a vertical configuration to a distance of approximately three feet, only however in the locations where previous observations have shown the sleet to have formed to any

considerable degree. We expect in the future to complete this off-setting in order to eliminate the chances of failure in any locality throughout the length of the line. On account of the design of our steel tower being such that it greatly weakens the same if we lengthen the middle crossarm or reduces the clearance to ground at the tower should we shorten the arm, we have followed the scheme in use on the Pacific Gas & Electric Company's lines, using an additional string of insulators on the middle arm to pull the conductor towards the tower.

We are not certain whether our three-foot off-set is sufficient and would like to ask Mr. Jollyman, if, in his opinion, it is enough for operation at 130-kv.?

R. H. Halpenny: On one tower line of The Southern Sierras Power Company, some trouble resulting from sleet on conductors has been experienced, particularly at a point where the line crosses a mountain range at an elevation of approximately 4000 feet. No trouble of this nature has been noticed, however, which could be traced to the swinging together of conductors when loaded with sleet, this being due possibly to the arrangement of conductors, which offsets the middle conductor of each circuit five feet from the vertical plane in which the top and bottom conductors lie, with a resultant normal vertical separation of twenty feet between top and bottom conductors. The longest span in this section of line is approximately 1400 feet.

The most severe kind of trouble in this locality has been tower failure. Line conductors have failed due to sleet loading in a few instances but an excessive dead load of this nature has ordinarily resulted in the deformation of the cross arms or some other tower member.

This trouble has been overcome to a great extent by additional bracing of tower members showing a tendency to fail under such loading, also in some cases by the addition of towers at points liable to be most heavily loaded.

John B. Fiskens: This discussion takes me back to the Vancouver Convention in 1913, at which convention the same subject was discussed. The question has been asked, and the desire has been expressed for actual testimony, as to what occurs. I can't of my own knowledge give any such testimony, and, as a general rule, I don't always believe all that the average farmer says, but we have one farmer in our region who I believe told us the truth. He gave us, some years ago, a very full description of what he actually saw. The conditions were vertical arrangement of conductors on a two-circuit tower line, the wires in vertical planes having horizontal separations of about six inches. He said that while he was passing the line one day, and this was after we had all been driven nearly crazy with the shutdowns, he saw the frost drop off one wire and that wire fly up and strike the one above it. This is not sleet loading but frost that forms and drops off when the day gets warmer. After that we separated the vertical planes of the wires horizontally by moving the top conductor in towards the tower, and lengthening the middle crossarm and moving the conductor from the tower. This gave horizontal separations between vertical planes through the conductors of top to center, 5 feet, 10 inches, center to bottom 3 feet, 5 inches and top to bottom, 2 feet, 5 inches. Since then we have had no trouble at all and I am satisfied that all of our troubles were due to the same thing, the unloading of the conductor in one span and the excessive weight of the adjoining spans causing it to hit the wires above it.

Harold Michener: Referring again to the line of which Mr. Wood spoke—I was over it on Saturday and Sunday, last, trying to determine what we could do to it. We selected a span about 890-ft. long that was held by suspension insulators at each end, calculated the load for the span with half an inch of ice, and concentrated one-fourth this load at the one-eighth and one-fourth at the three-eighths points of the span. This pulled the center wire down about one foot below the bottom wire and showed that if the bottom wire should be unloaded and the center

wire loaded, the center wire would go down into the bottom wire for more than three-eighths of the length of the span. That was only an indication of what might happen in a territory where we had not assumed any sleet load in designing the line, and we are of the opinion that in the territory where the design assumptions include a sleet load, and, for that reason, a lower stringing tension, and where the spans are longer, the top wire would come down to the bottom wire if the top wire were loaded in one-half the span and the bottom wire unloaded. The vertical distance between top and center and bottom wires at the towers, is six feet, three inches.

H. H. Schoolfield: We have observed a very peculiar phenomena on one of our transmission lines which might be of interest to the engineers present. I have never yet been able to find a satisfactory explanation for it. Perhaps some of you gentlemen can enlighten me.

We have a 66,000-volt line, with suspension insulators, and conductors of three-strand copper clad steel. In connection with this we have a seven-strand steel ground wire. There are several places in the line where we get frost conditions similar to those described by Mr. Fiskén. I call it frozen fog. It builds up on the copper clad conductors to a considerable extent and we have experienced the same trouble of wires swinging together; the lower wire flying up and hitting the upper wire. The peculiar fact is that the frost does not accumulate on the steel ground wire. I don't know why it is and I can't find a satisfactory explanation for it, but it is a fact that the frost will build up to considerable extent on the copper clad conductors, but does not build up at all on the steel ground wire.

L. J. Pospisil: In addition to what Mr. Fiskén has said in regard to his experience, I want to say that in the year 1910, I believe it was, there was an effort made to reproduce the conditions, of what occurred from actual experience, by constructing two spans of a sample line and reproducing the loadings

along the conductors by means of weights, and then releasing the weights and observing what took place. At that time Mr. Geiser wrote a paper on those experiments, which I think was given at the Vancouver Convention in 1913.

H. T. Plumb: The Utah and Idaho power companies have had some trouble with frost conditions; but along most of the lines it has caused no trouble. The frost referred to is a wonderful formation; it happens only in a very still valley where no wind is blowing; it builds up in the night, and disappears as soon as the sun begins to shine when it drops off. It adds considerable weight to the conductors, and their diameter may become four or even six inches. An explanation of why it might form on copper conductors more than on iron conductors is that the iron is probably smaller in diameter and the amount of growth seems to be dependent on the diameter of the thing to which the frost fastens itself.

Not long ago one of the smaller power companies in Utah had difficulty with a very wet sleet bridging over insulators and causing them to ground, or flash across. It was a sleet so wet that it could hardly be called ice and yet it would stick and build up on the lee side of an insulator.

M. T. Crawford: Experience with wires arranged in a vertical plane has been universally unsatisfactory in our territory through snow country and it should be noted that, in the line described in this paper, a horizontal arrangement was used. Longitudinal movements of the wire accompanying the vertical movements sufficient to cause short circuit with a ten-foot vertical displacement would necessarily produce severe stresses at dead end points, and it was to avoid damage from these stresses that the special form of suspension construction was employed. Since writing this paper the line has gone practically through another winter without a repetition of the failure described although ice and frost formations have been equally severe.

Insulation Design of Anchors and Tower Supports for 110,000-Volt 4427-Foot Span Over Carquinez Straits

BY L. J. CORBETT

Member, A. I. E. E.
Pacific Gas & Electric Company, San Francisco, Cal.

Review of the Subject.—The first crossing of the Carquinez Straits by a high-tension transmission line was one of the stepping stones in the progress of the electrical industry. The pioneers built well, and the march of events, with its demands for greater and greater blocks of power, found the crossing structure adequate for the new requirements.

Constructed in 1901 for one 60,000-volt circuit with a spare cable, two additional cables were added in 1914, making two 60,000-volt circuits. In 1922, coincident with the replacement of 60,000-volt pole lines by a 110,000-volt tower line, the crossing was modified to

allow 110,000 volts on the two circuits, thus again practically doubling the transmission capacity.

The original design made use of insulating materials in compression. A clear record for over 20 years led the company to adhere to the compression type in the reinsurance for the higher voltage, thus making the crossing unique among long high-voltage spans. The methods by which some of the problems were solved, the hinged anchor structure, the sturdy insulated support for the towers, the movable top for the middle tower support to allow for relative motion and the supplementary cable system to obviate crystallization at the supports, are described in the paper.

WHEN the Bay Counties Power Company installed the 4427-foot span across the Carquinez Strait on San Francisco Bay to operate at 60,000 volts it was considered a noteworthy achievement. So carefully and so thoroughly had all the features been investigated that it established and maintained a record for many years under operation by that company and its successor, the Pacific Gas and Electric Company.

As at first constructed in 1901 there were four cables—one for each phase of the three-phase circuit, and a spare cable. The steel towers were fitted with wooden crossarms supporting saddles of wood and

were left in but on the two cables added, a steel structure pulling against six pin-type, 60-kv. insulators in compression was installed at each cable end. These have given no trouble whatever since their installation in 1914.

To care for the growth of power load in the San Francisco Bay district and to allow entry for the power from the company's developments on the Pit River, a substation was built about 50 miles northeast of San Francisco where the power is stepped down from 220,000 to 110,000 volts and brought down to the Bay district over new 110,000-volt tower lines replacing the old 60,000-volt pole lines which were no

FIG. 1

iron upon six pin-type insulators. The anchor insulators, two in series, each consisted of a steel link against micanite in compression in a container filled with oil. These insulators have given complete satisfaction at 60,000 volts for the past 22 years.¹

In 1914 two additional cables were added, making two circuits at approximately 20-foot separation with cables at 10-foot spacing in each circuit. The crossarms were changed from wood to steel and wood was also eliminated from the saddles. The old anchor insulators

longer adequate. The crossing, mechanically suitable, had to be reinsulated for the new voltage.

So successful has the compression type of insulation proved on this crossing that it has been adhered to in the work carried out during 1922, notwithstanding the fact that the tension type of insulation has been developed to a fair degree of reliability and has been adopted on a number of important spans.

Fig. 1 is a profile of the complete cable system. The cables merely rest upon the supports at the three towers, the direct tension being held by concrete anchor blocks at the ends. The South Tower, 140 feet from the extreme anchor block, is 64 feet high to the top crossarm. The Main Tower on the north

1. A description of the original installation will be found in the *Engineering News* for October 3, 1901.

Presented at the Pacific Coast Convention of the A. I. E. E., Del Monte, Cal., October 2-5, 1923.

side of the strait is 4427 feet from South Tower and is 225 feet high. The North or Leaning Tower is 1385 feet farther on and is 84 feet high. The north anchors extend 325 feet beyond this tower. Due to the differences in elevation of the bases the elevations of the supports of the top cable are 478, 394 and 201 feet on the respective towers. The leaning tower is so called because its upper portion is inclined at an angle of 13 degrees from the vertical in order to resist to best advantage the resultant stress at its location part way down the catenary.

Analysis of the crossing showed that the unequal expansion of the 4427-foot span and the 1385-foot span would cause unbalanced horizontal stresses in the direction of the cable unless provision was made to allow the small amount of relative motion necessary to keep the horizontal stresses on both sides of the tower equal.

FIG 2A—VIEW OF CABLE END OF ANCHOR STRUCTURE

ANCHORS

For the anchors was adopted in part the method used on the cables which were added in 1914. The end of the cable was passed around a 24-inch sheave and securely clamped. From the sheave axle the pull is transmitted through a system of springs to a round bar which forms an axle at the end of the stem of a deep Y-shaped steel frame. The arms of the Y are braced across, and at the extremity of each arm is a round bar which acts as an axle for one end of a set of three pillar insulators on each side. The insulators are inclined outward from the arms of the Y and at their extremities additional axles transmit the strain to two columns which form part of a steel cage which surrounds the insulator system and converges to a point at which it is attached by a hinge to the concrete

anchor block. The weight of the Y-shaped frame is supported by two additional pillar insulators with universal joints at top and bottom. Each pillar insulator has a simplified jack at its base by which the strain can be approximately equalized in each set. These features are shown in Figs. 2A and 2B. The anchors are housed in steel and corrugated iron structures affording ample clearances.

FIG 2B—VIEW OF GROUND END OF ANCHOR STRUCTURE

The aim of the design is to relieve the insulators entirely of bending moment, leaving them to resist compression only. While stiffness is relied upon in the planes of the two sets of insulators at the sides of the Y, with care in assembly it is believed that the side strain in these planes can be almost entirely taken up by the two insulators holding up the Y frame. The structure, including the Y frame and six insulators,

FIG 3—ANALYSIS OF FIVE-HINGED ANCHOR STRUCTURE

rocks into equilibrium on the five hinge bars so that the load is firmly placed on the two sets of insulators.

This five-hinged system was decided upon after analysis and trial of a number of possible arrangements. A rigid rectangular structure, while satisfactory for 60,000-volt insulation with only one insulator in depth, would not serve for 110,000-volt insulation with pillar insulators three times as long, as the side strains would introduce bending moments which it was thought best to avoid, especially since with such a structure, any

yielding to the strain would increase the moment and probably result in complete collapse.

An analysis of the hinged system is shown in Fig. 3. Hinges *A* and *D* are fixed in position, while hinges

the pull of the cable tends to keep it in the center, the low point of the curve. It will be a stable structure even though containing five hinges, and the load will be divided equally between the insulator systems *B A* and *C D*.

TOWER SUPPORTS

At each support on the towers a cast steel saddle is mounted on six pillar insulators consisting of three units each, with a jack at the bottom of each pillar to permit equalization of load.

In order to resist side strains caused by wind on the cable and unequal strains in the direction of the line without introducing objectionable bending moments in the insulators, they are mounted in two inclined planes at $22\frac{1}{2}$ deg. from the vertical, and the two outer insulators on each side are inclined at the same angle relative to the center insulator in that plane. (See Fig. 4). The insulators are mounted on cast steel brackets on the 15-inch I beams which form the crossarms of the towers and on two H beams which span between them.

At South Tower and the Leaning Tower, both adjacent to the anchorages, the saddles are stationary and any unequal stresses in the direction of the line will be transmitted to the towers by the rather sturdy insulator structure. These towers are so close to the anchorages, it is believed that such stresses will be very small.

At the high Main Tower, however, with spans of

FIG 4—VIEW OF TOWER SUPPORT ON TOWER ADJACENT TO ANCHOR

The saddle is electrically connected to the cable to obviate possible burning at the support.

B, *C* and *E*₃ are free to shift. The cable is attached at *E*₃.

The location of *E* along the stem of the *Y* is extremely important. If the center hinge were set at some point high up on the stem such as *E*₁ where the axis would

SECTION-B-B

SECTION-A-A

FIG 5—SADDLE WITH MOVABLE TOP
Used on main tower between 4427-ft. and 1385-ft. spans.

trace a curve convex upward, any displacement would cause *E* to run down the curve and the structure would “jackknife” or turn inside out with great rapidity. This was very neatly illustrated by means of a model of a single element made of cardboard in which the pull of the cable was simulated by an elastic string.

Part way down the stem was a point *E*₂ which traced a straight line. Attachment to this point would render the cable indifferent as to its position, judging by the model, and such a structure would of course be unsafe to use where clearances must be maintained on both sides of the cable.

When attached at the position *E*₃ well down the stem of the *Y* the curve traced is concave upward, therefore

4427 feet on one side and 1385 feet on the other, unbalanced stresses do result with changes in temperature. For this tower, the saddle is made with a movable top which glides back and forth on rollers, (See Fig. 5). A part of this motion is free, but the last inch in each direction is against buffer springs to transmit any such unbalanced strain to the tower gradually. The rollers are immersed in a thin grease to prevent rust as well as for lubrication. It is found that this motion is freely exercised by the saddle top with daily temperature changes. The limit was approached during construction when a man was sent out in a suspended car to paint the cable, as is the company's practise to do at intervals.

SUPPLEMENTARY CABLES OVER TOWER SUPPORTS

The cables on the long spans are subject to serious vibration which in time would cause crystallization of the steel at the tower supports unless precautionary measures are taken. This vibration changes with the velocity of the wind and is of two types,—one is evidenced by a continuous hum, the other is in the nature of an impulse which travels back and forth across the span at intervals of a few seconds. To afford cushioning for these vibrations at the tower

being varied on the different spans to provide suitable cushioning for the vibration. The distances to which the cable ends extend vary from 21 to 55 feet from the centers of the towers, one cable however being terminated at a lesser distance in each case. The arrangement may be better understood by reference to Fig. 6. The cables may be seen in the view of South Tower, Fig. 7.

The equipment was designed by the writer with the assistance of Messrs. A. T. Church and G. S. Tune

FIG 6—SUPPLEMENTARY CABLES OVER TOWER SUPPORTS

supports and to add to the strength at these important locations, supplementary cables are used over the saddles. By thus adding to the weight of the main cable before it reaches a support, the vibration is absorbed gradually and its concentration at one point is avoided. Two supplementary cables of the same size and quality as the main cable are used at each tower support and arranged with turnbuckles so that all or part of the tension can be taken off the main cable.

As the wind alternates from sea breeze to land breeze, the main cable is swung first east and then west on the spans on both sides of the main tower simultaneously. For mechanical reasons it is simpler to have the three cables in a horizontal plane over the support, but it is necessary to equalize the strains and prevent the entire pull from coming on the outside cables alternately.

This is done by changing from a horizontal to a vertical plane a short distance out from the saddles, by means of a single-tree arrangement which equalizes the load on the two outer cables across the saddle and permits the main cable in the center to go free.

The supplementary cables across the saddles are short sections with sockets on both ends. The turnbuckles are joined to these portions for tightening as much as desired to equalize the load and relieve the main cable of a part or all of the strain. These short sections and turnbuckles go between the equalizing plates at their outer holes at each end, the main cable passing through between the plates. The center holes of the plates engage pins in open sockets on the ends of cables which parallel the main cable in a vertical plane. These cables are also of the same character as the main cable and are attached to it and to each other by five clamps which hold all three cables at suitable spacing. The ends of the supplementary cables beyond the clamps are attached to the main cable by serving or Crosby clips, the lengths

of the drafting room staff and under the supervision of Mr. J. P. Jollyman, chief of the division of hydro-electric and transmission engineering for the company.

Discussion

L. M. Klauber: I wish to point out one fact, namely, that a line of such importance, crossing a water way open to traffic where great clearances are necessary, would naturally involve special structures and relatively high costs. One not familiar with long spans might deem it essential that whenever such spans are constructed, regardless of the character of the line, equally expensive structures are essential. I would like to point out that for spans of this magnitude in less important lines, a much less expensive construction may be used with entirely satisfactory results.

For instance, it was recently necessary for our company to construct a line serving a load of only 50 kw. We have in that line one span which in length approaches this one within one

hundred feet; it is approximately 4300 feet long and yet the construction is inexpensive, utilizing wood poles for towers. Of course, it is obvious that this line does not cross a waterway through which ship traffic must be accommodated and thus great clearances are unnecessary. On the contrary it crosses a rather wide canyon and had it not been for a spur of a hill that came up in the center, the span would have been 7600 feet instead of 4300 feet long. As it was we had to locate a tower in the middle on the spur between the 4300 foot span and a 3300 foot span. The line including these spans is no more expensive than an ordinary pole line following the road would have been.

H. H. Schoolfield: We have some long spans but nothing like Mr. Klauber mentioned. We have one about 2800 feet long on wood pole construction and it is no more expensive than following down the canyon.

J. P. Jollyman: The detail of the design of there-insulation of the Carquinez crossing is not offered as a sample of how long span construction should ordinarily be made. As has been pointed out, this crossing is one over a navigable stream. The crossing was designed over twenty years ago and represents a very remarkable achievement for that period.

It is rather seldom that we find spans of that length with conductors of that character supported on rigid insulators; most of our new work is with suspension or strain insulators where the rigid points of support are at the tower and not at the conductor. In the Carquinez span, the long time success of the compression theory of insulation led us to conclude it would be a wise thing to continue and for that reason the insulators for the higher voltage were determined to be of the rigid type. A rigid form of support introduces the very pressing problem arising from the vibration of the conductor and our endeavor to terminate that vibration at a fixed point. Experience has shown the necessity of absorbing the vibration before it strikes the rigidly supported point, or in a short time, crystallization of the conductor will occur. A rather striking experience was had in this crossing. A few years ago the crossing was worked over and was changed from four wires to six wires in order to give two

complete circuits. At that time it was known that some reinforcements of the original cables over the rigid supports was necessary and an attachment was put on designed to take most of the strain off the main cable. Within a few weeks crystallization occurred and a strand broke at the attachment. The attachment was several feet out from the original point of the support, but it was a little too heavy; so in redesigning the work we have taken particular precautions to add weight gradually as the point of rigid support is approached.

First we add one cable for reinforcement and a few feet further on we add a second. These cables are then attached to the main cable by means of relatively light clamps sufficient in number to take the entire strain and amply spaced, and finally the main cable with its reinforcing cables changed from the vertical to the horizontal plane, is brought to the point of rigid support. The construction has been up over a year. We have had no mechanical trouble with it whatever, or any electrical trouble except with some windows at the entrance to the anchor houses. We installed those windows thinking that they might be of some use, but they proved to be the weak point in the construction and have been removed. It is not our intent to replace the windows. We have had no mechanical trouble and I believe our experience has been sufficient to justify the assumption that the mechanical design is going to function correctly.

L. J. Corbett: There is little to add as no questions have been raised. The important link this particular crossing forms in the transmission system; the fact that it crosses a navigable waterway, a main line railway and other power and communication circuits, and the adherence to the compression type of insulation have resulted in the rather elaborate construction described. Our company has other long spans on lines in mountain districts of the type described by Mr. Klauber and Mr. Schoolfield.

I wish to emphasize the importance of the proper design of the five hinged anchor structure of Fig. 3. E_3 is the only point at which a hinge can be located on the stem of the Y. The entire Y frame between the hinges E_3 , B and C, must be absolutely rigid.

Test Results on the Performance of Suspension Insulators in Service

BY C. F. BENHAM

Associate, A. I. E. E.
Great Western Power Co., San Francisco

Review of the Subject.—Megger test results on suspension insulators on the lines of the Great Western Power Company covering records since 1908 giving the percentage of depreciation by

districts, viz., mountain, valley and coast conditions; also results covering the different types.

* * * * *

THE suspension insulator has been the subject of much discussion, particularly during the last decade, when the faults of most of the products of earlier manufacture were brought to light and the great increase in their use, due to the general tendency toward higher voltages, considerably extended the interest in their behavior.

Extensive investigation has been carried on as to the cause of their deterioration, which was so pronounced in the older units and from which the later output is

not entirely free. Many valuable data have been collected, from observation of insulators in actual service,—and experimentally as well,—and many conclusions have been drawn. At the present time the most generally accepted theories attribute failure to improperly fired porcelain,—either porous from underfiring or brittle from overfiring,—and even more to the mechanical stresses set up by the unequal expansion of the various elements of the usual cap and pin type of unit.

Most of the manufacturers have profited from the light which has been thrown on the subject; by a

Presented at the Pacific Coast Convention of the A. I. E. E., Del Monte, Cal., October 2-5, 1923.

combination of better porcelain through more scientific mixing and heat control of the firing and the elimination of a large part of the temperature stresses through better design and methods of assembly, they have produced an insulator which is fairly long lived, as compared to the article supplied fifteen years ago.

FIG. 1—DETERIORATION OF SUSPENSION INSULATORS UNDER DIFFERENT CLIMATIC CONDITIONS

Records are available covering the performance of a fairly large number of suspension units in use in the high-tension lines of one company,—a majority of which have been in service for about fifteen years,—and most of the balance from eight to twelve years.

FIG. 2—DETERIORATION OF SUSPENSION INSULATORS, COMPARISON OF DIFFERENT TYPES

Curves designated by same letter are products of same manufacturer.

After about six years of operation, the frequency of insulator failures was increasing at an alarming rate, and interruptions to service became so numerous that it was necessary to adopt a system of field testing to eliminate the faulty units.

From the indications of the first testing it was deemed advisable to replace one type of insulator completely—as well as the defective units of all types—using a new insulator of improved design and material. Subsequently other types were replaced as a whole and all insulators in certain sections where the rapid depreciation coupled with the inaccessibility made testing very costly. As a result failures have been reduced to only one or two sporadic cases in a year, at the most,

INSULATOR SHOWN IN CURVE B-1

INSULATOR REPRESENTED BY CURVE B-2

with one period of twenty months in which none occurred at all. Testing intervals have also been increased to a fairly reasonable period, varying from one year in a few sections to from two to three years for the majority. This is governed partly by the type of insulator preponderating, but more especially by the climatic conditions prevailing, which vary considerably over the entire system.

Periodic testing has been carried on for the past nine

years, and an analysis of the test records, with reference to the effect of different climatic conditions and also comparing the behavior of various types, is presented graphically in Figs. 1 and 2.

Fig. 1 brings out the decided effect of temperature changes on the life of an insulator, and is rather conclusive proof that expansion stresses are a more serious problem than porosity. The four geographic divisions selected are quite sharply defined with distinct characteristics as to climate; while they vary greatly in extent, each is large enough to include a representative number of each of the various insulators and hence affords a fair comparison. The mountain and coast hill sections are subject to almost daily ranges of temperature of considerable magnitude, while in the upper

INSULATOR SHOWN IN CURVE A-3

and lower valley sections the only variations of any consequence are seasonal, though the daily range in the lower valley is perhaps a trifle greater on account of the winds. Again, the mountain and upper valley districts are comparatively dry, while the lower valley and coast sections are quite humid, the one being in a river delta and the other subject to fogs. Thus we have four distinct combinations of temperature cycles and humidity.

Fig. 2 covers the general performance of several different types of insulator, and is particularly interesting in the manner in which it brings out a comparison between different designs and stages of development of the same manufacture. The slight tendency of Curve B-1 to show a decrease in the deterioration can

be accounted for in the fact that it includes insulators of two different ages. It has not been possible to segregate them generally in the test records, as they are alike in appearance, but a few specific cases indicate that the newer insulator has a much greater life due to improvements in porcelain and details of assembly. The proportion of older insulators is gradually being reduced through replacement, with a resulting decrease in the rate of depreciation of the combined group.

The most striking feature is the very slight deterioration of the insulator shown in Curve B-2, which represents a fairly recent output of a design which is standard at the present time. Actual figures are perhaps more conclusive. Of some 10,000 units subjected to test, no failures developed in six years, and only nine in the seventh year and 10 in the eighth year or a total of only 19 units out of 10,000 after eight years of service. This would rather indicate that the insulator question is no longer a very serious problem, at least under the conditions which prevail among those in the foregoing study.

Discussion

J. A. Koontz: I think there is one point that Mr. Benham has mentioned which should be emphasized, *viz.*, that if the loading on the dead end insulator is kept within reason, there is no greater depreciation on the dead end insulator than on insulators in suspension. A great many engineers feel that insulators at the dead end points are quite a hazard. In fact on the lines in question all the early type insulators used at the dead end positions had to be removed, but when they were replaced by later designed units, the trouble ceased, as shown by the curves, and from tests, we find no more failure in the dead end position than when the insulators are used in suspension. With this in view, we feel that from a depreciation standpoint, we do not have to worry about the dead end insulators, so long as the mechanical loads are not excessive.

J. E. Woodbridge: I might speak of the progress of the insulation art. So far as the suspension insulator is concerned, it has been practically developed within the last ten years. I say ten years because the difficulties with suspension insulators were first noted about ten years ago. They had then been used about five years, but nobody dreamed that they had qualities differing from those of the pin type. About the year 1913 suspension insulators began to deteriorate very rapidly; there were burnouts, punctures and flashovers, and we went out on the lines with meggers and discovered that the insulators were practically all to the bad, that they were depreciating at a high rate and that total replacement would be required within a few years. Of course, that developed a new problem and we were up in the air for some time. Some blamed the porcelain, some the metal parts, and some the cement—everybody had a different idea and each engineer proposed a different cure for the other man's diagnosis, but the whole problem is now crystallizing, as shown in this paper, to a definite knowledge of what the troubles are.

Telephone Transmission Over Long Distances

BY H. S. OSBORNE

Fellow, A. I. E. E.

Transmission Engineer, American Telephone and Telegraph Company

Review of the Subject.—In this paper are pointed out some of the similarities and contrasts of power transmission and telephone transmission over long distances. The problems of telephone transmission on open-wire lines are illustrated by a discussion of the methods by which the over-all efficiency of the transcontinental telephone circuit has been greatly improved. A brief discussion is given of recent important developments in telephone transmission

through cables over long distances. An outline is given of the results obtained in the commercial application of carrier telephone and telegraph systems. Finally, a demonstration talk between Havana, Cuba, and Avalon on Catalina Island off the Pacific coast, is described as an illustration of what can be done with the commercial telephone system in its present stage of development.

* * * * *

AT a convention where the main topic of discussion is the transmission of power over long distances, it would appear interesting to review some of the problems involved in the transmission of telephone currents over long distances. This review does not contribute very much which could be used directly in solving the power problems but serves to point out some interesting similarities and some very important differences between these two branches of electrical art.

In essence, both consist in the transmission of alternating currents over very long electrical circuits and in both, therefore, the problem of reducing the losses of electric power in transmission is very important. In the case of power transmission, however, the commodity delivered is the power itself and, therefore, for commercial success a large percentage of the power transmitted into the line must be delivered at the output. In the telephone problem, on the other hand, the commodity delivered is communication and the delivery of electrical power is only a means to this end. The efficiencies of the telephone transmitter and of the telephone receiver are such that under many conditions satisfactory communication can be given when only a small fraction of 1 per cent of the transmitter output is delivered to the receiver at the distant end of the line, the rest being absorbed largely in line losses. Furthermore, in many cases the power delivered does not come directly from the transmitting end but comes only from the nearest repeater station on the line.

The power engineers are free to choose, with a view to transmission efficiency and other features of economy, the frequency of alternating current to be used. As a result, a relatively low frequency is always chosen. In telephone transmission, on the other hand, the frequency of transmission is necessarily high, for it cannot be lower than the important harmonic components of the complex waves which constitute speech. How complicated these waves are is illustrated by Figs. 1 and 2. Fig. 1 shows oscillograms of telephone currents corresponding to the vowels "o" and "e". The most prominent oscillation in the vowel "o" is, roughly, 800 cycles a second and the most prominent

oscillation in the vowel "e" is about 1900 cycles. Fig. 2 is an oscillogram of the word "Pacific." The pronunciation of this word occupies less than a second, but the oscillations are so complicated that it has been necessary to crowd them together very closely in order to get the whole word in one figure. These two figures are illustrations of the fact that the important harmonic components of telephone currents cover a frequency range from 200 cycles to well over 2000 cycles and that components as high as 3000 or 4000 cycles in frequency contribute somewhat to the intelligibility of speech. By using the speech currents to modulate a carrier current the frequencies transmitted over the

FIG. 1—OSCILLOGRAPH RECORDS SHOWING THE FLUCTUATIONS IN THE ELECTRICAL CURRENT WHEN THE VOWELS "O" AND "E" ARE SPOKEN INTO THE TELEPHONE TRANSMITTER, THE SPEED OF THE FILM WAS ABOUT 10 FEET PER SECOND.

line can be raised as may be desired, but no feasible method has been suggested for lowering them materially.

This difference in frequency between power and telephone currents is an important difference from the standpoint of transmission, because the losses per unit length go up rapidly with the frequency. Furthermore, the wave lengths are shorter for higher frequencies, so that long telephone lines may be many wave lengths in length.

Another fundamental difference between the power and telephone transmission systems arises from the difference in type of service which they perform. In

the case of the power system all customers can be served from the same circuit and the tendency is, therefore, towards interconnection and toward the development of large systems consisting of a relatively small number of very large units. In the telephone system, on the other hand, an independent channel of communication must be given to each pair of talkers. This necessity has led to great efforts to find ways to make a moderate amount of copper provide a large number of circuits either by the use of small conductors or by the superposition of a number of independent channels of communication on one pair of wires.

In the telephone system also the amount of power is necessarily small. When talking in an ordinary tone of voice the power delivered to the telephone transmitter in the form of acoustic waves by the talker is in the order of millionths of a watt. The telephone transmitter amplifies this power by a large ratio, so that the power delivered to the telephone lines has peak values of the order of 0.001 to 0.01 watt.

throughout and was provided with six repeater points between New York and San Francisco.

Loading¹ is the means by which in telephone practise the electrical efficiency of the line is increased by using lower currents and higher voltages to transmit a given amount of power. In a power circuit the voltage can be raised by simply changing the ratio of terminal transformers. In a long telephone circuit the voltage cannot be raised in that way. The ratio of voltage to current at the transmitting station depends not on the impedance of the receiving station, but as the telephone line is electrically long, it depends upon the characteristics of the line itself. Therefore, to raise the impedance, the characteristics of the line itself must be changed.

There are several ways in which this can be done. For the transmission of a single frequency, it can be done very effectively by connecting inductive loads across the circuit at regular intervals. For telephone transmission, however, where a uniform efficiency of

FIG. 2

Both power and telephone transmission systems have important insulation difficulties. In the telephone system, however, the difficulty is of course, not in the strength of the insulation to withstand voltage stresses but is to prevent, as far as practicable, the absorption of power in or over the surface of the insulation at the relatively high frequencies of the alternating currents transmitted.

TRANSCONTINENTAL TELEPHONY

As a result of the different fundamental requirements and different technical conditions, the development of the two industries has led to the transmission of telephone currents over considerably greater distances than power currents. A conspicuous example of long distance telephone transmission is the much used service between the Atlantic and Pacific Coasts. The circuit between New York and San Francisco is about 3400 miles (5500 kilometers) long, largely in open-wire construction of copper weighing 435 pounds to the wire mile. (600 kg. per km.). Recent improvements in this circuit have very greatly increased its over-all transmission efficiency, and it is believed that a brief discussion of these improvements will be of interest as illustrating the technical problems involved in telephone transmission over very long open-wire lines.

As originally constructed, this line was loaded

transmission over a wide range of frequencies is necessary, the result is accomplished by the use of series inductance loads, designed for very low energy losses and located regularly at eight-mile intervals throughout the line.

The extent to which the efficiency can be improved is rather narrowly limited in open wire by the insulation losses in the line which are, of course, increased as the voltage is raised and in part offset the decrease in series resistance losses due to decreased current. By means of loading, however, it is possible on a circuit such as the transcontinental telephone line to raise the voltage by about 80 per cent. and reduce the losses per unit length by a factor of about 2.2 in dry weather.

The benefits from the use of loading are insufficient to make transcontinental telephony commercially practicable without the use also of telephone repeaters² which receive the attenuated telephone currents after transmission over a few hundred miles of line and deliver to the adjacent section of line greatly amplified

1. For detailed information regarding the loading of telephone circuits, see paper entitled: "Commercial Loading of Telephone Circuits in the Bell System," by B. Gherardi, TRANSACTIONS, American Institute of Electrical Engineers, 1911.

2. For discussion of the design and action of telephone repeaters see paper entitled: "Telephone Repeaters," by B. Gherardi and F. B. Jewett, TRANSACTIONS, 1919, Vol. XXXVIII.

currents of the same wave shape. The results obtained on the transcontinental circuit by the combination of loading and repeaters are shown in the upper part of Fig. 3 which is drawn to represent the amount of energy at different points of the circuit when 1000 microwatts are delivered to the circuit at the San Francisco end. The power rapidly decreases along the circuit, due to line loss, at Winnemucca is amplified to 700 microwatts, falls off again rapidly, and so by successive stages of attenuation and amplification 10 microwatts are at last delivered to the local telephone circuits at New York.

FIG. 3

The improvements in the transcontinental line mentioned above have been brought about by removing the loading from the circuit and modifying the characteristics of the repeaters. Also, in view of the much larger line losses to be made up by the repeaters and in order to stay within economical upper and lower limits of power output and input of the repeaters, the number of repeaters was doubled. This change, however, was not essential and would not have brought about the improvements in transmission without the other changes. The energy level at different points in the circuit under the improved conditions is indicated in the lower part of Fig. 3, and it will be seen that now instead of 10 microwatts, 70 microwatts are delivered at New York when 1000 are transmitted into the San Francisco end of the line.

In view of the benefits which can be obtained by

loading, it may seem surprising that improvements in the efficiency of this circuit were obtained by removing the loading. The explanation of this result requires the discussion of some very interesting transient phenomena which are important in very long distance transmission.

When a train of oscillations is launched upon a long electrical circuit, it travels along the circuit attenuating in magnitude but without reflection so long as the impedance characteristics of the circuit are uniform. When a non-uniformity in line impedance is reached a part of the wave is reflected and the reflected wave travels back towards the transmitting end, being of course attenuated in the process. By this process of successive reflection the steady state of transmission is produced, although in the process there are of course other transient components of the currents which do not concern us here. In open-wire telephone circuits a few hundred miles in length, or less, the steady state is established very rapidly and the reflected currents are not noticeable. In very long circuits, however, which are made of high over-all efficiency by the use of repeaters or otherwise, the reflected current may have sufficient volume and time lag to be noticeable and even to be heard as distinct echoes. Hence they have been named "Echo Currents."

Echo currents, of course, may be heard by the listener

FIG. 4

as well as by the talker, for the reflected current, striking a second irregularity, is reflected again towards the listener.

In order that the transmission may be satisfactory the conditions of the circuits should be such that this echo current is not noticeable, having either a very short time interval or a small magnitude. It has been found that there is a definite relation between the time lag of an echo and the maximum amount of echo current which can be permitted without appreciable effect on the clearness of speech. This is indicated in Fig. 4 in

the form of relative weighting factors for echo currents of different time lags, showing for both talker and listener and for different time lags the reciprocal of the relative maximum amount of power in the echo for no material interference with conversations.³

In the transcontinental line, which is chosen as our example, the most important echoes heard by the talker come from the irregularities at the distant end of the line where there is a marked change in the characteristics of the line due to the change from toll line to local construction. With the loaded circuit the velocity of propagation is about 55,000 miles (88,000 km.) per second, and the time lag of this echo is about 0.11 second. On the non-loaded circuit, however, the velocity of propagation is much faster, being about 180,000 miles (290,000 km.) per second, and the time lag of the echo from the distant end is only about 0.04 second. The corresponding weighting factors are 670 and 15, which means that on the non-loaded line this echo could be about 44 times as loud as on the loaded circuit for the same effect of the terminal irregularities on transmission.

FIG. 5—DIFFERENCE BETWEEN LINE AND REPEATER IMPEDANCE EXPRESSED AS A FRACTION OF THE SUM OF THESE IMPEDANCES.

(A) THE LOADED TRANSCONTINENTAL CIRCUIT
(B) THE NON-LOADED TRANSCONTINENTAL CIRCUIT

The magnitude of the echo for a given irregularity depends upon the over-all transmission efficiency of the circuit, and the increase in permissible volume of echo current, therefore, means that the over-all efficiency of the circuit may be increased without interference from the echo currents.

So far we have been discussing the effect of reflected currents due to terminal irregularities. This, however, is not the whole story. On a line provided with repeaters there are irregularities not only at the terminals but also at the repeater points, due to the impracticability of making the impedance of the repeaters identical with that of the lines at all frequencies. In making the line non-loaded, it was found possible by modifying the telephone repeaters to improve the

similarity of impedance of the repeaters and the line, thus reducing the amount of reflected current at these points. The extent to which this was practicable is indicated in Fig. 5 which shows the ratio of difference to sum of line and repeater impedance over a range of frequencies for the loaded circuit condition and for the non-loaded circuit condition.

The result of these two improvements, namely, increasing the velocity of transmission over the line and decreasing the amount of the irregularities is

indicated in Tables I and II. Table I summarizes the effect of echo currents on the loaded circuit. This table shows for the worst current path the percentage of transmitted and received energy appearing as echo current, the time lag in seconds, the corresponding weighting from Fig. 4 and the product of energy and weighting.

This detail is shown only for the worst echo current but has been computed for all the echo current paths,

3. For further discussion of echo currents, see Mr. A. B. Clark's paper on "Telephone Transmission on Long Cable Circuits," JOURNAL A. I. E. E., January, 1923.

and the sum of the products of energy ratios and weighting factors is given in the table. This total gives a good means for comparing the echo-current effect in different circuits.

Table II shows the corresponding figures for the non-loaded transcontinental circuit after improvement of the repeaters and establishment of the higher over-all efficiency. It will be noted that in spite of the facts that the amount of energy represented by the worst echo current paths is greatly increased and that the number of echo paths is also increased, the much shorter time lag due to the higher velocity of propagation results in a total weighted echo current of about the same magnitude as the total for the loaded circuit at a very much lower efficiency.

For comparison, Table III is made up for the loaded circuit, assuming it to be operated at the same over-all efficiency as the non-loaded circuit, i. e., 7 per cent. This table shows how much greater the effect of the echo currents would be at that equivalent.

In addition to the improvements discussed above, the changes in the transcontinental line made it practicable to improve the quality of telephone transmission by increasing the degree of uniformity of transmission of the different frequencies within the important telephone range. For long stretches of line the non-loaded open-wire transmits current with much more uniform efficiency than the loaded open wire. This is illustrated in Fig. 6 which shows the percentage of output to input power at different frequencies in the telephone range for a 281 mile (452 km.) section of non-loaded open wire 0.165 inches in diameter (435 pounds per wire mile) and a 563 mile (907 km.) section of loaded open wire of the same size. The distances chosen are in each case an average repeater section.

Furthermore, in modifying the telephone repeaters, changes were made to improve the uniformity of amplification given by the repeaters over a wide range

of frequencies. Fig. 7 shows the amplification frequency characteristic of these repeaters before and after their modification.

These improvements in the transmission characteristics of the line and repeaters made it possible to get a very good over-all transmission frequency characteristic in spite of the very great length of this line.

FIG. 8—POWER RATIO—FREQUENCY CHARACTERISTICS OF COMPLETE NON-LOADED TRANSCONTINENTAL CIRCUIT

The result expressed in terms of net over-all efficiency is indicated in Fig. 8.

An incidental advantage of the change from loaded to non-loaded construction is greater independence of weather conditions. The loaded circuit being a higher voltage circuit, varies much more in efficiency between

wet and dry weather conditions than the non-loaded circuit. On the other hand, the non-loaded circuit involves twice as many telephone repeaters and the over-all efficiency of the circuit depends on a very exact maintenance of the amplification of each of these repeaters. This requires very carefully planned and faithfully executed maintenance routines. It should be said that the results which have been obtained over this circuit have been exceedingly satisfactory.

TOLL CABLES⁴

The transmission of telephone currents through cables has always been difficult in comparison with the transmission over open-wire lines. One factor of difficulty is the much greater loss in the cable circuits per unit of length. This is due in part to the close proximity of the two sides of the circuit and in part to the fact that economical construction in cable requires relatively small conductors. The telephone repeater has been developed to a point where a practically unlimited number of them can be used in tandem in a

this type of construction is illustrated by Fig. 9 which indicates important toll cable routes in the Northeastern part of the country. In this section, because of the congestion of population and business, the toll cable development has been most pronounced, and as you will note, the cable which was completed some years ago up and down the Atlantic Coast, between Boston and Washington, has been supplemented by cable stretching westward now as far as Cleveland. This cable will be extended as far as Chicago as rapidly as the work can be carried out and will provide high grade telephone circuits entirely in cable between Chicago and the Atlantic seaboard cities.

An outstanding advantage of the cable type of construction is the ability thereby to concentrate very large numbers of circuits along a single route. Typical aerial toll cable construction is shown in Fig. 10 which shows a section of the cable between Pittsburgh and Cleveland, carrying about 260 circuits. In open-wire construction 6 or 7 very heavy pole lines would be required to provide this number of circuits. In many

FIG. 9—LONG TOLL CABLES, EXISTING, PROPOSED AND IMPORTANT BRANCHES

circuit without distortion of the telephone currents. This has, therefore, removed the limitations which were set by high attenuation losses in the cable conductors. Although there are other important limitations and there have been large difficulties to overcome, cable transmission has been made practicable up to distances of at least 1000 miles (1600 km.).

As a result, the development of toll cables has become an exceedingly important phase of long distance telephone development and during the next few years it is expected that toll cables will be built in the Bell System at the rate of more than 500 miles (800 km.) a year. The extent of present and prospective use of

4. For a more detailed discussion of modern toll cable developments, see paper entitled: "Philadelphia-Pittsburgh Section of the New York-Chicago Cable" by J. J. Pilliod, JOURNAL A. I. E. E., August, 1922, and "Telephone Transmission on Long Cable Circuits" by A. B. Clark, JOURNAL A. I. E. E., January, 1923.

places where cable construction is now being used the available highway routes for pole lines are largely occupied and purchase of numbers of rights-of-way would be exceedingly expensive, so that in many cases the toll cable development furnishes almost the only practicable method of providing for the large numbers of circuits which the great development of toll business is requiring.

Another advantage of cable construction is the fact that where underground sections are necessary in passing through cities no irregularity is caused in the constants of the circuit as is the case with open-wire construction. With the general use of repeaters in connection with long toll circuits these irregularities in type of construction are important factors in limiting the efficiency.

Another important advantage of cable construction is its relative immunity from the effect of weather and

particularly from the effect of sleet. The damage which can be done by sleet storms is illustrated in Figs. 11 and 12. The cable construction can be made very substantial and capable of withstanding severe conditions of sleet.

The large number of circuits provided by one cable are obtained by the use of very small conductors, the gages in common use being 19 B. & S. (20 lb. to the wire

ferent frequencies. By loading, this variation is reduced with a corresponding improvement of the quality of transmitted speech and at the same time the efficiency of transmission is raised. This is illustrated in Fig. 13 which shows the transmission efficiency at different frequencies of 1 mile (1.6 km.) of 19-gage toll cable circuit non-loaded and when provided with the type of loading most used for toll cables. With the

FIG. 10

mile) and 16 B. & S. (40 lb. to the wire mile). In the longest circuits two 19-gage circuits are required, each carrying the transmission in one direction only. Nevertheless, the amount of copper required is only 80 pounds to the mile as contrasted with 870 pounds per mile for the open-wire circuits which these circuits replace.

FIG. 11

In contrast to the recent developments on open-wire lines discussed above, toll cable circuits are always loaded. A non-loaded cable circuit consists largely of resistance and capacity, and as a result there are very wide differences in efficiencies of transmission at dif-

type of loading shown in the figure, the voltage for 1000-cycle transmission is increased by loading by 70 per cent and the losses per unit length are reduced by a factor of about 3.6.⁵

In the loaded cable circuit, as in the loaded open-wire circuit, the velocity of transmission is relatively low, being about 10,000 miles (16,000 km.) per second for the type of loading mentioned above, as compared with 180,000 miles (290,000 km.) per second on non-loaded open-wire lines. Therefore, for circuits more

FIG. 12

than a few hundred miles long, care must be taken to avoid excessive echo currents. On the very long toll cable circuits, say over 500 miles (800 km.), a lighter weight of loading is used, whereby, because of the

5. In part, this improvement is due to improvement in power factor, in addition to the improvement caused by higher impedance.

lesser inductance per mile inserted in the cable, the velocity of propagation is as high as 20,000 miles (32,000 km.) per second. In addition to the echo currents, care must be taken in the design of the cables to avoid interference with speech by the transients produced by the periodic structure of the loaded cable circuit.

One of the interesting problems involved in the

cable, and manufacturing methods have been carefully worked out to give the greatest possible degree of symmetry in the construction of the two insulated conductors which are twisted together to form a pair and of the two pairs which are twisted together to form a quad. The construction of the various pairs and quads, also, is such as to properly coordinate all of the circuits which will be near each other in the cable.

FIG. 13—POWER RATIO—FREQUENCY CHARACTERISTICS FOR NO. 19 GAGE SIDE CIRCUITS

(A) WITHOUT LOADING

(B) WITH MEDIUM HEAVY HIGH CUT-OFF LOADING

design of long toll cables is the prevention of excessive crosstalk, that is, of excessive transfer of electrical energy from one circuit to another. The difficulty of avoiding this with a very large number of circuits crowded within a $2\frac{5}{8}$ -in. sheath, is increased in the long circuits by the very long distances throughout which these circuits parallel each other and the frequent

FIG. 14

large amplifications of both transmitted current and crosstalk at repeater stations along the line. An adequate discussion of this problem would require a paper in itself. In this paper we must be content to note merely a few of the more important methods which have been developed.

The problem starts with the construction of the

FIG. 15—TRANSMISSION ON LEVEL DIAGRAM OF NEW YORK—CINCINNATI, No. 1

These manufacturing precautions are supplemented by very careful tests made when the cables are installed, and by splicing procedure by means of which, based on the results of the tests, the induction between circuits is still further greatly reduced. As a precaution against slight series unbalances, all joints are soldered. Further precautions include the segregation into different parts of the cable of groups of circuits which would be particularly likely to interfere with each other.

Similar precautions are used in the design, manufacture and installation of loading coils and other apparatus used with the circuits.

The toll cables require telephone repeaters at intervals of 50 or 100 miles (80 or 160 km.), and this has led to much work in the development of economical repeaters and auxiliary equipment for use with cable circuits.⁶ Fig. 14 shows a considerable group of telephone repeaters in the repeater station at Bedford, Pa., and illustrates the degree of condensation which has been worked out in the present types of apparatus developed for this service.

The telephone cable benefits not only traffic between points along its route, but at important points connects to open-wire lines along other routes. This use of the toll cable is well illustrated by Fig. 15, which shows the relative power levels at different points of a typical circuit now in use in the New York-Chicago cable

6. Refer to paper by Mr. Pilliod noted above and to paper entitled: "Telephone Equipment for Long Cable Circuits," by C. S. Demarest, A. I. E. E. Convention, Swampscott, June, 1923.

route. This circuit is in cable between New York and Pittsburgh and takes open-wire between Pittsburgh and Cincinnati, forming a New York-Cincinnati circuit. This figure has been drawn to represent the ratio of power at any point in the circuit to power transmitted to the circuit at New York and shows the variations in the amount of power transmitted due to variations in the resistance of the cable with temperature. It is to be noted that these resistance variations would introduce a variation of more than 7:1 in the amount of received power, which would be sufficient to prevent a satisfactory use of the circuit. These variations are automatically compensated for by the use of the automatic transmission regulators described in Mr. Clark's paper.

CARRIER-CURRENT SYSTEMS

It has already been mentioned that the necessity for providing large numbers of mutually non-interfering telephone circuits has led to great efforts to find ways of making a moderate amount of copper provide a large number of independent telephone and telegraph channels. One way in which this is done is by the use of very small conductors in toll cables which have just

FIG. 16

been discussed. This is in general economical only where the traffic is heavy.

Another way of obtaining the same result is by requiring each pair of conductors to transmit a wider range of frequencies and using different portions of this range for independent channels of communication. A telephone conversation occupies the range between 300 cycles and something over 2000 cycles. It has long been the custom to use the range below 300 for telegraph and signaling purposes. The range above two or three thousand, however, was not commercially useful until the development of carrier-current systems.⁷

In the carrier-current telephone system the voice frequency telephone currents are made to modulate a higher frequency current. The frequencies of the modulated currents used in the carrier system represent the same width of band arithmetically as the original telephone frequencies, but all are shifted in magnitude by the frequency of the carrier current. That is, a

7. Refer to paper entitled: "Carrier-Current Telephony and Telegraphy," by E. H. Colpitts and O. B. Blackwell, A. I. E. E. TRANSACTIONS, Vol. XL, 1921.

telephone band of 300 to 2000 cycles, when used to modulate a 15,000-cycle carrier current, produces a band of frequencies ranging between 15,300 and 17,000 cycles in addition to other bands which are not used in existing systems and which need not be considered in this discussion. The principle of modulation is the same as is employed in radio telephony, but in the carrier system the modulated waves are carried along wire circuits, rather than radiated into space.

This development considerably increases the range of frequencies which can be used commercially for communication. The present situation is indicated in Fig. 16 which shows the ranges of frequency of electromagnetic waves which are used in different ways for communication, together with the frequencies which at the present time have no practical application to communication.

FIG. 17—TYPICAL POWER RATIO-FREQUENCY CHARACTERISTICS OF 165-IN. DIAMETER COPPER OPEN WIRE, 200 MILES LONG

The question may naturally arise why the lower frequencies have been chosen for the wire carrier systems developed for commercial use. A very important argument for using the lower frequencies in commercial telephone practice is that a number of carrier systems covering the same frequency ranges are used on different pairs carried on the same pole line. The crosstalk between the pairs is prevented by specially designed systems of transpositions in the circuits. The difficulty of preventing interference between the

two circuits, however, goes up more rapidly than the frequency of the currents, so that at frequencies very much higher than those now used it would probably be impracticable with present forms of construction to avoid excessive interaction between the circuits.

FIG. 18—ATTENUATION OF THE 4-6 K. C. BAND FILTER

The types of loading which were designed for voice frequency currents do not transmit currents of more than 3000 cycles frequency and for the carrier frequencies used in commercial telephony special loading with a very close spacing of loading coils has been developed.

Another way in which the lower frequency is advantageous is indicated in Fig. 17 which shows the ratio of output to input power at different frequencies under typical wet and dry weather conditions, for 200 miles (320 km.) of metallic circuit composed of copper wire 0.165 inches in diameter (435 pounds per wire mile). It will be noted that this loss increases rapidly with increasing frequency and furthermore that the variation of the loss between the wet and dry weather conditions also increases with frequency.

One of the problems involved in using low-frequency carrier currents for telephony arises from the fact that the width of the band of frequencies is appreciable compared with the frequency of the carrier current. For example, the carrier band of lowest frequency used in present Bell System practice is the band between 4000 and 6000 cycles. It is necessary to transmit all frequencies within that range with approximately uniform efficiency and to sharply cut off frequencies outside the range. A sharply tuned circuit would obviously be of no use, as it would very greatly distort the speech. This problem is beautifully solved by the invention of the electrical filter which provides a path for transmitting with almost uniform efficiency any selected band of frequencies and excluding all others.

FIG. 19

Another important reason for using the lower carrier frequencies is the relatively great effect on high-frequency currents of short sections of cable inserted in the open-wire line. These effects can be reduced to a considerable extent by loading but the difficulties of loading efficiently increase rapidly with the frequency.

The action of an electrical filter is illustrated in Fig. 18 which shows the measured transmission characteristics of one of the filters in use in a carrier-current system.

The use of carrier systems saves the installation of additional copper conductors, but to offset this requires

involved a considerable number of very interesting problems.⁸ The demonstration referred to was a conversation between Havana and Catalina Island. This circuit was about 5500 miles (8800 km.) long, included the submarine cables lying at the bottom of the Florida Straits, open-wire lines extending up the Atlantic Coast to New York, across the continent to San Francisco and down the Pacific Coast to Los Angeles, and finally the unique circuit from Los Angeles to Catalina Island which at that time included a wireless telephone link between Long Beach and the Island.

A feature of interest in connection with this demonstration is to note that the telephone circuits involved carry regularly in commercial service not only the voice frequency channel used for the demonstration but many other channels of communication. This is indicated in Fig. 21, which shows the number of

second. This emphasizes the necessity for using electrical means for the transmission of speech over great distances. If the means were acoustic and transmission was through the air, it would take seven hours for the sound to be transmitted from one end of the circuit to the other.

The essential part which amplifiers at intermediate points play in giving service over these very long circuits is evident. The Havana-Catalina circuit passed through 25 amplifying stations. The impossibility of getting equivalent results by amplification of the terminals is perhaps best illustrated by an example. In talking from San Francisco to Havana, for example, with the transmitter delivering 1000 microwatts at San Francisco, the power delivered at Havana is about 25 microwatts. If there were no intermediate amplifiers, and assuming for the moment that the circuit could carry unlimited power without burning up, it would be necessary in order to deliver 25 microwatts at Havana that power sufficient to light an incandescent lamp would be flowing in the circuit at some point in North Carolina, and at Philadelphia the power would amount to five kilowatts. It is estimated that the total mechanical and electrical power generated in the world is equivalent to that required for about 20 billion electric lamps, and this power would have to be flowing in the circuit a little east of Denver. This power is, however, only about 1/200,000 of the power which is received by the earth from the sun, but all of this power would be required to be flowing in the circuit at Sacramento.

FIG. 21

independent channels of communication provided in the different sections by the single pair of conductors used. The heavy line represents a telephone conversation and the dotted heavy line indicates that the wires used form one of two pairs which together provide a phantom circuit. The heavy lines between Harrisburg and Chicago and between San Francisco and Los Angeles represent additional channels obtained by carrier telephone systems. The light lines indicate telegraph circuits, two circuits being obtained over the pair of wires throughout by direct-current composite telegraph system and 10 additional telegraph circuits being obtained between San Francisco and Chicago by carrier telegraph systems.

It is interesting to note that the sound is transmitted over this 5500-mile circuit in less than one tenth of a

As pointed out at the beginning of this paper, the practical requirements of telephone transmission and of power transmission over long distances are very different. However, to solve the telephone transmission problems it has been necessary to work out the electrical transmission theory both for steady and for transient states⁹ for circuit conditions which are more extreme than any which are likely to be met with in power transmission, and it may be that the solution of these purely electrical parts of the problem will contribute to some extent to the power transmission problem in cases where very long distances are involved.

The writer gratefully acknowledges the assistance of Mr. O. B. Jacobs and of many others of his associates in the Departments of Development and Research and of Operation and Engineering in the American Telephone and Telegraph Company in the collection of data used in this paper.

Experience with Bearings and Vibration Conditions of Large Hydroelectric Units

BY JOHN HARISBERGER

Member, A. I. E. E.
Puget Sound Power & Light Co.

IN 1905 there was installed at Snoqualmie Falls, a 9000-h. p. single-runner, single-discharge Francis turbine. The end thrust of this runner gave considerable trouble, since the balancing of the run in a turbine of this type had not been perfected at that time. This experience determined that any future horizontal hydraulic turbine should be of the single-runner, double-discharge type unless a satisfactory solution was found for balancing the runner in a single-discharge turbine.

In 1910 a 12,000-h. p. single-runner, double-discharge turbine was installed under a 280-ft. head. When this turbine was put in operation it was found that it would begin to vibrate badly at about $\frac{3}{4}$ load and would not stop vibrating until the load was reduced to $\frac{1}{4}$ gate opening. This vibration was similar to that caused by running a high-speed turbine with a badly unbalanced runner. Numerous experiments were tried to stop the vibration, but without satisfactory results. Finally water was piped from the penstock to the turbine case to be used in the pocket between the runner and other parts, such as the side covers and inner and outer seal rings, resulting in an increased pressure and a steadying effect on the runner. It was then possible to carry full load without vibration. With this arrangement we were able to adjust the clearance between runner and seal rings very closely, so that very little wear of the seal rings and periphery of the runner resulted.

In 1911 two 20,000-h. p., single-runner, double-discharge turbines were installed in our White River station, under a head of 440 ft. The experience with these units was similar to that at Snoqualmie Falls, and the same remedy proved effective. A third unit was installed in this station in 1917, and an attempt was made in its design to overcome the vibration, such as occurred in the previous units, without the introduction of pressure water to the side covers. Since we were satisfied that the main cause of vibration was the long distance between bearings made necessary by the two draft tubes, (this being over 20 ft.), the change in design consisted principally of a larger and stiffer shaft. Nevertheless it was found necessary to apply water pressure between seal rings and side covers and runner as on the previous units.

No. 3 turbine did not come up to the capacity expected, so another runner of somewhat different design was installed, which exceeded our expectations as to capacity. With this new runner, we found that a decided hum, or vibration, developed, beginning at

about $\frac{3}{10}$ gate opening and continuing to a little beyond $\frac{5}{10}$ gate opening with a maximum intensity at about $\frac{4}{10}$ gate opening. At its maximum, this vibration in the runner is quite annoying and is sufficient to start vibrations in any loose metal parts, such as valve wheels, covers, or balancing rings, so care must be taken to fasten these parts to keep them from wearing rapidly. We have not obtained any expression from the manufacturer of the turbine as to the cause of this hum, but we came to the following conclusion. The tone of this hum is somewhat above the 60-cycle hum. A study of the frequency of the vibration was made by comparing the generator and the turbine as follows:

Let S = speed of turbo generator in revolutions per minute.

C = the number of vibrations per minute of the generator tone.

E = the number of vibrations per minute of the turbine tone.

N = the number of poles on generator field.

V_1 = the number of vibrations per minute of generator.

V_2 = the number of vibrations per minute of the turbine.

X = the number of vibrations per revolution of turbine.

Then

$$V_1 = N S$$

$$V_2 = \frac{V_1 E}{C} = \frac{N S E}{C}$$

$$X = \frac{N E}{C} = 25$$

In this particular case

$$N = 20$$

$$S = 360$$

$$C = 60 \times 256$$

$$E = 60 \times 320$$

As there are 25 buckets on the turbine runner and a vibration occurs only over a limited range of gate opening, vibrations have been considered as due to the relative entrance angle of the runner-blades to the flow angle of the entering water. This flow-angle is varied at different gate openings by the angle of guide vanes and the velocity of the water as it enters the runner, the speed of the runner remaining constant.

Fig. 1, the efficiency curve of this runner, shows a

decided sag in the curve between points where this vibration takes place, owing no doubt, to the deflection of the entering water caused by the blades.

The original bearings furnished with two of our large generators were babbitted with a lead base babbitt which was unsuitable for heavy service. Before satisfactory operation could be obtained these bearings had to be rebabbitted with babbitt suitable for heavy pressure. These bearings were 15 by 45 in. with five brass oil rings, and carried a rotor complete, with shaft, weighing 120,300 lb., and operating at 360 rev.

FIG. 1—GATE OPENING EFFICIENCY CURVE
Turbine No. 3, White River Generating Station

per min. The bearings as originally constructed were equipped with cooling coils consisting of several longitudinal tubes placed at the bottom of the oil reservoir, and were not effective for cooling the oil as there was not sufficient circulation to carry the hot oil to the bottom of the well. During the hot weather considerable difficulty was experienced with high temperature. It was necessary to install a temporary system for feeding the oil into the top of the bearings. Different kinds of oils were tried out with the hope of reducing

the bearing temperature, and also copper cooling coils were installed in oil wells immediately below the bearings. The cooling coils so reduced the oil temperature that it was not necessary to continue feeding oil into the top of the bearings. The third unit installed in this station, was somewhat larger than the previous two, having bearings 17 by 34 in., with 4 oil rings, and carrying a rotor weight of 136,000 lb., and operating at 360 rev. per min. The cooling coils of these bearings are imbedded in the babbitt. These bearings were so successful that bearings of this type have replaced the original ones in turbines No. 1 and 2. The only difficulty experienced since the changes were made in the bearings, as mentioned above, was that the shaft, on being started after having been shut down for a number of hours, cohered to the babbitt and wiped a spot in it on the lower half of the bearing. In some instances this effect was indicated by smoke rising from the bearings just as the shaft started to turn over but subsequently the bearings continued to operate without further trouble. When after trouble of this kind the bearing was dismantled, a small spot was found wiped near the bottom of the bearing, but the cohesion was not sufficient to pull the babbitt all the way around. On other occasions wiping was more serious and as a result it was necessary to shut down the turbine and scrape the bearing. As a precautionary measure in starting the turbine, a small amount of clean oil is poured on the bearing to supply lubrication during the first revolution. To overcome completely this tendency to cohere, we are installing a high-pressure oiling system to force oil under the shaft before starting up.

Discussion

Waterwheel Construction and Governing

BY E. M. BREED

Pelton Water Wheel Co., San Francisco, Cal.

THE design and manufacture of hydraulic turbine equipment has been very considerably accelerated within the past few years; more particularly since the World War, as the lessons it taught us in regard to diminishing fuel sources and the interruption to fuel supply through labor disturbances, both directly in fuel production and indirectly in its transportation, have stimulated in a very decided manner the investigation and development of the water powers of the nation. The remarkable strides made in the long-distance, high-tension transmission of power have rendered economically available water power sources formerly considered impossible and, particularly, in the West where long distance power transmission and super power zones have now become realities.

This very considerable increase in the actual and prospective use of hydraulic prime movers has resulted in the past few years in pronounced activity in study and experimentation, to improve the design features of existing types of hydraulic turbines and in the development of new types. This progress is evidenced, not only in the turbines themselves but in their auxiliary equipment, as well as in the water conduits above and below the turbine proper. The rather gratifying results of this investigation and study have introduced a new period in turbine design, characterized by a desire to design the hydraulic equipment to fit the physical conditions and load requirements existing, rather than an attempt to modify the physical conditions to suit certain recognized types of turbine design, based on accepted "type characteristics."

This present healthy condition in the field of turbine design, gives the hydraulic engineer a very considerable latitude in the choice of type and speed of turbine, and in the general arrangement of the hydraulic equipment. As a result, the collaboration of the turbine manufacturer and the power company engineers in the preliminary study of any certain development becomes more desirable than ever, thus emphasizing the community of interests between the manufacturer and the power company. This broadening of the field of possible types and designs of turbines, becomes apparent in three principal directions; a very considerable increase in speeds available for low and medium head turbines; a considerable extension of the maximum heads for which turbines can be designed, and an increase in the capacity of unit considered economically feasible.

The record, as far as size of unit is concerned, is set by the Niagara Falls Power Company which placed contracts last year for three single-runner vertical

turbines each of 70,000 h. p. capacity. The engineering fraternity is inclined to expect such records to be set, from time to time, at Niagara Falls as conditions are such there as to warrant the installation of large units, but there have been a number of other installations throughout the country of large size turbine units, and the time seems to have passed when turbine units of less than 40,000 or 50,000 h. p. occasion any comment. It is not too much to say that should the economics warrant, the capacity of individual hydraulic turbine units will reach 100,000 h. p. in the not distant future.

Under conditions where the operating heads are moderate, that is to say 300 ft. or 350 ft., these large size units do not produce design requirements differing materially from those with which we are ordinarily familiar. There are, of course, vast differences in the physical sizes of component parts but, generally speaking, large turbine units under these moderate heads may be said to have been developed homologously from designs of lesser capacity. The 70,000-h. p. units referred to, will be of the same general design as the 55,000-h. p. units manufactured by the same company for the Queenston Plant of the Hydraulic Power Commission of Ontario, and as the 37,500-h. p. units manufactured for Station No. 3 of the Niagara Falls Power Co. They will operate at 107 rev. per min. under 213.5 ft. head. Some idea of the physical dimensions may be gained from the fact that the casing inlets will be 14 ft. in diameter; the power water being controlled by means of 21 ft. by 14 ft. Johnson needle-type valves. The over-all diameter of the cast steel spiral casing will be approximately 42 ft. and the outside diameter of the cast steel runner will be approximately 15 ft. 6 in.

In general, however, it may be said that size in a unit is not an advantage in itself, as seems to be sometimes considered. The increase in efficiency, if any, resulting from an increase in capacity beyond say, 30,000 h. p. to 35,000 h. p., is probably very small, and the decrease in cost per h. p. in most installations of extremely large size units is problematical when the increase cost of foundations, super-structure and auxiliary hydraulic equipment is considered. On the other hand, there are probably only a few power systems in the country where units of 50,000 h. p. or larger, can be used to advantage and a very careful study should certainly be made of the present and expected load requirements, stream flow conditions and expected shape of the efficiency curve below half load before large capacity units are decided upon. In many cases it will probably be found that large capacity units would be operating a considerable percentage of the time on a low part of the efficiency curve. This not

only means inefficient use of the water resources, but also rapid deterioration and, consequently, high up-keep charges on the runner, wicket gates and adjacent parts, with frequent removal of the unit from service.

The next most important forward step in turbine construction as marking the progress of the art, is found in the development on the Pacific Coast of what may be termed high-head turbine design. Indeed, from the viewpoint of engineering significance, the high-head turbine should probably be named first as the large number of high-head power sites available in the Rocky Mountains and West, where some seventy per cent of the total undeveloped power of the nation exists, gives rise to the expectation that a considerable proportion of turbine development in the future will be of the high-head type. The development, at their Kern River No. 3 Plant, by the Southern California Edison Company pioneered the field of high-head turbine construction with an installation consisting of two, 25,000 h. p. vertical turbines operating under an effective head of 810 ft. Many problems not ordinarily met in low-head turbine design required solution. Since the plant has been successfully operating for some three years, it may be definitely said that the solution of the high-head turbine has been proved.

The Portland Railway Light & Power Company has at the present time under construction for its Oak Grove Plant a high-head reaction turbine of 35,000 h. p. capacity to operate at 514 rev. per min. under an effective head of 850 ft. This plant when put into operation will be the highest head turbine installation known, this distinction at the present time being held by the two turbines of the Southern California Edison Co., previously described.

While in the larger low-head installations lignum-vitae bearings, water-lubricated, are still extensively used, the trend is nevertheless toward babbitt-lined bearing, oil-lubricated, and in the high-head turbines these have been used exclusively. It will be obvious that in the high-head installations the clearance space between the runner and the stationary parts of the turbine casing must be kept at a minimum if the leakage and consequent erosion of the high-velocity water is to be properly controlled. It is customary, therefore, to keep the high-head turbine runners rigidly in their position of alinement and babbitt-lined bearings, in which the space allowed for the maintenance of the lubricating oil film is kept as small as possible, are essential. Coincident with the necessity for keeping the runner clearances at a minimum, is the requirement for some kind of runner seal which with such close clearances will not leak, seize, nor wear. These needs have been met by the company, with which the writer is connected, through the development of rubber seal rings and several units have been in successful operation for a couple of years under very difficult silt and sand conditions, using this type of seal ring.

A great deal of attention and study has been given to the problems arising in high head turbine design, due to the increased velocities in the water resulting from operation under these higher heads. The utmost care must be taken in the design of turbine casing, speed ring, guide vanes, etc., to prevent as far as possible, formation of eddies and disturbance of the stream line flow. The volute casing is so designed that the cross-sectional area of the volute passage will decrease when passing around the circumference of the turbine at a rate sufficient to provide a continually increasing velocity in the water, inversely proportional to the radial distance from the axis of rotation of the runner. This will deliver the power water to the guide vanes under the same velocity and pressure head at all points of the guide vane circle, and it is interesting to note that the use of the Overn disk-type guide vanes, as developed by one of the Eastern hydraulic manufacturers, tends to reduce hydraulic losses at this point to a negligible quantity through the thin stream line shape permitted by this design of vane.

With the increase in the size of turbine units, the problem of governing has undergone very considerable change. The greater capacities of single-turbine units have come about to a considerable extent, from the fact that they are being installed by companies which are operating large systems and which can, therefore, effectively absorb the output of these single high-powered units en bloc, with the normal load fluctuations of their systems being easily taken care of by other units or plants of smaller capacity tied into the same transmission net work. Therefore, from the viewpoint of regulation, the governing problem on the larger units is not severe. On the other hand, the importance of perfection in the governing mechanism in these larger units can very properly be considered by realizing the responsibility placed upon it and its power to do extreme damage if it fails to function properly. For instance, the length of governor stroke on a large turbine operating under moderate head may not be in excess of 9 in. to turn on the load from zero to maximum capacity. Obviously, the rate with which this vast amount of energy may be turned on or shut off must be absolutely under control. These considerations alone have led to studies in governor design that, without question, are producing a much higher type of construction than in the past. Facilities have been provided for changing from governor control of the turbine unit to hand control by the movement of a single lever. Governors are also usually equipped with devices for automatic emergency operation to close down the plant should almost any unusual condition develop, either electrically or mechanically. Complete switchboard or remote control in the matter of synchronizing, limiting or adjusting of load and emergency shut-down are now included in the modern governor.

It has become quite general practise to install individual oil-pressure sets for each governor and

turbine unit, as this gives an independence in operating control and also largely helps to keep the physical size of the pressure-oil units within such limits as will make them fit harmoniously into the power house plan. Advocates of the central oil-pressure systems usually cross-connect the individual oil pressure sets by means of suitable piping so that any one oil-pressure set may be used for any turbine. Where conditions permit, individual oil-pressure sets are made large enough not only to provide pressure oil for their own turbines but also to operate an adjacent turbine under emergency conditions.

Pressure regulators, or relief valves, have undergone considerable change of design by reason of the large water quantities that now must be handled and on occasion also because of the high heads under which they must discharge. Mechanically-operated relief valves which take their motion directly from the gate-shifting mechanism on the turbine are essential and the entire pressure regulator structure should be so designed as to safely withstand the full effort of the governor so that should an obstruction block the opening of the relief valve, the turbine guide vanes will be effectively prevented from any further closure, as otherwise a serious ram or rise of pressure in the pipe line would result. It is also essential that the pressure regulator shall have a discharge characteristic which will approach as closely as possible the discharge characteristic of the turbine guide vanes, as otherwise the inverse movement of the guide vanes and relief valve will cause variations of the velocity of flow in the pipe line which may result seriously.

Another development of importance in the turbine field is the rapidly increasing use of the so-called high-speed or propeller type runner. The Francis type runner, which has been the standard for many years, has been developed and perfected so that for low head work, specific speeds as high as 80 or 85, in the English system, can be gotten with fairly high efficiencies, but as these appear to be about the limit to be expected, a great deal of experimentation and study has been given to the development of a new high-speed type of runner. Some of the advantages gained by the use of the propeller type or diagonal runner are:

First. A reduction in the first cost of the hydroelectric unit, due to the smaller dimensions resulting from the higher speed, and a reduction in the cost of the super-structure of the power house, cranes, etc. owing to the lighter weight of the rotating element and other parts to be handled.

Second. The mechanical strength of the diagonal runner is improved over that of the Francis type as the overhang of the vanes is less and the connection between runner hub and vane considerably longer, resulting in smaller bending stresses in the vanes. As the vane is unshrouded the construction permits of the use of separate vanes which can be bolted to a central hub, allowing the replacing of a single vane, if accidentally damaged.

Third. The design of the diagonal runner is much simpler than that of an equivalent Francis runner, thus eliminating to a very considerable extent the possibility of erosion, cavitation, etc., and providing a more direct passage for the water. The runner usually consists of from four to eight vanes, in comparison with the Francis type, having from fourteen to eighteen vanes, so that the clear openings through the vanes are considerably greater, preventing to a very considerable extent, the possibility of clogging with foreign material.

A considerable number of these high-speed runner units have been installed in the past two or three years and very satisfactory results obtained. Numerous tests have been made both of the model runners and of complete units installed, and efficiencies of 88 per cent to 90 per cent can reasonably be expected from this type of runner when designed for specific speeds ranging from 110 to 150, English system; the efficiency dropping off somewhat as the upper range of specific speed is reached. Possibly the most notable installation thus far made with this type of runner, is that of the Manitoba Power Company, installed last year consisting of three 28,000 h. p. vertical hydroelectric units with propeller type turbines, designed to operate at 138.5 rev. per min. under a net effective head of 56 ft. This corresponds to a specific speed of 153, English system. The runners of these turbines contain six blades and have an over-all diameter of approximately 16 ft. These units have indicated very clearly the remarkable characteristics of this type of runner, in particular, its ability to operate at normal speed under greatly reduced heads, with a considerable power output, the range of effective head being from 28 ft. to 56 ft. It is interesting to note, in this connection, that the runner of the Manitoba Power Company turbines is within a few inches of the same diameter as the Francis type runner of the turbines installed at the Cedars Rapids Plant on the St. Lawrence River, which were manufactured by the same company eight years earlier, but that the specific speed of the Manitoba turbines is practically twice that of the Cedars Rapids units, notwithstanding the Cedars units represented the highest specific speed obtainable at that time.

The subject of draft tube design is one which has caused a great deal of discussion in recent years and on which there is a considerable diversity of opinion. Numerous tests have been conducted for the purpose of determining the relative values of the different types, but as most of these tests have been made with model runners and tubes where slight variations in construction and setting of the tubes produced widely differing results, there still exists a great difference of opinion as to the most efficient form.

Discussion

A Study of Irregularity of Reaction in Francis Turbines

BY ROY WILKINS

Associate, A. I. E. E.
Pacific Gas & Electric Co., San Francisco, Cal.

Review of the Subject.—Irregularity of reaction in hydraulic machinery causing vibration has up to the last few years been of relatively little importance and treated as a more or less necessary evil.

With the advent of larger units, particularly for high heads, it became of prime importance that there be little or no vibration. In cases where vibration occurred, a cut and try system of remedying

it was usually resorted to and as little publicity as possible given the procedure.

For the study of such phenomena as vibration caused by irregularity of reaction manifesting itself in several impulses per second the electrical methods long since developed are admirably adapted and this paper gives a brief description of a successful method of study.

DURING the last few months there has arisen an occasion to study the hydraulic conditions causing vibration in some of the Francis type turbines on the system of the company by which the writer is employed.

Preliminary reconnaissance showed that these vibrations had a period in the order of the electrical frequencies commonly used and that for their study special equipment must be used which, so far as is known, had not been developed.

FIG. 1

There was accordingly developed somewhat hurriedly from parts available a device for converting pressure variations to electrical impulses and then viewing or recording these by means of an oscillograph.

As shown in Figure 1 a 1½ in. pipe union was used to hold a diaphragm of spring steel of a thickness such that at the maximum pressure used its deflection is still approximately proportional to pressure change. (Several well known gas engine indicators operate on

this principle and it is known to be trustworthy.) Rigidly attached to its center is an arm bearing on its outer end the center elements of two microphones of a variety used commonly in amateur wireless work.

The outer elements or shells of these microphones are rigidly attached by an insulating member to the union in such a manner that the supports are used as current-carrying terminals.

A third terminal grounded to the union makes electrical connection through the arm to the center elements of the microphones.

With the connections as shown the device forms an elementary bridge with microphones and batteries as members and an oscillograph element as a detector. The 2-volt batteries forming two arms of the bridge

FIG. 2

are so connected that they tend to cause current to flow through the oscillograph element in opposite directions so that as the diaphragm moves due to pressure changes we have a curve resembling an alternating-current curve traced on the oscillograph film proportional to and in correct sequence with the pressure changes back of the diaphragm. The device can be attached to any point that an ordinary pressure gage can and a ½ in. connection if comparatively short is more than ample to actuate it.

Using one of the portable oscillographs now available studies have been made on several turbines under varying conditions of load, head, gate opening, etc., with a view of determining the fundamental reason for vibration. It is known that the pressures across the face of a turbine runner opening vary both from top to bottom and from trailing to leading sides and

are dependent upon design characteristics as applied to running conditions.

As a check on probable values, tests were made using a Pitot tube traveling with the runner and passing to the center of the draft tube and out through a packing gland either to a pressure gage or the pressure indicator described above.

By filling this rotating tube with air under pressure and then closing, the supply air is trapped under the pressure of the water at the end of the tube and centri-

FIG. 3

fugal action and leakage are minimized. In this way the whole face of the runner entrance may be explored under actual running conditions.

Having established the fact that there is a difference in pressure on the water over the entrance of a runner bucket gives us a clue to the reason for the changes in pressure on the scroll case and penstock supplying it because as a low-pressure area in the runner is presented to the guide vane opening, the water velocity is augmented, while when a high-pressure area is presented the entering velocity is checked.

FIG. 4—5000 Kw., 220 LB., 450 REV. PER MIN., 19 RUNNER VANES, 20 GUIDE VANES. HUM APPARENT IN BOTH POWER HOUSE AND PEN STOCK. 15 OHMS IN VIBRATOR

This difference in pressure has been measured where the difference between leading and trailing sides of the runner entrance pressures was approximately 10 per cent of the total head on the turbine.

If we have a turbine in which the number of runner vane openings ($n - 1$) are one less than the number of guide vane openings (n) the openings will register successively around the scroll case each $1/(n - 1)$ revolution as a vernier backward from the direction of rotation.

This gives $(n - 1)$ impulses per revolution or the

revolutions per second times the number of runner vanes in impulses per second.

A difference of two in the number of guide and runner vanes gives two impulses traveling at half speed around the scroll case while combinations such as 20 and 17 gives irregular impulses. These combinations are best studied on small drawings to scale on cardboard, the runner portion of which may be rotated by hand.

Fig. 4 shows a pressure curve of a turbine having 20 guide vanes and 19 runner vanes with a timing wave of 60 cycles. This gives the Vernier action described above and the machine has a decided hum and a vibration which persists with gradually lessening intensity up the penstock 3600 feet to the forebay where it is scarcely perceptible.

FIG. 5—5000 Kw., 220 LB., 450 REV. PER MIN., 17 RUNNER VANES, 20 GUIDE VANES. NO APPARENT NOISE OR VIBRATION 15 OHMS IN VIBRATOR

Fig. 5 shows the curve from an identical scroll case with 17 runner vanes and a 60-cycle timing wave. In this case there is apparent neither hum nor vibration yet the curve shows just as high a hydraulic pressure variation which is, however, not regular.

FIG. 6—5400 Kw., 238 LB., 400 REV. PER MIN. NO NOISE OR VIBRATION. 15 OHMS IN VIBRATOR. 20 RUNNER VANES, 24 GUIDE VANES

Fig. 6 was taken on a turbine of somewhat older design and different specific speed and is almost ideal as regards hydraulic vibration. Just a slight wave may be traced which corresponds to the frequency we would expect.

Fig. 7 is an example of a combination of 18/16 and in operation this machine has a perceptible hum and vibration which persists up to the forebay 1600 feet from the turbine.

There are some conditions under which this is more pronounced than others due to the manner in which the water enters the runner.

Fig. 8 is a high-speed film on large ordinates of a record of a turbine with a 20/19 combination of guide and runner vanes taken to study the effect of the guide

FIG. 7—4600 Kw., 3.34 GATE, 83 LB. PRESSURE, 3.5-IN. VACUUM, 15 OHMS IN VIBRATOR, 18 GUIDE, 16 RUNNER VANES

vaness; a ripple corresponding to each guide vane appearing in the pressure wave.

Fig. 9 is a record of a traverse around the scroll case at the center of the runner opening taken with the

rotating pipe referred to above to see if pressure conditions were uniform around the entire circumference.

Little ripples caused probably by the scroll case guides, that is, the fins back of the guide vanes at points around the scroll case to direct the water into the guide vanes are evident though of no particular importance.

Fig. 10 shows the condition in a large somewhat elastic pipe line connected to a turbine having a uniform vibration. Here the pressure waves are influenced by reflection at the natural period of the penstock, by draft tube variations and by irregularity of flow in the penstock itself.

FIG. 12—12,600 Kw., 202 LB. PENSTOCK PRESSURE, 360 REV. PER MIN., 15 OHMS IN VIBRATOR

FIG. 13—3240 Kw., 60 CYCLES, PRESSURE SCROLL CASE 59 LB., PENSTOCK 72.8 LB. DRAFT TUBE $4\frac{1}{2}$, GATE $\frac{6}{8}$. RELIEF VALVE CLOSED. 20 GUIDE 16 RUNNER VANES

FIG. 14—4470 Kw., 60 CYCLES. PRESSURE SCROLL CASE 65 LB., PRESSURE PENSTOCK 65 LB., DRAFT TUBE $3\frac{1}{2}$, GATE $\frac{7}{8}$, 20 GUIDE, 16 RUNNER VANES

Fig. 11 shows a turbine in which the flow conditions are critical at a certain gate opening, that is, the pressure difference across the runner inlet face is greater at this particular opening than at others, though not serious on any.

Fig. 12 shows the same machine as Fig. 11 with a greater gate opening.

Fig. 13 shows a curve for a turbine on which abnormal conditions of head and load were imposed. The flow relations were unstable and were manifest in irregular vibrations or "shivers" of the unit.

Fig. 14 shows the same turbine under more nearly normal conditions.

The mechanical vibration was about in the proportion of the curves and there was very little hum on

account of the irregularity of pressure variations and the lack of elasticity in the equipment.

All of the curves shown have a 60-cycle timing wave for comparison.

OPERATION OF APPARATUS

In taking such records the so-called auxiliary data are of as much importance as the record itself and all conditions should be faithfully recorded in order to study and fully appreciate all of the changes made evident by a film of pressure variations.

Only ordinary precautions are necessary in using the apparatus such for instance as making sure that there is no trapped air behind the diaphragm, that all electrical connections are good and that the oscillograph is properly adjusted and handled.

The microphones are adjusted originally by disconnecting one microphone lead and observing the shift in the zero line caused by current through the one connected and then repeated with the other, adjusting until the shift is the same for each. The adjustment in the present device consists in moving the microphone shell in or out a small distance with respect to the *central* part fast to the diaphragm.

It is but a few minutes work to set up and observe the waves and changes in pressure waves may be watched while operating conditions are changed. Once adjusted, different points may be explored wherever a half-inch pipe connection can be made.

Nearly all of the cases studied have to do with the manner in which the water enters the runner and are fundamental in turbine design.

It is thought that the shock due to sudden changes in velocity of moving water has not been fully appreciated in many cases.

Using the ordinary formulas for surges and water hammer as given in Prof. Durand's *Hydraulics of Pipe Lines* it is seen that with 80 cycles per second, that is, 160 changes, there is required somewhat less than four one hundredths of a foot change in velocity per second to cause 100 lb. pressure change, provided all of this change were effective.

Elasticity in the scroll case and penstock and large clearances between guide and runner vanes together with the combinations of guide and runner vanes which set up conflicting pressures all tend to prevent the difference in pressure across a runner opening from causing high-pressure variations in the scroll case and penstock.

Certain design characteristics cause most of the energy in the water entering the runner to be in the form of velocity and therefore incapable of causing any of the phenomena observed. In other designs more reaction and therefore more pressure is necessary and greater care must be used in entrance angles and clearances.

The subject is as yet very new and very little concerning it is known. It is only hoped that such work as has been done may be of assistance in further study.

Discussion

EXPERIENCE WITH BEARINGS AND VIBRATION CONDITIONS OF LARGE HYDROELECTRIC UNITS¹

(HARISBERGER),

WATERWHEEL CONSTRUCTION AND GOVERNING²

(BREED),

A STUDY OF IRREGULARITY OF REACTION IN FRANCIS TURBINES²

(WILKINS) DEL MONTE, CAL., OCTOBER 3, 1923

R. Treat: The device which was developed by Mr. Wilkins, appeals to me as being applicable to investigations of other similar problems. It appears to be a very simple, and it is hoped, reliable device which may be used for determining among other things, the pressures in the interior of oil circuit breakers at the time of opening the circuit and the stresses which are brought to bear upon bus insulators at times of short circuit.

R. L. Hearn: As one of the staff to install and put in operation the first two 55,000 h. p. units in the Queenston-Chippewa station, I had an opportunity to closely watch the operation of these units for some time after they were put in service. While we did not find the vibration in these units to be of such magnitude as to be dangerous, yet it was there to such a degree that it has made us give this problem consideration. We found the vibration to be worse at part gate and were inclined to consider the draft tube to be the prime cause due to the unstable condition of the water column in the draft tube under part load. Mr. Wilkins has shown in his paper that vibration can come from other sources.

I would like to ask Mr. Harisberger whether he has considered the affect of the draft tube on the vibration found in the units which he discusses in his paper. I have in mind the condition we found with two different types of draft tubes which were installed on the Queenston plant on two wheels of identical design. One draft tube was of the bent tube type, while the other was a Moody type draft tube. In comparing the vibration in these two units we found very little difference at full gate opening, but at part gate there was considerably more vibration with the bent tube than with the Moody tube. This difference we contributed to the design of the draft tube.

In many of the recent large installations of vertical type Francis turbines, the upper portion of the draft tube immediately adjacent to the runner has been constructed of cast iron and has been so designed that it can be removed, thus allowing the dismantling of the runner from the lower side of the machine.

In many cases vibration has caused the cast iron section of the draft tube to loosen from the turbine casing and I believe it is the consensus of opinion, that it is advisable to concrete in this section of the tube in order to absorb the vibration and thus protect the draft tube from being shaken loose.

In order that the work of investigating problems, such as we have just been discussing, might be more effectively carried on, we should develop a spirit of cooperation between the operating companies and the manufacturers. So often in the past, it has been the case that the manufacturer delivers his equipment and after acceptance by the purchaser obtains very little knowledge as to the performance of this equipment during its operating life.

E. R. Stauffacher: I would like to ask a question in regard to the interpretation of a curve, Fig. 4 of Mr. Wilkins' paper. In the later part of the notation underneath the figure the statement is made: "Hum apparent in both Power House and Pen Stock." By reference to the curve it can be seen that it is quite regular.

In Fig. 5, you will notice: "No apparent noise or vibration." By referring to the curve you can see that it is quite irregular.

Am I right in interpreting these curves to mean that if the curve is regular, you have a source of danger, whereas, if it is irregular there is no danger?

Also, in reference to Mr. Harisberger's paper, as to the tech-

nique of determining the tone of the generator and the tone of the turbine, what method to determine pitch was used? Was it by means of a tuning fork, or just by the ear of this musical operator?

R. J. C. Wood: I would like to ask Mr. Wilkins whether any experiment was made by varying the speed of the machines slightly above and below the point at which he obtained these diagrams that he gives us, to see whether there was any resonance that might be in some portions of the casing or a water column of a length that would respond to certain frequencies, just as in some automobiles there is a certain speed at which the machine tries to vibrate itself to pieces, and below that speed you are comfortable, and also above it?

John Harrisberger: In reply to the question as to how the tone was arrived at, this was done by the chief operator of this particular station by tuning in on a keyboard of a piano in the club house, which is near the power house, so the hum can be distinctly heard.

As to Mr. Hearn's question—Was anything done, or any attempt made to correct the difficulty by changing the draft tube?—No, this particular unit has a single-runner double discharge turbine with boiler riveted steel draft tubes similar to that of the two other units which have given no trouble. As the vibration occurs only at partial gate, in the neighborhood of 3/10 to 5/10 opening, and as it is rarely that the unit is operated at this gate opening, we did not think it necessary to go to much trouble or expense to correct the difficulty. In fact, we have not had any very definite information to work from until Mr. Wilkins' paper was presented, which seems to me gives us something well worth considering.

I would like to ask Mr. Wilkins if all the runners considered in his paper were Francis runners?

John Sturgess: At one period in our forward progress some particular problem seems to be right in the lime light and demands first attention, and during that period some of the other problems are side-tracked.

Now, I feel that is particularly true in the case of vibration, because many years contact with hydraulic turbines leaves the impression on me that this problem was relatively more fully solved several years ago than it is today. It is almost an example of partial retrogression.

In 1898 I spent three weeks on top of a hydraulic turbine at Niagara Falls, where the vibration was quite severe. At that date, 1898, hydraulic calculations and engineering were very inadequate. The wheel was designed for 2500 h. p., but it accidentally developed 5000 h. p. The hand wheel for opening the gate was 18 in. diameter but before the gate could be opened it was necessary to strap to the hand wheel a 12-ft. beam with block and tackle at the outer end. While there was severe vibration in this unit, it was no worse, if as bad, as on some recent units, and I do not feel that this apparent retrogression is to be entirely accounted for by size of unit, or the head, for some of the new units were not materially different from the 1898 unit in respect to size or head. There has been recent discussion regarding synchrony between vanes and gates, but this was the subject-matter of discussion from ten to twenty years ago.

I would like to express a thought in regard to that part of Mr. Breed's paper illustrating the propeller type turbine, which, by the way I believe, if proper credit is to be given the original proponent, should be called the Kaplan turbine. It is obvious that the propeller type is nothing but the continuation to its logical conclusion of a process we have all gone through in developing high specific speed runners,—diminishing the inflow element and amplifying the axiflow element. It is easy to see that the complete elimination of the inflow element was the logical conclusion of this process. Yet it is called a "new" turbine.

Looking ahead, I expect to see for this type, before it is finally established as a standard, an entirely new type of gate developed.

The swivel gate, while obviously correct in connection with the inflow turbine, is illogical when applied to the axiflow type.

L. A. Barnes: In regard to the 2.5 in. which Mr. Wilkins took off the runner. I assume he took that off in small amounts at a time. If he did not I would like to ask how he determined that amount? And, if he did take that off a little at a time I wonder if he could tell the success that he had in the successive cuts, that is, whether it was progressive or whether he arrived at it all at once.

R. Wilkins: In answer to Mr. Stauffacher, Curves No. 5 and No. 6 were taken on identical scroll cases with different runners and under the same head on the same pipeline. On No. 4 there was sufficient noise to make talking difficult, that is, the hum was so loud that you had to raise your voice to be understood in the power house; this gradually decreased up the pipeline yet you could hear the hum at the penstock. With the seventeen vane runner in an identical scroll case just beside it on the same pipeline, there was no noise that you could hear at all. There was no vibration that you could feel with your hand, yet the hydraulic pressures inside the pipeline were just as violent as those in the other unit. Both these, however, are considerably smaller than some of the other curves. Fig. 13, for instance, gives no hum; it is not regular enough to give a hum and it didn't give an actual noise, yet that unit vibrated so that we were afraid to run it for fear it would shake out the bearings; it was put under different conditions and it toned down as is shown in one of the other curves. I would not say that it entirely stopped but the pulsations were not audible or perceptible, that is, it wasn't dangerous. These pressure pulsations in pounds per square inch are quite high and we don't know just what they do; which is the reason for the investigation, because of the things that we were afraid they might do.

In answer to Mr. Wood's question: As far as the frequency of the system would permit, curves were taken from as low to as high as we could get with the load. Without load these pressure variations are light because there is little water entering the runner and as you decrease the speed you change the conditions under which that turbine operates at a different head and it depends on head and load conditions where it is the worst. If it vibrates at all it vibrates over all speeds, but there is a place where conditions are the worst and this depends on the design, principally, of the runner.

In answer to Mr. Harrisberger: All runners, as stated in the title of the paper, were Francis runners. In fact, all the runners we have on the system are Francis runners and the pressure that is built up in them depends on their design and the amount of clearance between them and the guide vanes. It is the way the water enters the runner that causes the variation in pressure. If there can be obtained between the runners, even on runners not correctly designed, sufficient clearance to equalize part of the pressure, vibration will be cut down. On the runners in which we tried to correct the vibration we cut back as far as we dared. On a runner 105 inches in diameter, we cut back about five inches, 2½ inches on each side.

R. J. C. Wood: I would like to know whether Mr. Wilkins noticed any relation between the shape of the guide vanes in these different units and the degree of vibration hum, or the oscillations?

R. Wilkins: The guide vanes, so far as we could determine, had very little effect on the water as it entered the runner. We tested practically all of the types of guide vanes available, and found no difference.

In answer to Mr. Barnes: The cuts taken off were as much as we possibly dared take off, but I don't think that we have enough off yet. There were no preliminary cuts and there have been none since. It is quite a job to disassemble a unit of that size and to make the cut at the same time; it is quite a loss to a power company to have to put out of service a unit of 35,000-kw. capacity on which such work is being done. We did the best we could at one guess.

Recent Hydroelectric Developments of Southern California Edison Company

BY H. L. DOOLITTLE

Southern California Edison Co., Los Angeles, Calif.

THE important water power plants constructed by the Southern California Edison Company in the last two years are Kern River No. 3, Big Creek No. 8, additional high-head impulse units in Big Creek plants Nos. 1 and 2, and the new Big Creek No. 3 plant which will be placed in operation the latter part of this summer. This paper will review some of the outstanding features of interest that have been incorporated in this work.

THE KERN RIVER NO. 3 PLANT

In this plant are installed two 22,500-horse power vertical turbines operating under head of 800 feet. To date these are the highest head reaction turbines that have been constructed, although a contract is now under way for another company for similar units to operate under total head of 850 feet. A recent inspection of the Kern River No. 3 runners showed them to be in good condition after nearly two years of operation.

One novel feature of these units is that they were designed to operate at a frequency of either 50 or 60 cycles, this being due to the fact that the load to be supplied by this plant is in 60-cycle territory part of the year and in 50-cycle territory for the remainder. Every precaution was taken to make the changing of runners as easy as possible and a design was finally adopted which accomplished this result very satisfactorily. Acceptance tests of the equipment show that an efficiency of 90 per cent was obtained and that the 50-cycle runner gave practically the same efficiency when operating at either normal speed of 500 rev. per min. or the 60-cycle speed of 600 rev. per min. There was, however, a somewhat lower maximum output when operating at the higher speed. The 60-cycle runner showed the same efficiency at normal speed but was considerably less efficient at the 50-cycle speed.

While the good condition of the runners after this long period of operation is mainly due to proper design it is also partly due to the absence of sand and silt in the water. Realizing that sediment of any kind would be very undesirable with these high head turbines an elaborate sand box was constructed for precipitating all foreign matter from the water. This sand box is 80 feet wide and about 500 feet long, reducing the velocity to about one-half foot per second. After several months of operation the sand box was inspected and it was found that about six inches of fine silt had been precipitated in the lower half of the

box. This silt was so fine that forty-five per cent of it would pass a 150-mesh screen.

BIG CREEK NO. 3 POWER PLANT

The Big Creek No. 3 power plant which is now under construction will consist at present of three 35,000-horse power turbines operating under a head of 740 feet. There is nothing unusual about the design of the main units, although several special features have been worked into other parts of the plant.

At the intake to the tunnel for this plant a cylindrical gate 22 feet in diameter and 90 feet high has been installed for shutting off the water to the tunnel line. This gate is motor-operated and is installed in a concrete tower located two or three hundred feet up stream from the dam.

A surge chamber is being constructed at the lower end of the tunnel. This surge chamber is excavated from solid rock and has an hour glass section, the bottom diameter being 60 feet, the central shaft 25 feet and the top diameter 75 feet. This hour glass section was adopted on account of the wide variation in water level at the intake under normal operating conditions. The large section at the bottom provides for a load suddenly applied and the large section at the top will take care of any surge created by loads rejected.

Connecting to the outlet of the tunnel is an 18-foot steel pipe which terminates in a manifold providing connections for six 7-foot, 6-inch diameter penstocks. The design of this manifold, which will operate under a total head of approximately two hundred feet, offered many difficulties. After much study a design was finally developed which consists of two plate steel spheres joined by a short section of pipe. To one of these spheres the 18-foot pipe and two of the penstocks connect, the other sphere providing connections for four penstocks. The adoption of this type of manifold permits taking care of the excessive stresses in a very simple manner and has successfully solved a rather difficult problem.

Several novel features have been incorporated in the penstocks for this power plant. The entire pipe lines will be of forge welded steel. As the pipes are to be installed above ground, expansion joints are used between anchors. These expansion joints are made so that the portion of the pipe on which the packing bears is copper-plated to a thickness of about 1/16 of an inch. This will provide a perfectly smooth and non-rusting surface for the packing and it is expected that all future trouble due to leakage will be eliminated.

Presented at the Pacific Coast Convention of the A. I. E. E., Del Monte, Cal., October 2-5, 1923.

In a pipe line of this sort the friction on the supporting piers make necessary extremely heavy anchors at the bends. In order to reduce the size of the anchors to relieve the pipe of excessive longitudinal stress and also to facilitate erection, these pipes will be installed on cast iron rockers. Tests have shown that the friction will be reduced so greatly that a very large saving can be made in the cost of anchors and supporting piers. These rockers will be installed every 40 feet instead of every 20 feet as has been the custom heretofore with ordinary concrete piers.

In the power plant one of the important improvements that has been adopted is the elimination of an exterior lubricating oil system consisting of filters, supply tanks, pumps, piping, etc. It is felt that much more reliable operation will be obtained by simplifying the lubricating oil system to the greatest extent. The bearing on the water wheel and the generator bearings will be provided with gear-driven oil pumps which will pump the lubricating oil from a small sump below the bearings to the top of the bearings and thus keep it circulating continuously. Motor-driven pumps will also be installed, arranged to be started automatically in case the gear-driven pumps should cease to operate.

In the general arrangement of the station it is felt that a great improvement has been made, from an operating standpoint, by the elimination of the basement. The main floor of the generator room will be on two levels; about half of the generator room will have a floor on a level with the generator base and the other half will be on a level with the turbine. This will permit the maximum amount of equipment to be in view of the operators at all times.

VENTURI METERS

It is now this company's practise to install Venturi meters in all new hydraulic plants. The Kern River No. 3 plant was equipped with Venturi meters at the time the plant was constructed. Venturi meters will be installed on the three units for the Big Creek No. 3 plant and similar meters have already been purchased for the six units in the Big Creek No. 1 and Big Creek No. 2 power plants. The importance and value of a reliable meter for measuring the water supplied to a water wheel has been proved in many ways. At Kern River No. 3 the Venturi meters are constantly used by the operators in their effort to obtain the maximum kilowatt hours output from the water available. Some recent tests on one of the Big Creek impulse units showed that the difference

in output between a new and a somewhat worn nozzle was in the neighborhood of \$1,000.00 per month. As this amount is several times the cost of installing new nozzles it emphasizes the value of having a continuous check on the efficiency of the wheels.

DRAFT TUBES

The Kern River No. 3 turbines are equipped with the regular quarter bend draft tube. The turbine in the Big Creek No. 8 plant has a spreading type of draft tube while the new turbines for the Big Creek No. 3 plant will have a modified spreading type of tube which is supposed to embody the advantages of the regular spreading type of tube but is somewhat simpler to construct. As far as our experience goes we have been able to notice very little difference in the operation between any of the types of draft tubes that we have. This is undoubtedly due to the fact that all our turbines operate at very high heads so that any increase in efficiency due to the more modern tube is difficult to detect.

IMPULSE WHEELS

The impulse wheels installed by the company in the last two years do not embody any novel features, being duplicates of others that have been in operation for many years. We do have under way, however, a preliminary study of a new plant that will operate under a total head of 2400 feet. At the present time preliminary plans are being worked out for double over-hung impulse units for this plant which will have a capacity of 75,000 horse power per unit. These wheels will undoubtedly be the largest impulse units ever constructed from the standpoint of total output but on account of the high head will probably not be any larger in physical dimensions than the wheels in the Caribou plant of the Great Western Power Company. The chief difficulties to be overcome in the design of a unit of this size are the penstock and the water wheel and generator bearings.

RUBBER SEAL RINGS

For several months we have had in operation a small hydraulic turbine equipped with rubber seal rings. These rings have not been in operation long enough to definitely determine their practicability but it appears that when this type of ring has been fully developed it will have great possibilities. Arrangements are being made to try out these rubber rings on one of the turbines in the Kern River No. 3 plant. This trial will give some valuable information as it will be the first time this type of ring has been installed on a unit of this size.

Upper Falls Development of The Washington Water Power Company in Spokane, Wash.

BY L. J. POSPISIL

Associate, A. I. E. E.
Washington Water Power Co., Spokane, Wash.

Review of the Subject.—This describes a late hydroelectric development in the center of a city having a single vertical shaft generator and delivering its output to the busses of an existing distribution substation 350 ft. distant, the excitation and load control of the new generator being from the substation. The principal features of the development are the auxiliary devices to assure reliable operation of a remotely controlled unit and provision for an automatic shutdown of the unit in case of major trouble; also the

automatic by-passing of a large portion of the water used by the wheel if the load is greatly reduced or dumped. Other features are a 20-ft. diameter reinforced concrete penstock, a Moody spreading draft tube and a large concrete volute casing, reinforced against 110-ft. head; also 60 ft. by 15 ft. gates remotely operated, the operator having before him devices indicating gate travel and elevation of water level being controlled.

* * * * *

BEFORE the main features of the development that forms the subject of this paper are described, some mention should first be made of the prior developments to which the Upper Falls is an important addition.

The four earlier developments of The Washington Water Power Company totaling 125,000 h. p. as well as the one described, are all located on the Spokane River and utilize successively the same water with only a small additional inflow between plants.

Spokane River has its source in Lake Coeur d'Alene, a body of water some 42 square miles in area, where a storage and draw down of 5½ feet is possible. A few miles below the outlet of this lake is the Post Falls station which utilizes a head of 50 to 55 feet. At this station, the second one constructed by the company, are located the flood gates by which the lake level, except at times of flood, is controlled.

At Spokane, the next station downstream from Post Falls, there is a rare situation where a city of considerable size has been built up around a series of falls. Here the initial hydroelectric power developments, utilizing about 53 per cent of the total available head within the city, were begun in the very early days of the electrical industry and completed in 1904. This development, known as Monroe Street station makes use of the lower 73 ft. of the available head. The development of the upper head of 64 feet is the subject of this article.

The other two power plants of the company are at Long Lake, utilizing a head of 172 feet, and at Little Falls, which is immediately below Long Lake, where the head is 73 feet.

In addition, Spokane River water operates a part of the pumping equipment of the city of Spokane and the hydroelectric station of the Spokane & Eastern Ry. & Power Company located between Spokane and Long Lake. Unregulated flow of the Spokane River varies from a minimum of about 1200 cu. ft. per second occurring usually in October to a maximum so far

recorded of approximately 50,000 cu. ft. per sec. The mean low-water flow is about 1400 cu. ft. per sec.

Lake Coeur d'Alene in turn is supplied from mountain streams having their sources up to 6000 ft. in elevation. Precipitation is mostly in the form of snow and the annual flood, which reaches its peak between May 10th and June 5th is the result of melting snow and is usually over by the 15th of July. There is usually very little precipitation in the drainage basin between July 10 and September 15th and the inflow into Lake Coeur d'Alene from July 15th until the fall rains arrive is the yield from ground storage.

The Spokane plants have practically no storage in their forebays but there is most excellent storage in the forebay of the Long Lake station. Long Lake serves as storage also for Little Falls, which is hydraulically in series, and has power units of the same water capacity as the turbines at Long Lake.

After the passing of the summer flood the gates at Post Falls, which control the level of Lake Coeur d'Alene, are closed and a practically uniform load is carried by the units in this station. Because of lack of storage in Spokane the uniform flow released from the lake passes through unchanged to the forebay of the Long Lake station. This station and the one immediately below it take care of the daily variation in the load carried by the system.

Among the early installations at the Monroe Street station for lighting and power was the so called Edison 3-wire d-c. system to supply the principal business district, and 600-volt., d-c. current for street railway service, the generators being driven by direct-connected water wheels. These have been added to as the demand grew and since 1904 about 4300 kw. of direct-current energy has been produced at this station by water-driven machinery.

A dependable supply of direct-current energy for the Edison system and street railways having thus been in part assured by its production near the center of load, there still remained the problem of a dependable source of a-c. energy for power outside the economic limits of the Edison system and for residential lighting.

Up to the time of the complete Upper Falls development this a-c. energy was mainly supplied from outside plants by transmission lines which for the most part center in Post Street substation where there are also located the step-down transformers, additional motor-

it was agreed at once that the next development should be made in Spokane where all necessary water rights had been acquired many years previously and where is also located the principal loads on the company's system. Some physical features of the situation may

FIG. 1

FIG. 2—PROFILE ALONG MAIN AND MIDDLE CHANNELS OF THE SPOKANE RIVER THROUGH PORTION OF SPOKANE.
SCALE: HORIZONTAL, 1 IN. = 400 FT. VERTICAL, 1 IN. = 20 FT.

generators, lighting and power feeders, and feeders of the series street lights. To assure for these classes of services a dependable supply of a-c. energy its generation close to the point of feed was needed.

When in 1920 it became apparent that an additional supply of power would be required in the near future

be gathered from the map of Fig. 1, on which the location of Monroe Street station, Post Street substation and the company's office building are also shown. A profile, taken along the main and middle channel of the river, giving some idea of the elevations that exist here, is shown in Fig. 2.

Originally the south channel rejoined the main stream at the junction of the middle and north channels but this was dammed in the early history of the city and the water utilized to furnish the drive for a sawmill. This water-driven equipment remained in operation up to the time of the Upper Falls development. The water level in the end of the south channel is the same as at the branch of the main stream below Division Street. The shortest distance between the upper and lower water levels is from the end of this channel to the main stream at Monroe Street.

Making the development of the total head in one step was naturally considered first but this required a rather large tunnel of considerable length passing under important structures of other ownerships. Lack of room needed for the new station would have further required immediate abandonment of the Monroe Street station whose equipment, though somewhat obsolete and of low efficiency, still produces energy that can be provided otherwise only by large additional

4. Supply of excitation current and complete control of unit from a distribution station located 350 feet away.

5. Control works designed to pass a flood of 60,000 cu. ft. per sec. and partly under control of the system operator.

PENSTOCK

It was desired to pass a flow of 2200 cu. ft. per second and the conditions which influenced the selection of reinforced concrete were as follows:

The penstock was to connect a concrete headgate dam to a concrete volute casing in the power house.

It had to be constructed in an excavated rock cut, increasing in depth from a few feet at the headgate dam to over 20 feet near the power house. It had to pass for most of its length under a heavy wooden platform used for saw mill purposes, and under lumber sheds thus carrying a heavy fire hazard.

It had to pass under a double track steam railway line and it was desired to make it as resistant as possible

Fig. 3

capital investments in transformation equipment with its attendant losses. This would have also duplicated in part an investment already made and still possessed of additional useful life.

Location of the station at the point shown on the map and containing a single a-c. unit generating at the bus voltage of Post Street substation more nearly satisfied the requirements of service protection against interruptions, production of needed energy at the point of feed, a minimum of transmission and transformation, at the lowest cost for investment.

The principal points of interest of this development are as follows:

1. A reinforced concrete penstock 18 ft. in diameter and 370 ft. long.

2. A motor-controlled Johnson valve electrically interconnected with water wheel to open automatically and by-pass a large part of the river flow should the wheel load fall below a predetermined amount.

3. A vertical type water wheel having a concrete volute casing and Moody spreading draft tube.

to damage from accidental derailment.

Since the location would make maintenance and upkeep very difficult it was desired to make the construction of a type least subject to depreciation and decay.

Concrete reinforced with steel satisfied the above requirements to a greater degree than any other type available. Fig. 3 gives the principal construction details.

A few small leaks appeared when the penstock was first filled with water but disappeared after a few months time. There is every reason to believe that the type of construction selected could not have been better.

JOHNSON VALVE

It has been mentioned above that for a large portion of each year this station would utilize the full regulated flow of the stream. The tailrace of this station is the forebay of the older Monroe Street station, with pondage that would be exhausted in a few minutes time.

In case of a sudden shut down of the Upper Falls

single-unit Monroe Street station would cease operating for want of water before the gates at the control works could be opened and the released water reach the forebay through the main river channel.

To prevent this contingency a 9-ft. diameter Y branch was led off from the main penstock within the

from the control works arrives in sufficient volume.

Location of the valve, its shape and the supply line branching from the main penstock may be seen in the cross-section of Fig. 4, where this valve is shown open.

Operation of the Johnson valve is from a motor-driven Dean Control unit, the valve starting to open

FIG. 4

power house foundations to a 62-in. Johnson discharge regulator located so as to discharge into the tailrace of the station. Under the existing head it is rated to pass 1000 cu. ft. per second and this will keep Monroe St. station operating until additional water released

when the servo-motor piston has closed to within 0.25 of its travel and the valve will start to close when this piston has reached 0.4 of its travel in opening. Closed or open positions of the valve are indicated by green and red lights respectively in the generator room of the

power station and also in the System Operator's room in the company's office building. If it is desired to shut down the wheel without opening the valve this is accomplished by simply opening a switch in the motor circuit of the Dean Control unit. This arrangement functions splendidly and has been tried out a number of times within the past 9 months.

WATER WHEEL, GOVERNOR, CASING AND DRAFT TUBE

The vertical shaft type water wheel, designed to operate under an effective head of 64 ft. is rated at 14,250 h.p. and contains a cast iron runner of 11 ft. 7 in. maximum diameter, mounted on a steel shaft of 21 in. diameter and revolving at 105.8 rev. per min. A water lubricated lignum-vitae guide bearing, 6 ft. long, steadies the shaft just above the runner.

The volume of water of 2200 cu. ft. per sec. for which the wheel was designed, necessarily involved a large casing which would have made a casing of metal very expensive. The total head, static plus surge at the power house, was found to be close to 110 feet. The "speed ring" or distributor, made of cast iron, was not designed to take any appreciable tension and so it became necessary to reinforce the concrete surrounding the casing as a cantilever beam to resist the upward thrust of the water within the casing. Space does not permit a presentation of the design in detail but some idea of the reinforcement used may be obtained from the photograph of Fig. 5 taken before the concrete around the volute casing was poured.

FIG. 5

The peculiar shape of the draft tube, originated by Lewis F. Moody, Consulting Engineer for The Wm. Cramp & Sons Ship & Engine Building Company, builders of the water wheel, may be gathered from the cross-section of Fig. 4. The outlet of the draft tube is through two rectangular openings 19 ft. wide and 12½ ft. high separated by a pier 6 ft. thick.

The governor is the latest design double-floating, lever-type, belt-driven. It is provided with the Taylor Control System which permits of the change from governor control to hand control, and the reverse, to

be done by the oscillation through a small angle of a single lever which can be done in the fraction of a second.

GENERATOR, EXCITATION AND CONTROL

The generator, built by the General Electric Company is of the vertical shaft revolving field type, 3-phase, a-c., 60-cycle, 4200-volt, rated at 11,750 kv-a. and 10,000 kw., power factor 0.85.

The revolving weights of generator, water wheel, and hydraulic thrust due to runner amounting to a

FIG. 6

total of 188 tons, are carried by a General Electric Company's spring supported thrust bearing mounted on the generator upper bracket. This bearing is immersed in a bath of oil that is water-cooled and continuously filtered. The circulating oil pump is of the gear type, driven directly from the shaft but a similar motor-driven pump has been installed as an auxiliary.

Guide bearings, supplied with forced lubrication, are placed on generator shaft both above and below the rotor. The generator is provided with air-operated brakes which assist in bringing the rotor to a stop. These brakes are also arranged for a supply of oil from a hand pump up to 1500 lb. pressure which will lift the total suspended weight and thus relieve the thrust bearing.

The generator rotor is equipped with fans for forced air circulation through the stator windings. Supply of air is taken from the outside through an air washer of 50,000 cu. ft. per minute capacity. Air may also be taken in part or totally from the generator room and recirculated.

In the station with the generator are two gear-type oil pumps one of which is driven by an a-c. motor and the other by a d-c. motor, supplied from the Edison System, thus assuring reliability of fluid pressure supply to the governors; also oil pressure and sump tanks for the servo-motors, and a motor-driven, two-stage air compressor connected to a receiver. Air is used in the oil accumulator tank and for the air brakes under the generator rotor.

Here are also located an indicating thermometer showing the temperature of the thrust bearing and a flow

meter showing the quantity of water supplied to the lignum-vitae guide bearing.

The generator mains consist of three, 1,250,000 cir. mil. lead-covered, paper-insulated cables per phase laid in fiber duct embedded in concrete. As there are duplicate feeder busses in Post Street substation to which this unit is connected there are also two circuit breakers, one to each bus, each with its usual complement of disconnecting switches.

An attendant is kept continuously on duty at the power station and he is depended on to look after governor operation, oil pumps and air compressor, water supply to lignum-vitae guide bearing, air washers, and similar tasks. He starts the wheel and brings it up to part speed before turning it over to the switchboard operator at the Post Street substation and also has control of the Johnson valve separate from the interlock with water wheel gates. A Klaxon horn actuated from a pressure gage is used to warn the attendant should the supply of water to the lignum-vitae guide bearing fail for any reason. By means of a controller located in the power station the attendant can also close the head gates of the penstock that supplies this unit.

The motor-driven exciter and the generator field rheostat used for field excitation of the main unit are located at Post Street substation. Should this supply of energy fail an auxiliary supply may be had from the Edison mains connected to a storage battery floating on the system.

Location of the main generating unit of the size of this one in a separate building some distance from the point of control naturally necessitated a number of safeguards to assure reliability of service and to protect the equipment from damage. It is hoped that a brief description of some of them will be of interest.

The generator is Y-connected and, as is now common on generators of like capacity, differential relays have been provided to open the circuit breakers in case of trouble within the machine itself or in the cables leading to feeder busses.

As already explained the power station attendant is relied on to look after governor operation, oil pumps for governor pressure system, and water supply for cooling and lubricating purposes.

Operation may be interfered with, in addition, through any of the following causes which, though they do not require an immediate shut down of the wheel, need to be brought at once to the attention of the switchboard operator at Post Street substation.

Heating of the thrust bearing or guide bearings; failure of supply of lubricating oil to generator guide or thrust bearings; the breaking or slipping off from pulleys of the governor belt.

Warning is given through the ringing of a bell and the lighting of a signal lamp at the Post Street substation switchboard.

Thermal relays, normally closed, are inserted in each

of the three generator bearings. A small current is kept circulating through this relay circuit and keeps open, by means of a solenoid switch, an auxiliary circuit containing the bell and light. Should any of the bearings become over-heated this relay will open the circuit. This will de-energize the coil holding open the switch in the auxiliary circuit and thus give the alarm.

Warning of the failure of flow of lubricating oil to the three bearings is given by closing the alarm circuit connected to Richardson-Phenix sight flow indicators, one in each of the supply lines to these bearings.

On the governor belt drive there is a tightener pulley mounted in the small end of a bell crank lever. Pressure against the belt is exerted through the bell crank lever by means of a weight. A switch of an auxiliary circuit, normally open, is mechanically connected to the bell crank lever. Should the belt break or climb off the pulleys the weight will move the bell crank lever far enough to close the switch in the auxiliary circuit. This will in turn effect a closure of the alarm circuit, thus causing the alarm to be given.

A balance coil meter having a scale showing percentages is located in Post Street substation. This is electrically connected to a rheostat in the power station, the rheostat being actuated by a mechanical connection with the water wheel gates. As the gates open resistance is cut out which causes the balanced coil meter at Post Street substation to indicate corresponding gate openings. Thus the switchboard operator can tell at all times at just what gate openings the wheel is working.

It has been mentioned that air-actuated brakes are provided to assist in bringing the rotor to a stop. A rapid or slow application of the brakes may be made. There are two parallel air supply lines, each one controlled by a solenoid-operated valve, leading to these brakes. One of these lines contains a small orifice which has a throttling effect on the air supply. This will cause a slow application of the brakes and a relatively slow shut down which does not cause rapid wear of the brake shoes. This is normally used. The other supply line contains no restriction and its solenoid-operated valve is opened by a solenoid in a circuit interlocked with the differential relays. It is considered that if the differential relays act it is the result of serious trouble requiring a rapid shut down. In that case the application of the brakes is rapid so that the rotor is brought to rest very quickly. Provision is also made for applying the air to the brakes by means of a hand-controlled three-way valve.

CONTROL WORKS

In order to obtain the maximum possible head throughout the entire year it was necessary to install gates to maintain a practically constant forebay level and pass a flow varying from nothing to an amount in excess of the maximum measured since records have

been kept. Since the forebay extends through a portion of the city it was desired to have means showing the water level at all times and for quickly passing a large volume of flow should the water wheel suddenly lose its load for any reason.

The arrangement adopted was the installation of two motor operated "Rolling Sector" type gates each 60 ft. wide and 16 ft. high, operated either from a control house located on one of the abutments or by the system operator in the office building. Also the provision of four 40-ft. by 11-ft. openings, each closed by five vertical lift gates supported by adjacent piers and four top-hinged girders. One of the rolling sector gates is normally held in reserve while control for a flow up to about 9000 second feet is exercised by the second rolling sector gate. Flows in excess of this are normally passed by clearing the 40-foot openings as needed. A plan of the Control Works is given on the map of Fig. 1 and in Fig. 6, taken when a moderate flood was passing, shows the works with one sector gate open and the other closed.

Each sector gate is operated by a 15-h.p. series d-c. motor mounted in the middle of a bridge spanning between gate piers and controlled either from a drum controller or from a contactor panel, both being contained within a house on one of the gate abutments. Connecting one gate motor through selector switches to drum controller connects at the same time the other gate motor to control by contactor panel. Both systems of control give dynamic braking in lowering and in the off position.

Motor rheostats have been adjusted so that the current on the first point of the rheostat is about three times the value of normal load current. This assures

operation even if the contactors should fail to short out the succeeding resistance steps. In lowering there is only one resistance adjusted to suit over-haul of gate.

The contactor panel may be operated from either of two parallel double-throw knife switches one of which is mounted on the contactor panel itself and the other one is in the system operator's room in the office building located some 3000 feet from the gates.

The system operator has mounted above the remote control switch a gate position indicator which shows at once any travel of the gate. Should the indicator fail to show a change in gate position a few seconds after the control switch is closed it is evidence that motor has failed to start and the switch can be opened to prevent burning out of motor and shortly another trial made. Should the supply of power fail for any reason a double acting breaker opens the control circuit and closes the motor circuit for dynamic braking. This breaker may be reset by a switch in the system operator's room as soon as power is restored and the gate again operated in the direction desired.

There are two power supply circuits for the motors partly under ground and partly overhead, one directly from Post Street substation and one from the Edison mains serving the district adjacent to the Control Works. This arrangement has been found satisfactory in practise and has made it possible to dispense with continuous attendance at the Control Works.

The Upper Falls development was designed and constructed under the general direction of V. H. Greisser, Chief Engineer, assisted by H. L. Melvin, in charge of electrical features and the writer in charge of mechanical and structural work.

High-Voltage Switches, Bushings, Lightning Arresters

Experiences of the Southern California Edison Company on its 60,000, 150,000 and 220,000-Volt System

BY HAROLD MICHENER

Associate, A. I. E. E.

Southern California Edison Company, Los Angeles, Cal.

Review of the Subject.—This paper describes the experiences of the Southern California Edison Company with oil switches on its 60-kv., 150-kv. and 220-kv. systems, with air break switches on its 220-kv. system, with bushings on its 60-kv., 150-kv. and 220-kv. systems, and with lightning arresters on all voltages from 11 kv. up.

In some instances the experiences do not lead to unquestionable conclusions. This is particularly true in the case of lightning arresters. More nearly complete information in regard to actual occurrences will aid in drawing definite conclusions.

* * * * *

SWITCHES

FOR many years the Southern California Edison Co. has been equipping its 60-kv. system very largely with western made oil switches. As the system has grown it has been necessary to increase the capacity of these switches. The first switches were made with three rectangular tanks, each tank having two horizontal breaks in series. The next step consisted of increasing the size of each rectangular tank and putting four breaks in series. And now we are installing switches, each consisting of three cylindrical tanks with round top and bottom and each tank having six or ten horizontal breaks in series. The rupturing capacity of these switches has never been known, but they have handled the job with a fair degree of satisfaction. Of course, the changes in design have been forced by increases in system capacity, which have proved the type in use to be inadequate. And it is not known how long the present type will be adequate.

In addition to the switches of local manufacture there are a considerable number of 60-kv. switches on the system which were furnished by eastern manufacturers. These switches, in general, have given good results, but it seems impossible to draw any reasonable conclusions in regard to whether the performance of the locally made switch is better or worse than the eastern made switches.

It would be very desirable to make comparative tests of oil switches under conditions similar to those under which the switches operate, but these tests would be very difficult to arrange.

It seems quite certain, however, that the capacity of the 60-kv. system can not be indefinitely increased. Although it may be physically possible to make oil switches which would not blow up when opening automatically under severe short circuits, their cost would be greater than the earnings would justify. This situation will probably be avoided by dividing the system into two or more partial systems and by the judicious use of the current-limiting reactors.

Presented at the Pacific Coast Convention of the A. I. E. E., Del Monte, Cal., October 2-5, 1923.

The 150-kv. oil switches on the Big Creek system have given good satisfaction as non-automatic switches. The method of operation has been such that automatic opening has not been required. The greater number of these switches have been in operation since 1913. They were furnished by two large eastern manufacturers.

The 220-kv. oil switches which were put into operation at 220-kv. on May 6th, 1923, have not been allowed to operate automatically up to the time of writing (June 20th, 1923). However, it is intended that

FIG. 1

they shall operate automatically to drop out a section of line which may be in trouble.

These switches were furnished by two large manufacturers. Aside from minor defects due to careless workmanship, or careless details of design, these switches have given satisfaction during the brief period they have been in operation.

There are three types of air brake switches in use on the 220-kv. system, namely, disconnecting switches for the oil switches; line-sectionalizing switches, and line-paralleling switches, the two latter types being used at line crossover stations other than those equipped with oil switches.

The disconnecting switches on either side of the 220-kv. oil switches are mounted on the tops of insulator tripods which in turn are carried on the top of steel frame-work. (See Fig. 1). Each leg of the

tripod consists of fourteen insulator units and has a total length of seven feet. The insulator unit is made up by cementing pillar type hardware to the porcelain of a standard 10-in. suspension insulator and the units are bolted rigidly together.

The switch blade is 10 ft. 6 in. long from the hinge to the jaw end and is composed of two pieces of 1¼-in. copper pipe joining at the jaw end and spread apart at the hinge end. The blade also extends back of the hinge to form a lever to which the operating rod is attached. The jaws are solid without any spring. The contact part of the blade is formed of two parallel copper straps which have considerable spring in them. These copper straps are drawn together or forced apart by a cam mechanism which in turn is operated by a rod which extends above the blade of the switch, past the hinge end to the operating rod. The operating rod consists of a fourteen-unit pillar type insulator and a rod extending to the ground, where a bell crank and operating handle complete the mechanism.

In opening the switch the first few inches of movement of the operating handle pulls the blade straps

Fig. 2

together enough to free the blade in the jaws. Further movement of the operating handle swings the blade upward. In closing, the blade reaches its closed position and then the last few inches of travel of the operating handle forces the blade straps out against the jaws. The blade is counterweighted to make the operation easy. The clear opening of the switch is approximately 8 ft. 1½ in.

The line-sectionalizing switches take the place of the jumper loops in a dead-end tower and are in reality two switches in series, each switch blade when closed short-circuiting a string of eight pillar type insulators; the string length being about 4-ft. (See Fig. 2). This gives two 4-ft. openings between a live section and a dead section of line.

These switches are not to be operated except when

Fig. 3

the line is dead. The operating is done by means of a switch pole from a platform built into the tower.

The paralleling switch, Fig. 3, is placed between the lines with a set of sectionalizing switches in each line on each side of it, thus making four sets of sectionalizing switches and one set of paralleling switches for each crossover station.

Each single-pole paralleling switch consists of a pipe switch blade which bridges across a horizontal diamond of four strings of strain insulators (standard suspension insulators). The grounded corners of this diamond are supported on steel poles. The other corners are carried by the conductor of the crossover connection. The switch is operated through a 6-ft. column of twelve pillar-type insulators and a rod reaching to a bell crank and operating handle located on the ground. The switch blade opens upward and will break the current passing across it when the lines are still in parallel at another point, provided that the wind is not blowing too hard. In one instance when the wind was blowing hard the arc went to ground on the

inadequacy of records makes it almost impossible to say whether arresters are or are not worth the money invested in them. The fact that they are installed shows where the predominant opinion lies.

The 150-kv. system was completely equipped with electrolytic arresters until about a year ago, with the exception of a considerable period some years ago when the arresters at Big Creek No. 2 were out of commission. Since about a year ago the arresters have been taken off the lines as the 220-kv. construction work made that necessary, and the fire at Eagle Rock eliminated those at that station. The fire brought forth the decision to permanently abandon the use of lightning arresters on the 150-kv. stations at Big Creek No. 1, No. 2 and at Eagle Rock, where the arrester tanks were inside the buildings. It had previously been the intention to leave these arresters in service, although the lines had been changed to 220-kv. It has not definitely been decided whether or not the outdoor arresters at Vestal will be re-installed.

On the 150-kv. lines there have been only two or three cases of trouble due to lightning, one of these was at Eagle Rock after the 150-kv. arresters had been removed. A 150-kv. insulator inside the building flashed over during a storm which was causing trouble on the 60-kv. and 15-kv. lines out of the same station. Another case of trouble attributed to lightning occurred on the 150-kv. bus connection inside the building at Big Creek No. 1, when the arresters were connected to the lines and apparently in perfect working conditions. At Big Creek No. 2, it was reported that the arresters discharged heavily at a time when lightning struck so near that the operators thought the building had been struck.

The arresters on the 150-kv. lines always discharged when 150-kv. line switching was being done. The statement is often made that arresters are not needed on 150-kv. and 220-kv. lines as a protection against lightning, but what will these voltage surges, which cause the lightning arresters to discharge during switching, do if the arresters are not there? The answer is, even though these voltages are high enough to jump the arrester gaps, they are not high enough to damage the station equipment. The fact that Big Creek No. 2 operated for many months without arresters indicates this. And some recent studies made with a surge recorder on the 150-kv. lines indicate that switching of a 100-mile section of line does not produce surges of more than 200 per cent normal voltage. These studies were made at Eagle Rock while the 150-kv. arresters were in service, however.

At Vestal, near the middle of the 150-kv. line, there were two cases of 150-kv. transformer insulation breakdown. The transformers were old and the insulation was admittedly of a quality inferior to that used in modern transformers. Yet the extreme thickness of insulation punctured made it difficult to believe that inferior insulation could be the cause of the failure. Perhaps high voltage did it, but the 150-kv. lightning arresters were in service, having very advantageous connections to the 150-kv. lines.

On the 220-kv. lines there are no lightning arresters and there probably never will be.

In regard to the types of arresters used by this company, the electrolytic arresters, which, until the last two or three years, have been considered the only arresters at all adequate for station service, have several faults, one of which is that they require expert maintenance, which often they do not get. Another fault is the fire hazard.

The oxide film arrester has become popular and this company is installing many of them on voltages of 60-kv. and lower. Thus far they have given no trouble and it is assumed that they will give at least as good protection as the electrolytic arresters. There is apparently no fire danger from them and this is greatly to their advantage. The maintenance promises to be very low. There has been one case of a discharge throwing some of the active material out of a stack of the disks. Examination showed that there had been many discharges through this stack. This discharge occurred at the time of a heavy short circuit on the system and the arrester was located in the heart of the system.

There is only one installation of the autovalve arresters of the distribution type on the system. This is on a 15-kv. line on Mt. Wilson at an elevation of 5000-ft., and though it is not definitely known to have functioned, at least one lightning storm has occurred on that part of the system since its installation.

The graded resistance type of lightning arresters have been installed on 11-kv. lines at several stations during the last two years. These have given no trouble to date and have functioned satisfactorily in several instances.

There is one installation of the Water Column Surge Arrester on the system. It functions properly when an arc is formed intentionally across the horn gap, but that is all that is known of it as yet.

Discussion

High-Voltage Circuit Breakers

BY A. W. COPLEY

Assoc. A. I. E. E.

Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

Review of the Subject.—The 150-kv. system operated for some years by the Southern California Edison Company has not made use of automatic operation of circuit breakers. The multiplication of generating stations and connections which accompanied the change to 220-kv. makes desirable the automatic section-

alizing of the line in cases of trouble and, therefore, requires circuit breakers for automatic operation similar to that obtained on more moderate voltage systems. Circuit breakers have been manufactured for this service with high rupturing capacity and the designs have followed closely the standard designs for more moderate voltages.

IT has been standard practise for some time to take care of fault conditions on moderately high-voltage lines of about 110,000 volts by the automatic operation of the high-voltage circuit breakers.

On the 150,000-volt circuits which have been operated for several years by the Southern California Edison Company high-voltage circuit breakers have been in service but have not been tripped automatically on the occurrence of trouble but, instead, there has been utilized a scheme of clearing high-voltage trouble by means of lowering the line potential.

In the case of flashovers this scheme has been efficacious. The operation has been entirely manual, the power house operator cutting in field rheostat by hand upon obtaining indication of ground current as shown by an ammeter connected in the neutral of the step-up transformers at the power house. With two power houses in service it has been necessary for the operators at the two plants to cut in field rheostat at the same time and approximately at the same rate. This has been found to be quite feasible.

With the growth of the system, involving increases in the number of power plants and generating units, and with the growing importance of absolute continuity of service, it has been considered desirable to carry out a scheme of breaker operation similar to that used on the moderate voltage systems.

The 220,000-volt double-circuit line, which has this year been put in service by the Southern California Edison Company, has, therefore, been provided with automatic high-voltage circuit breakers and a relay system to give proper sequence of breaker operation on the occurrence of trouble. The lines from the Big Creek Power Houses to Los Angeles are sectionalized at two intermediate points by means of 220,000-volt circuit breakers and upon the occurrence of a flashover or other trouble on any section the particular section in trouble is separated from the rest of the system by the operation of the sectionalizing circuit breakers.

The Pacific Gas & Electric Company, in laying plans for their 220,000-volt lines, running from Pit River to the San Francisco district, have likewise provided high-voltage circuit breakers and relays so as to give automatic operation in case of line trouble.

Presented at the Pacific Coast Convention of the A. I. E. E., Del Monte, Cal., October 2-5, 1923.

The desirability of this automatic breaker operation is self-evident, as it insures a maximum speed in the clearing of troubles and a minimum loss of service. With two parallel circuits there should be no interruption of power at the receiving end, under any circumstance, unless both lines are simultaneously in trouble. Operation of the more moderate voltage lines, in various parts of the country, has demonstrated that dependable relay operation for the automatic opening of circuit breakers is obtainable.

The problem confronting the engineers, in carrying out this method of operation, is therefore largely the design and manufacture of circuit breakers which would successfully handle the rupturing capacities required on these high-voltage lines. Such design and manufacture has been carried out and the circuit breakers for this service are now installed. In carrying out the design, it is noteworthy that no radical departure was made from the construction used in breakers for more moderate voltage service.

Circuit breaker tanks have been made larger and heavier in order to give the greater clearances required by the high voltages and to care for the heavy rupturing capacities called for. The actual contact parts for the 220,000-volt circuit breakers are practically identical with those of the larger moderately high voltage breakers. Solenoid operating mechanisms energized by direct current are employed in both types of breakers.

Bushings, for carrying the high voltage into the breaker tanks, are a continuation of the standard lines of design, both condenser type and the oil-filled type of bushing now being in service at 220,000 volts. All of the bushings have been made of the outdoor type with porcelain shields provided to protect against the weather. Bushing-type current transformers provide means for current measurement and relay protection. The bushings are made interchangeable with transformer bushings for the same voltage service and the insulation tests on breakers have been brought into line with the reduced tests on transformers, arrived at by consideration of the effect of the solidly and permanently grounded neutral of the system.

It has been necessary to determine the rupturing capacities of these high-voltage circuit breakers by calculation from certain determining data such as the strength of tanks, the amount of oil, the depth of the

contacts under the oil and the speed of moving parts or arc extinction and up to the present it has not been possible to make actual tests of these rupturing capacities.

Such tests, however, have been made on the similarly designed breakers used on 110,000-volt circuits and these tests have contributed empirical data which gave assurance that the 200,000-volt circuit breakers will take care of the rupturing capacities specified.

These rupturing capacities are considerably in excess of any current which they may be expected to be called upon to open until the systems on which they have been applied have grown still larger and more generating capacity has been installed.

Discussion

For discussion of this paper see page 1025.

Magneto-Mechanical Loads on Bus Supports

BY LLOYD N. ROBINSON

Associate, A. I. E. E.
Stone & Webster, Inc., Seattle, Wash.

Review of the Subject.—Current progress in electrical development and the increasing capacity of power systems has brought into prominence many factors of mechanical strength that were previously negligible in the design of electric stations and circuits. Heavy currents, that may develop during short circuits in stations that are connected to large generating systems, make it essential that bus and cable supports be strong mechanically as well as adequately insulated. Formulas are given for estimating the forces that may be developed under various conditions with different arrangements of conductors and supports.

The mechanical strength of bus and cable supports should be guaranteed by manufacturers and tested as well as the insulating qualities. In order to facilitate the selection of bus and cable supports, it is desirable that uniform terms for expressing the various kinds of loads, standard methods of conducting tests and a minimum factor of safety for mechanical strength be adopted.

THE successive improvements in the insulation and control of high-voltage circuits are the means of ever increasing the scope and capacity of electric power systems. This progress demands the solution of innumerable problems and naturally most of the factors entering these problems are of an electrical nature. However, one outstanding feature of the electrical development of the past decade or so, has been the increasing prominence of mechanical factors that were previously negligible in electrical station and circuit design.

Special attention is now given to the matter of anchoring and bracing generator and transformer windings. Safety catches are now a necessity on most disconnecting switches. And the oil circuit breaker is finally rated on the basis of its capacity to perform its originally intended function, namely to interrupt current. Numerous other cases might be cited but the above indicate the growing importance of mechanical features in the design of electrical apparatus and circuits.

In small stations, and especially in those that are blessed with double busses, the failure of a bus support may not involve a serious interruption of service nor a considerable expense for repairs. But in large stations, where every interruption of service is serious and

the breakdown of a bus is practically certain to entail costly repairs, it is doubly essential that busses be strong mechanically as well as adequately insulated.

As a rule bus supports must be spaced at such frequent intervals in order to prevent sagging of the conductors and the usual types appear so rugged compared to the weight of the conductor supported that, to a casual observer, there seems little reason to question their adequacy as mechanical structures. However, a brief computation of the magneto-mechanical forces, that may develop between parallel conductors in medium sized and large stations especially during short circuits, shows that these forces are far from negligible.

This has been recognized for some time and formulas and curves for estimating the forces involved have been published¹ so it does not seem necessary to present a complete discussion of the fundamental principles at this time, but merely to give some convenient formulas for the more common cases. The present purpose is rather to emphasize the fact that it is becoming more and more important to ascertain the mechanical strength of bus and cable supports for inside station wiring and to point out that there is room for standardization in this respect.

The magneto-mechanical phenomenon produced by

¹C. P. Steinmetz, TRANS. A. I. E. E., 1911, p. 367.

H. B. Dwight, *Electrical World*, Sept. 1917, p. 522.

S. G. Leonard and C. R. Riker, *Electric Journal*, Dec. 1917, p. 491.

electric currents in parallel conductors is fundamentally the same as the basic reaction in an electric motor. It can be thought of as the attraction, or repulsion as the case may be, between the current in one conductor and the magnetic field set up by the current in the other conductor or, perhaps more conveniently, as the force between the magnetic fields set up by the two currents.

In the design of motors and similar machines involving alternating currents the chief interest lies in the average force developed. But, in dealing with the mechanical requirements of bus supports, we are interested primarily in the maximum instantaneous force that may be developed.

The instantaneous force, corresponding to instantaneous currents, i_1 and i_2 in parallel conductors, is

$$S = \frac{5.40 i_1 i_2}{10^7 D} \text{ lb. per ft. of parallel}$$

FIG. 1—TYPICAL CROSS-SECTION OF THREE-PHASE BUS

where D is the interaxial distance in inches between the conductors. This is the general formula for the determination of the magneto-mechanical force exerted upon a conductor of electric current due to the proximity of another parallel current. In parallel conductors, currents flowing in the same direction attract each other, tending to draw the conductors together, and currents flowing in opposite directions repel each other, tending to force the conductors apart.

The derivation of the formulas that apply for certain arrangements and various conditions on direct-current and alternating-current busses are given in the Appendix in sufficient detail so that formulas may be derived readily for special arrangements of conductors or groups of busses and for other than single-phase and three-phase circuits.

It is seen from the formulas in the Appendix that, for one three-phase bus having its conductors arranged in a plane, the maximum stress on a conductor will be developed when two adjacent conductors are short-circuited. Then

$$S = \frac{2.62 I_3^2}{10^6 D} \text{ lb. per ft. of parallel (repulsion).}$$

For example, in a station where the symmetrical three-phase, short-circuit current for a short circuit

FIG. 2—TYPICAL CROSS-SECTION OF THREE-PHASE BUS

on the main bus is 30,000 amperes, and the conductors are arranged in a plane 18 inches apart on centers, the force of repulsion between two adjacent conductors when they are short-circuited may become

$$\begin{aligned} S &= \frac{2.62 (30,000)^2}{18 \times 10^6} \\ &= \frac{2.62 \times 900}{18} \\ &= 131 \text{ lb. per ft. of parallel.} \end{aligned}$$

FIG. 3—TYPICAL CROSS-SECTION OF THREE-PHASE BUS

If the bus supports along each conductor are spaced 27.5 inches apart, the corresponding force on each support will be

$$\begin{aligned} F &= \frac{27.5 \times 131}{12} \\ &= 300 \text{ lb.} \end{aligned}$$

If the conductors of the three-phase bus in the above example are arranged as in Fig. 1 and two adjacent conductors are short-circuited, the repulsion between these two conductors will result in a tensile force of 300 lb. on each bus support of the upper one, and a compressive force of 300 lb. on each bus support of the lower one; and the bus supports should have ultimate tensile and compressive strengths of not less than 1200 lb. if the factor of safety is 4.

On the other hand, if the conductors in the above example are arranged as in Fig. 2 or Fig. 3 and two adjacent conductors are short-circuited, the repulsion between these two conductors will result in a load of 300 lb. on each bus support as a cantilever beam. If the height of the bus support is such that the distance from the bottom of the base to the axis of the conductor is, say, 7.5 inches, the cantilever load will be

$$7.5 \times 300 = 22,500 \text{ pound-inches.}$$

And, if the factor of safety is 4, the ultimate strength of the bus support as a cantilever beam should be not less than 90,000 pound-inches.

After determining the magnitudes and character of the loads involved and the ultimate strengths required, the next step is to select bus supports of adequate mechanical strength. In this, reliance must be placed upon the experience of the manufacturers with their various types and sizes of supports. But it is clear that mechanical strength, as well as insulating qualities, should be guaranteed; and, in view of the inevitable variations from time to time among porcelains, it is only fair that at least a reasonable percentage of the supports covered by the order should be tested under specified types of mechanical loads up to the guaranteed ultimate strength.

In order to facilitate testing and to put the matter on a uniform basis for the benefit of the manufacturers as well as for the convenience of purchasers, it seems highly desirable that the field be canvassed and standards adopted because there now are considerable divergencies among manufacturers as to the meanings of terms and methods of test.

For instance, some manufacturers test the complete bus support and some test only the porcelains. It is clear that the complete support should be tested because metallic bases and clamps have been known to fail earlier than the porcelains, also because the method of clamping or cementing the metallic parts to the porcelain sometimes determines the breaking point of the porcelain especially under a cantilever load.

Tensile and compressive strength should mean strength in carrying loads applied along the line joining the centers of the base and bus clamp, and not refer to tension or compression along the axis of the bus.

At present, some manufacturers express the ultimate mechanical strength as a cantilever beam in pound-inches and others express it in pounds without giving

the length of the lever arm or radius. It is clear that the former is the preferable way because the strength of the bus support should be independent of the dimensions of the bus except in so far as the latter affects the size of the clamp.

Whether the factor of safety should be 4, based on the ultimate strength of the support, is somewhat a matter of opinion and judgment. But, as in machine and structural design, it is desirable to have a standard minimum factor of safety. In view of the metallic parts used and the variations in the quality of porcelain, it does not seem wise to use a factor of safety much less than 4.

There are undoubtedly other phases of the subject that might be standardized but only a thorough canvass of the field can bring out all of them.

Appendix

D-C. CONDUCTORS

In a direct-current bus, consisting of two conductors carrying equal currents, I , in opposite directions, the stress exerted by each conductor upon the other is

$$S = \frac{5.40 I^2}{10^7 D} \text{ lb. per ft. of parallel (repulsion)}$$

where D is the perpendicular distance in inches between the axes of the conductors.

The value of the current, I , that will develop in the case of a short circuit on a direct-current bus, will be determined by the generating capacity connected to the system and the equivalent resistance of all the paths feeding into the short circuit combined.

A-C. CONDUCTORS

In the case of an alternating current, having a root-mean-square value of I , the maximum instantaneous value of current is $\sqrt{2} I$. Consequently, in a single-phase bus, carrying a normal root-mean-square current, I , the instantaneous magneto-mechanical stress exerted between the busses pulsates between zero and the maximum value,

$$\begin{aligned} S &= \frac{5.40 (\sqrt{2} I) (\sqrt{2} I)}{10^7 D} \\ &= \frac{1.08 I^2}{10^6 D} \text{ lb. per ft. of parallel (repulsion).} \end{aligned}$$

SHORT-CIRCUIT REACTANCE

The current, that will develop at a short circuit, depends on the rated kv-a. of the synchronous equipment connected to the circuit and upon the impedance of the combined circuits feeding into it.

Obviously, it is tedious to determine the combined impedance of the numerous groups of series and multiple circuits that make up a generating and distribution system. However, it is usually true that the reactances involved are large compared to the respective resist-

ances so that the impedance is only slightly greater than the reactance numerically. Consequently, to simplify the calculations it is usually sufficiently accurate to neglect the resistances and to use the reactances in place of the impedances.

This approximation is customary in dealing with short-circuit problems and the term "reactance" is used in this sense hereinafter. It gives values of short-circuit current slightly larger than actually obtain and consequently the results are on the safe side. Of course, in cases where the resistances are large compared to the respective reactances or economies may be effected that will warrant the extra labor of the more precise determination, the total impedances, including resistances, should be used.

A-C. SHORT-CIRCUIT CURRENT

The maximum instantaneous value of current, that will be produced when a synchronous generator is short-circuited, depends upon the instantaneous value of the voltage when the short circuit takes place.

If the short circuit occurs at the instant of maximum voltage, the short-circuit current wave will be symmetrical about the time axis. And the effective value of the short-circuit current will be that corresponding to the rated kv-a. of synchronous equipment, that is connected to the circuit, divided by the transient reactance expressed as a decimal (that is, the per cent reactance divided by 100).

But, if the short circuit occurs at an instant when the voltage is not at its maximum, the current wave will be symmetrical not about the time-axis, but about an exponentially decaying curve which finally becomes tangent to the time-axis. Under the worst condition, namely, short circuit occurring at the instant of zero voltage, the axis of symmetry of the current may be so high as to produce a maximum instantaneous value of current approximately 1.8 times that which arises in case of a symmetrical short circuit.

In the case of a three-phase synchronous generator, if a short circuit of all three phases occurs at the instant of zero voltage in phase A, the factor of asymmetry for phase A is approximately 1.8, and that for phases B and C is approximately 1.35.

Since we are most often concerned with the maximum currents that may arise during a short circuit, these factors 1.8 and 1.35 are usually included in the formulas pertaining to short circuits of alternating-current conductors.

SINGLE-PHASE CIRCUIT

The symmetrical short-circuit current of a single-phase circuit is

$$I_s = \frac{100 I}{X}$$

where I is the total rated current of all the synchronous

machines connected to the circuit reduced to terms of the circuit voltage; and X is the per cent reactance of the circuits (including equipment), that feed into the short circuit, based on the total rated generating capacity of the synchronous machines.

The maximum peak value of current, in case of a short circuit occurring at the instant of zero voltage, then is

$$1.8 \sqrt{2} I_s.$$

And the stress on each of the two parallel conductors, spaced D inches apart and carrying this current, is

$$S = \frac{5.40 \times 1.8 \sqrt{2} I_s \times 1.8 \sqrt{2} I_s \cos 180^\circ}{10^7 D}$$

$$= \frac{-3.50 I_s^2}{10^6 D} \text{ lb. per ft. of parallel (repulsion).}$$

THREE-PHASE CIRCUIT

The symmetrical three-phase short-circuit current of a three-phase circuit is

$$I_s = \frac{100 I}{X}$$

where I is the total rated three-phase current of all the synchronous machines connected to the circuit reduced to terms of the circuit voltage; and X is the per cent reactance of the circuits (including equipment), that feed into the short circuit, based on the total rated kv-a. capacity of the synchronous machines.

(1) SHORT CIRCUIT OF TWO ADJACENT CONDUCTORS

The maximum peak value of current, in case of a short circuit occurring between two adjacent conductors of a three-phase circuit at the instant of zero voltage, is

$$1.8 \sqrt{2} \left(\frac{\sqrt{3}}{2} \right) I_s.$$

And the stress on each of these two conductors (if parallel and spaced D inches apart) then is

$$S = \frac{5.40 \times 1.8 \sqrt{2} (\sqrt{3}/2) I_s \times 1.8 \sqrt{2} (\sqrt{3}/2) I_s \cos 180^\circ}{10^7 D}$$

$$= \frac{-2.62 I_s^2}{10^6 D} \text{ lb. per ft. of parallel (repulsion).}$$

(2) SHORT CIRCUIT OF THREE CONDUCTORS

In calculating the currents that develop during the short circuit of all three conductors of a three-phase circuit, it is of course necessary to take into account the time-phase of the three currents. Assume the current in phase A is I_s , that in phase B is $I_s / 120^\circ$ and that in phase C is $I_s / 240^\circ$. The total magneto-mechanical force exerted on each conductor is a resultant of the

forces exerted by each of the other conductors. It is necessary to solve first for the forces exerted between conductors by pairs and then obtain the resultants by combining these individual forces, taking into account the angles between their directions.

The forces depend on the distances between the conductors and consequently upon their relative positions. The two most common configurations of three-phase conductors are: (a) at the corners of an equilateral triangle, and (b) in a plane. Formulas are given below for these two common types of arrangement. Equations corresponding to other configurations can readily be derived.

(a) *Three Conductors in Equilateral Triangle*

A
B C

Short-circuit occurring at instant of zero voltage in phase *a*.

Between Conductors by Pairs:

$$S_{AB} = \frac{5.40 \times 1.8 \sqrt{2} I_s^2 \times 1.35 \sqrt{2} \cos 120^\circ}{10^7 D}$$

$$= \frac{-13.1 I_s^2}{10^7 D} \text{ lb. per ft. (Repulsion)}$$

$$S_{BC} = \frac{5.40 \times 1.35 \sqrt{2} I_s \cos 120^\circ \times 1.35 \sqrt{2} I_s \cos 240^\circ}{10^7 D}$$

$$= \frac{+4.92 I_s^2}{10^7 D} \text{ lb. per ft. (Attraction)}$$

$$S_{CA} = \frac{5.40 \times 1.35 \sqrt{2} I_s \cos 240^\circ \times 1.8 \sqrt{2} I_s}{10^7 D}$$

$$= \frac{-13.1 I_s^2}{10^7 D} \text{ lb. per ft. (Repulsion)}$$

On each Conductor:

$$S_A = \frac{(13.1 + 13.1) I_s^2 \cos 30^\circ}{10^7 D}$$

$$= \frac{22.7 I_s^2}{10^7 D} \text{ lb. per ft. (Upward)}$$

$$S_B = S_B' + j S_B''$$

$$S_B' = \frac{(-13.1 \sin 30^\circ + 4.92) I_s^2}{10^7 D}$$

$$= \frac{-1.63 I_s^2}{10^7 D} \text{ lb. per ft. (Toward Left)}$$

$$S_B'' = \frac{-j 13.1 I_s^2 \cos 30^\circ}{10^7 D}$$

$$= \frac{-j 11.35 I_s^2}{10^7 D} \text{ lb. per ft. (Downward)}$$

$$S_B = \frac{I_s^2}{10^7 D} \sqrt{1.63^2 + 11.35^2}$$

$$= \frac{11.47 I_s^2}{10^7 D} \text{ lb. per ft. (Resultant)}$$

$$S_C = S_C' + j S_C''$$

$$S_C' = \frac{(13.1 \sin 30^\circ - 4.92) I_s^2}{10^7 D}$$

$$= \frac{1.63 I_s^2}{10^7 D} \text{ lb. per ft. (Toward Right)}$$

$$S_C'' = \frac{-j 13.1 I_s^2 \cos 30^\circ}{10^7 D}$$

$$= \frac{-j 11.35 I_s^2}{10^7 D} \text{ lb. per ft. (Downward)}$$

$$S_C = \frac{I_s^2}{10^7 D} \times \sqrt{1.63^2 + 11.35^2}$$

$$= \frac{11.47 I_s^2}{10^7 D} \text{ lb. per ft. (Resultant)}$$

(b) *Three Conductors in Plane*

C B A or A B C

Short-circuit occurring at instant of zero voltage in phase *a*.

Between Conductors by Pairs:

$$S_{AB} = \frac{5.40 \times 1.8 \sqrt{2} I_s \times 1.35 \sqrt{2} I_s \cos 120^\circ}{10^7 D}$$

$$= \frac{-13.1 I_s^2}{10^7 D} \text{ lb. per ft. (Repulsion)}$$

$$S_{BC} =$$

$$\frac{5.40 \times 1.35 \sqrt{2} I_s \cos 120^\circ \times 1.35 \sqrt{2} I_s \cos 240^\circ}{10^7 D}$$

$$= \frac{4.92 I_s^2}{10^7 D} \text{ lb. per ft. (Attraction)}$$

$$S_{CA} = \frac{5.40 \times 1.35 \sqrt{2} I_s \cos 240^\circ \times 1.8 \sqrt{2} I_s}{2 \times 10^7 D}$$

$$= \frac{-6.55 I_s^2}{10^7 D} \text{ lb. per ft. (Repulsion)}$$

On each conductor:

$$S_A = \frac{(13.1 + 6.55) I_s^2}{10^7 D}$$

$$= \frac{19.65 I_s^2}{10^7 D} \text{ lb. per ft. (Toward A)}$$

$$S_B = \frac{(-13.1 - 4.92) I_s^2}{10^7 D}$$

$$= \frac{-18.02 I_s^2}{10^7 D} \text{ lb. per ft. (Toward C)}$$

$$S_C = \frac{(-6.55 + 4.92) I_s^2}{10^7 D}$$

$$= \frac{-1.63 I_s^2}{10^7 D} \text{ lb. per ft. (Toward C)}$$

Discussion

HIGH-VOLTAGE SWITCHES, BUSHINGS, LIGHTNING ARRESTERS—EXPERIENCES OF THE SOUTHERN CALIFORNIA EDISON COMPANY ON ITS 60,000, 150,000 AND 220,000-VOLT SYSTEM (MICHENER), HIGH-VOLTAGE CIRCUIT BREAKERS (COPLEY), MAGNETO-MECHANICAL LOADS ON BUS SUPPORTS (ROBINSON).

DEL MONTE, CAL., OCTOBER 3, 1923

J. S. Thompson: I would like to have you consider what we believe is a step in the right direction in regard to oil circuit breakers. Our factory has developed an oil circuit breaker with six breaks per pole, which is not a new idea at all. We have done it in a novel way in that we have not increased the number of pieces of insulation between the conductors and the ground, but have simply introduced an auxiliary insulation between breaks. This auxiliary insulation is far from sufficient to maintain itself against the line's voltage, but it is only subjected to an impressed voltage at the instant during which the breaker is between the closed and the open position; it is of bakelite and relatively small and failure of this auxiliary insulation simply would cut out certain of the breaks in the circuit. We have such an installation on a 60,000-volt line. This breaker after breaking thirteen short circuits produced by the test of various fuses which failed to open the circuit, was then tested on direct dead short circuit. After having been tested once with no evidence of any form of distress, the engineers took the bold step of putting this breaker on the loaded system of the Pacific Gas & Electric Company, which was at that time being contributed to by Pit. River, Drum Electra, Oakland and San Francisco. The breaker was subjected to short-circuit operations with this power concentrated on it (though I will have to say that the power was brought to this distributing point by a 110-kv. system and transformed to 66-kv.), so you will see that the breaker was put to a thorough test. It operated at 2000 amperes, which immediately dropped to 1350 or 1400. A Westinghouse relay closed the circuit in about five cycles and then there were consumed ten cycles for the mechanical operation of the tripping coil, and the movement of the blade out of contact, and nine cycles of diminishing amperes while the arc was being drawn—then five cycles between the rupturing of the arc and the end of the travel of the oil circuit breaker.

So it took a total of just thirty cycles for the switch to range from the impression of the short through to the actual coming to rest of the switch. That was repeated again after the circuit breaker was opened and very minor injuries were shown, simply a certain amount of pitting of the arcing tips such as might be expected. The circuit breaker is in shape to be closed in again on a similar load.

R. W. Sorensen: Until very recently oil switches have found very little place in my technical experience, but within the past few weeks a problem involving the use of oil switches made it desirable to search our technical literature for articles expounding the theory of oil circuit breakers.

I found articles discussing mechanical features, test data, and applications, but almost nothing seems to have been printed in American technical literature as to the theory of oil circuit-breaker design.

Eventually I discovered in a recent number of the "Revue Generale de L'electricite" an article on "Oil Switch Design" by Mr. P. Charpentier who signed himself Chief Designer of Service Apparatus in a factory at Jeumont, France, and a series of papers by D. R. Davies published in the London Electrician, the first of which appeared in a number published June 16th, 1922.

These papers present the subject of oil circuit breakers entirely from a theoretical point of view but the language of the authors

indicates men familiar with the manufacture and use of oil circuit breakers.

Mr. Davies' paper includes this definition: 'Breaking capacity may be defined as the maximum kilovolt amperes which the circuit breaker can break under prescribed conditions, at stated intervals, a specified number of times.'

I have found it interesting to attempt to apply the theories advanced in these papers to some oil switches now made by one of our well known oil switch manufacturers, and these results I should like to call to your attention, not because of any conviction as to their accuracy in determining from the dimensions, and speed of operation of a switch just what rating it should have, but rather to stimulate a research program which will develop our knowledge of the theory of switching, and thereby give us a more definitely rated product.

Mr. Davies' first article which has to do largely with the carrying capacity of switch parts as determined by their thermal properties, and eddy current set up in them, needs no discussion at this time.

The facts pointed out in his second paper are the size of arc as determined by the current to be interrupted and its persistence as determined by voltage, switch speed, and stored energy in the circuit.

Also there are many other important phenomena discussed in this paper but we have time to glean only some apparent evidence as to the futility of long breaks, the uncertainty of reliance upon explosion chambers, and an important reference to Dr. Bauer's report to the Swiss Commission. From Dr. Bauer's report we have two important constants, one the energy factor of 0.07 as a maximum for the relation between kv-a. interrupted and the amount of energy which must be dissipated in the arc; the other is the figure 46.5 which represents the number of cubic centimeters of gas liberated for each kw. second of energy which must be taken up by the oil. These data were selected not because they are of necessarily greater importance than the other data given, but rather because they are likewise included in the formula by Mr. Charpentier, the application of which I wish to call your attention.

Time of break is fundamental, and according to Charpentier is equal to w/v where U is voltage per break and V is average velocity of blade in cm. per sec. This constant was used in the Charpentier formula for standard switches with two breaks in series, but if applicable directly to two breaks, should certainly also indicate much advantage for several breaks in series, even though some constant must be applied to allow for a possible uneven distribution of the voltage over the several breaks.

For example, last week I applied the Charpentier formula to several 45-kv. switches of standard make with the following results. Two break switch theoretical rating 3850 amperes. This switch is known to have interrupted successfully a number of times a short of 1,000 amperes, but finally it failed to properly care for a short of about this value. This shows a use of the formula not intended or else an omission of some factor that should be included. A four break switch of the same design shows by calculation a rupturing capacity of about 11,000 amperes instead of the 3600 which experience shows to be its probable rating. Using eight breaks the calculated rupturing capacity is 30,000 amperes.

We have however, a better check on a 30,000 ampere switch, from a known record of the operation of a 45-kv. switch with two breaks used on a 16.5-kv. circuit. The calculated breaking capacities for this switch 10,000 amperes, 27,600 amperes, and 103,000 amperes, for two, four, and eight breaks respectively. The four break switch actually did successfully rupture 20,000 amperes without damage.

Two sets of observations I have made also seem to check the value of the multi-break switch. One is the addition of more

series breaks, without any other changes has transformed faulty operating switches into perfectly satisfactory ones.

The second is that when two switches of like design but with different number of breaks are in series on a short circuit, the switch with the greater number of breaks shows less carbon deposit from the oil and less burning of the switch clip, than does the one with the smaller number of breaks.

J. P. Jollyman: What kind of oil was used in the test?

J. S. Thompson: We used a mineral sea oil, that is, one that is as free from water and acid as possible. We purposely avoid attempting to furnish a high grade oil. So, we use a mineral seal oil.

H. Michener: I would like to ask what the test value of that oil was when the experiment started?

J. S. Thompson: I don't think I am able to answer that because I don't think we tested that particular supply of oil. This oil, you know, deteriorates in a breaker.

A. J. Bowie: I would like to ask if there was any explosion chambers on this 220,000-volt breaker; also how many breaks they had and what was the most severe test to which the breakers had been subjected?

R. M. Spurck: In Mr. Copley's paper reference is made to the practise of lowering the transmission voltage by field control in order to extinguish short circuits or flashovers. Such procedure, although effective, will, or has the disadvantage that it generally interrupts service and is liable to cause falling out of synchronous or induction apparatus in the area of the lowered voltage. The newer practise, namely, that of using automatic oil circuit breakers in combination with suitable relay schemes, makes it possible in net works or parallel lines, to automatically drop a defective section of the line without interrupting the service.

Oil circuit breakers are available for interrupting any voltages and currents that are commercially required. These high-voltage breakers are necessarily expensive. This expense is due, primarily, to the large clearance required for insulation. That is, a breaker designed to give the insulation for a 220,000-volt system, will in general, have an interrupting capacity comparable with normal requirements of such a system. In spite of the expense of these breakers, it is believed that their use is justified for sectionalizing purposes because the fixed charges and operating expense on them is small compared with the benefits derived from continuity of service.

One of the types of breakers in operation on the 220,000-volt system on the Pacific Coast utilizes the explosion chamber principle. The advantages of the explosion chamber principle are many and among them are the following: In the inherent speed characteristic, that is, the pressure in the chamber acting on the moving contacts as a piston accelerates the opening speed by the amount it can load. The effect of the increased speed of the opening is also obtained by the pressure inside the chamber causing a rapid movement of oil through the breaking contacts. It is possible, by changing the clearance between the opening in the explosion chamber and the moving contacts to regulate the rate of liberation of gas from the explosion chamber to the outer tank and thereby control the pressure in the outer tank. The ability to control this pressure permits the maximum interruption to be obtained from a given structure. The expulsion of gas into a body of cooled oil cools the gas, reducing its value and causing the breaking capacity to be increased.

The interrupting rating of a flow exchange type breaker has been determined by tests not only in the field, but also in the factory. The factory tests have been made under the worst conditions, namely, that of opening the circuit of a fully excited generator directly at the generator. The factory equipment consists of a 27,600-kv-a. generator complete with high-voltage transformers, reactors, oscillographs, and speed and pressure measuring devices. Such apparatus, for instance, enables us to

determine the magnitude of the pressure in the tanks, or explosion chamber, the rate of pressure formation, the arc length and other factors affecting the rupturing capacity. From this definite data and conversion factors obtained therefrom, calculations can be made for other breakers.

In connection with what Mr. Sorensen said, I might add that all of the theories so far published that I have seen have constants in them that have not been adequately determined. For instance, taking a 15,000-volt breaker, opening a low current, the arc duration will be from five to six half cycles. However, if the same breaker is called upon to interrupt 35,000, 40,000 or 45,000 amperes, the arc duration drops down to one-half cycle.

A. J. Bowie: I would like to ask Mr. Michener what the short circuit would be on a 220-kv. line?

H. Michener: I don't know.

E. R. Stauffacher: I would like to emphasize something that Mr. Michener said in regard to the operation of the 220 oil circuit breaker. That is we do not know what amount of current the breaker had to interrupt. It might be stated that the current balanced relays were set to operate when an unbalance of 360 amperes occurs. The probable current interrupted was in the nature of 800 or 900 amperes.

I would like to emphasize as strongly as possible that there is a great need for a discharge recorder on lightning arresters. That is, a discharge recorder which will give a reliable record of the time, and if possible, the magnitude of each discharge, and which will be sufficiently rugged and inexpensive so that it can be installed on a large number of arresters. Such a record taken over a few years, would go a long ways toward settling the controversy as to whether lightning arresters justify their expense.

Time and again, we in the Southern California Edison Company, have wished we had some sort of a recorder available for the studying of the arresters. We have developed a discharge recorder which will give the time, but which does not give the quantity of current which was discharged. In fact, the instruments used in the past have been sometimes destroyed, at other times the chart has been destroyed.

If the manufacturers could see fit to attack this problem and develop some kind of an inexpensive recorder, I believe it would put the question of the application of lightning arresters on a much more definite and reliable basis.

O. R. Schurig: In the paper are given formulas expressing the electromagnetic force due to short-circuit currents in parallel conductors. It appears from the paper that the formulas are intended to be used for the calculation of the loads acting on the busbar supports, during short circuits, for the purpose of obtaining the strength required for the supports. In other words, formulas defining the electromagnetic force for a given value of current appear to be represented in the paper as defining, at the same time, the load acting on the support. While it may seem from mere superficial analysis that, in a busbar structure having a number of equal spans as a continuous beam, each support would be acted on by a load equal to the electromagnetic force per span,—a more thorough examination will show that the maximum load acting on the bus support will often differ materially from the maximum electromagnetic force per span. The reasons are (1) that the electromagnetic force is suddenly applied having periodic variations, and (2) that the busbar span and the supports have each their own natural frequencies and consequently respond differently to applied electromagnetic forces of different frequencies. Consequently, the formulas in the paper, give, in general, only roughly approximate values of actual loads acting on the bus supports during short circuits. Experiments, the results of which will be published later, have shown that the maximum load which the support has to withstand is in many cases, much smaller than the electromagnetic force (per span) calculated for the peak value of short-circuit current, but may rise well above the electromagnetic force so

calculated when the busbar is in resonance with the electromagnetic force. Both resonant and non-resonant structures occur among the customary designs.

The difference between the electromagnetic force and the load acting on the support will be seen more clearly from the following considerations:

When an a-c. short-circuit current is suddenly caused to flow in a pair of parallel busbars, the two bars carrying equal and opposite currents, a rapidly varying pulsating force tending to push the bars apart is suddenly applied to the two conductors. The force is called the electromagnetic force. It is the driving force which tends to set the busbars into motion. The deflection of the busbar, and hence the stress set up in the busbar material as well as the load on the support, depend not only on the magnitude of the driving electromagnetic force, but also to a large extent on the ability of the busbar to respond as a vibrating body to the rapidly recurring force pulses. The stresses caused in the busbar cross-section during its vibratory motion increase with increasing deflection of the busbar span and reach a maximum at the instant of its maximum deflection. In stress determinations it is convenient to consider the equivalent uniformly distributed dead load per span of busbar, to be called briefly the "equivalent busbar load," which may be defined briefly as the uniformly distributed dead load (per span) which creates the same busbar deflection (relative to supports) as that produced by the driving electromagnetic force in the busbar span at any instant during the vibratory motion. Thus the character of the equivalent busbar load is indicated by the character of the busbar deflection.

In order to form a picture of the busbar deflections, it is necessary to consider the various components of the electro-magnetic force causing the deflections. It can easily be shown that a displaced sine-wave short-circuit current produces, at the beginning of the short circuit, an electromagnetic force of the following three components: a direct component, an alternating component at current frequency, and an alternating component at twice current frequency. It follows then that a busbar of very low frequency with respect to the current frequency, will respond mainly to the direct force component, but only very feebly to the alternating force components, and will, therefore, vibrate almost purely at its own natural frequency, approximately as if the alternating electromagnetic force components were entirely absent. Thus the maximum busbar deflection, and hence the maximum busbar load, may not occur until several (current) cycles after the peak current has occurred. Hence the maximum load is but remotely dependent on the initial peak electromagnetic force.

On the other hand, a busbar of high frequency, with respect to the current frequency, will respond to all the electromagnetic force components with practically equal fidelity, in much the same manner as a high-frequency oscillograph vibrator traces true images of composite low-frequency current waves. Now, the maximum busbar load will be practically equal to the maximum electromagnetic force per busbar span.

Should, however, the busbar be at resonance with the electromagnetic force, *i. e.*, having a natural frequency equal to the frequency of one of the alternating components of the electromagnetic force, the busbar will show a decided preference for the vibrations at the resonant frequency. Cumulative vibrations will occur, limited in magnitude only by the relatively low motional resistance of the busbar span. Thus the maximum equivalent busbar load may occur considerably later than the maximum short-circuit current, but may reach a value materially greater than the peak electromagnetic force.

The above considerations indicate that the maximum busbar load will frequently differ substantially from the peak electromagnetic force, both in regard to magnitude and time of occurrence. The maximum support load will not generally be exactly equal to the maximum busbar load, because the support also has a natural frequency of its own, largely independent of the busbar

natural frequency, and will therefore respond selectively to the various frequencies of the driving-force components. Consequently, the support load will differ, in a great many cases, from the maximum electromagnetic force.

To summarize: The formulas in the paper give definite values of electromagnetic force. The maximum load acting on the supports during short circuits very often differs materially from the maximum electromagnetic force, the relationship depending on the natural frequencies of the busbar and of the supports as well as on the short-circuit current, as will be more fully brought out in a subsequent paper. Formulas for electromagnetic force, such as those presented in the paper, give as a rule only a very rough approximation to the support loads due to short-circuit currents.

E. G. Allen: Mr. Robinson calculates the force between conductors under a three-phase short-circuit which occurs at the instant of zero voltage in phase *a*. Under these conditions he finds the force at the moment the current in conductor *a* is a maximum which he calls $1.8 \sqrt{2} I_s$, evidently allowing 10 per cent decrement in the first quarter cycle. At this instant the current in *b* and *c* would be $-0.9 \sqrt{2} I_s$, as the current in *b* equals that in *c* and the sum of currents in *a*, *b*, and *c* equals zero. Under these conditions, the instantaneous force between conductors is—

$$S_{AB} = \frac{5.40 \times 1.8 \sqrt{2} I_s \times 0.9 \sqrt{2} I_s}{10^7 D} = - \frac{17.5 I_s^2}{10^7 D} \quad \begin{matrix} .A \\ .B \end{matrix}$$

$$S_{BC} = \frac{5.40 \times .9 \sqrt{2} I_s \times 0.9 \sqrt{2} I_s}{10^7 D} = + \frac{8.75 I_s^2}{10^7 D} \quad .C$$

$$S_{CA} = \frac{5.40 \times 0.9 \sqrt{2} I_s \times 1.8 \sqrt{2} I_s}{2 \times 10^7 D} = - \frac{8.75 I_s^2}{10^7 D}$$

$$S_A = - \frac{26.25 I_s^2}{10^7 D}$$

$$S_B = + \frac{26.25 I_s^2}{10^7 D}$$

$$S_C = 0$$

Although the above equations show the force at time of maximum current in *a*, they do not give the condition of maximum stress. Under the short circuit conditions assumed, the force in the middle conductor is a maximum 160 deg. after the moment

of short circuit, when it is, without decrement $\frac{35.7 I_s^2}{10^7 D}$. The

maximum force in the outer conductor is slightly less and occurs $164^\circ 28'.65$ after the moment of short circuit. However, analysis shows that the stress in conductor *a* is still greater when the short circuit occurs 15 deg. before the current in *a* is a maximum, and that the maximum force occurs 180 deg. after the short circuit. Under these conditions the instantaneous force on *a*, without

decrement, is equal to $\frac{34.8 I_s^2}{10^7 D}$ and on *b*, $\frac{37.4 I_s^2}{10^7 D}$.

If 10 per cent current decrement is allowed, these values will be reduced to 81 per cent of their given value, but it should be borne in mind that these are instantaneous values of the force upon the conductors. The average values over the cycle are much less. The difference is a pulsating force tending to put the bus bars into vibration. The inertia of the bar is generally such that if the average force were withstood, the pulsating force would cause vibrations amounting to but a small fraction of an inch. This leads to the thought that stresses set up by short circuits might be greatly reduced if some sort of flexible support were provided which would permit the pulsating forces to be absorbed by the inertia of the bar.

The analysis leading to the above is briefly as follows:

Neglecting decrement of current, the equations of the unsymmetrical short-circuit currents are:

$$i_1 = A [\cos (\theta + \alpha) - \cos \alpha]$$

$$i_2 = A [\cos (\theta + \alpha - 120) - \cos (\alpha - 120)]$$

$$i_3 = A [\cos (\theta + \alpha - 240) - \cos (\alpha - 240)]$$

Where A = max. value of symmetrical current

= elapsed time (degrees) between moment of short circuit and moment under consideration.

= time (degrees) between moment of max. current and moment of short circuit.

$$\text{Force in middle bus} = \frac{5.40}{10^7 S} (i_2 i_3 - i_1 i_2)$$

$$\text{Force in outer bus} = \frac{5.40}{10^7 S} \left(i_1 i_2 + \frac{i_1 i_3}{2} \right)$$

Where S = distance between bus bars in a plane—

From the above:

$$i_2 i_3 - i_1 i_2 = \sqrt{3/2} A^2 [\sin (2\theta + 2\alpha - 240) - 2 \sin (\theta + 2\alpha - 240) + \sin (2\alpha - 240)]$$

This is a maximum or minimum with respect to α when

$$\alpha = -15 - \theta/2 \text{ or } 75 - \theta/2 \text{ or } 165 - \theta/2$$

It is maximum or minimum with respect to θ when

$$\theta = 40 - 4\alpha/3 \text{ or } 160 - 4\alpha/3 \text{ or } 280 - 4\alpha/3$$

For maximum with respect to both α and θ

$$\theta = 180 \text{ deg.}$$

$$\alpha = -15 \text{ deg. or } 75 \text{ deg. or } 165 \text{ deg. or } 255 \text{ deg.}$$

Under any of these conditions

$$i_2 i_3 - i_1 i_2 = 2 \sqrt{3} A^2 \text{ and } F = \frac{18.72 A^2}{10^7 S}$$

If I_s = root mean square current = $A / \sqrt{2}$

$$F = \frac{37.4 I_s^2}{10^7 S}$$

L. H. Robinson: I agree with Mr. Schurig that the method submitted in my paper, gives only approximate results and consequently I prefer to use a liberal factor of safety. If vibrations of the bus and its supports, due to currents of ordinary frequency (25, 50 and 60 cycles per second) with common sizes of bus bars, lengths of span, etc., may augment or partially neutralize the external force; formulas correlating these factors with the bus currents, and experimental confirmation of these formulas will be valuable and useful.

H. Michener: Twelve of the twenty-eight 220-kv. oil switches referred to in the paper have been operating on balanced relays since early in September. These switches have given very satisfactory performance. A ground on a section of line thus protected causes only a momentary drop in system voltage of approximately 10 per cent. After as many as five automatic operations under short circuit to ground conditions and perhaps fifty non-automatic operations for routine line switching, inspections have shown only slight burning on the contacts and some minor mechanical defects.

The longest section of line being switched out automatically up to the present time is 98 miles. About March first, a section of the line 166 miles long will be arranged for automatic isolation on balanced relays.

The actual current values which occur at the time of a short circuit to ground are very problematic. Using the calculating

table which has been constructed for the purpose of studying short-circuit currents on the system, it has been determined that with the present generator capacity the maximum current value on the 220-kv. lines is about 5000 amperes in case of a three-phase short circuit. This is the instantaneous current. In about two-tenths of a second the current is reduced to about half that value.

A. W. Copley: With reference to Mr. Bowie's question as to the construction of the 220-kv. circuit breaker which I described, I will say that this breaker is built with two breaks per pole and without explosion chambers.

A high speed of contact separation is obtained by means of arcing contacts held to the stationary contact parts by a spring and latched to the moving contact parts in such a way that the arcing contacts maintain connection until the main moving contacts are open several inches. The latch then releases allowing the arcing contacts to be quickly retrieved upward by means of a spring while the moving contacts are at the same time moving downward at high speed.

Mr. Bowie also asks concerning the tests for the determination of interrupting capacities. Tests at full rupturing capacity on the 220-kv. breakers naturally have not been made because of the inability to obtain the necessary combination of high energy and high voltage for adequately determining such interrupting ability. However, tests have been made on similarly designed breakers for somewhat lower voltages and these have demonstrated their ability to more than meet the guaranteed interrupting capacity. It is fully expected, therefore, that the rated interrupting capacity of the 220-kv. breakers will be found to be conservative when the systems to which they are connected have grown to the point where this rating is reached by the requirements of service.

Mr. Spurek has described another design of circuit breaker for 220-kv. service in which the explosion chamber is utilized. While the value of this device may be open to question in theory, the only complete answer as to the dependability of the breakers will be obtained by service records at a later date. Testing interrupting ability by means of a special generator and other testing equipment is of very great value and should be followed out further. But, it is evident that obtaining of the necessary energy and voltage to make adequate tests on a breaker with an interrupting capacity of more than 1,000,000 kv-a. at 220 kv. is hardly possible at this time.

The theories as to the mathematical determination of oil circuit breaker interrupting capacity as described by Professor Sorensen, are of considerable interest. But the best guide at present in determining capacities is obtained by actual test and operating experience with the various types of breakers. I believe that the factors entering into the determination of rupturing capacity are so numerous and complex that it will be difficult to express the result in a mathematical formula. It is of value, however, to continue to work toward this end along with tests and operating experience from which the final answer must be obtained.

It might be inferred from the discussion by Mr. Thompson that high quality of oil is not of vital necessity in high-voltage circuit breakers. While there is some evidence in favor of such a conclusion, there is also much reliable evidence to the effect that a poor quality of oil has caused many switch failures. It is therefore premature, to say the least, to ignore this factor and until much more is known about breaker operation on high voltages no oil but the best should be used.

High-Voltage Insulation

BY J. L. R. HAYDEN and CHARLES P. STEINMETZ

Member, A. I. E. E.

Fellow, A. I. E. E.
Chief Consulting Engineer, General Electric Co., Schenectady, N. Y.

I. General

THE most important chapters in electrical engineering are those dealing with efficiency, heating, magnetism and insulation.

In the field of insulation, our knowledge is most backward.

In regard to efficiency, with efficiencies of electrical apparatus of 90 up to over 99 per cent, no further radical progress appears feasible.

In magnetism, the losses in an alternating field have been reduced so far, that they have ceased to limit, by their heating effect, the size of apparatus, but are merely a factor in the efficiency. An increase of the saturation density would decrease the size of apparatus, but is excluded by its inherent chemical limitations.

Heating specifications are not made for other classes of apparatus, such as prime movers, etc., and if an important subject in electrical engineering, it is almost entirely because the insulation of the apparatus is destroyed by the higher temperatures. Thus the problem of the heating of electrical apparatus is essentially one aspect of the insulation problem.

In our high-voltage apparatus, cables, etc., we operate the insulation at voltage stresses which rarely exceed much the disruptive strength of air, though laboratory tests often show this insulation to have a disruptive strength of 10 to 20 times that of air.

All phenomena of nature are very complex. Therefore, in calculating a phenomenon or designing an apparatus, we must approximate by neglecting "secondary terms," and take care of these by an allowance, a margin or a factor of safety. Obviously, the more completely a phenomenon is known and understood, the closer it can be calculated, in other words, the less is the margin or safety factor required in order to allow for the unknown stresses, etc. The margin or safety factor, which experience shows as necessary, thus is an indication of the exactness of our knowledge of a phenomenon. For example when dealing with magnetic phenomena, with efficiency, with heating, etc., we have to allow a margin of a few per cent only. In testing the insulation of apparatus however, the A. I. E. E. standards specify a test voltage more than twice the delta voltage, though the normal stress is the Y voltage. That is, we require a safety factor of over 3.46, a margin above normal of over 246 per cent.

The insulation problem has become of increasing importance with the rapid advance of electrical engineering into higher voltages. Not many years ago 44 kv. was the highest transmission voltage for reliability of operation of overhead lines. Now we have

reached 220 kv. Then 12 kv. was the highest satisfactory cable voltage; now we have reached 22 kv. and a few cables of 33 kv. and higher, but cables at 33 kv. are still semi-experimental. The comparison shows that the advance in pushing cable voltages up to higher values, has been slower than with overhead lines, and our knowledge of liquid and solid insulation, such as come into consideration in the cable wall and the machine insulation, is materially less advanced than that of air as dielectric. With regard to air, a good working theory has been established, by considering the dielectric strength of air as analogous to the mechanical strength of structural materials. The theory recognizes a definite dielectric strength of air, or a disruptive breakdown gradient, of 30 kv. per cm. at normal air density. Puncture occurs when this dielectric strength is exceeded, just as mechanical disruption occurs, when anywhere in a mechanical structure the stresses exceed the elastic limit of the material. This conception of a definite breakdown strength then was extended to liquid and solid dielectrics, but with these, it failed to give a satisfactory explanation of the mechanism of the breakdown, more particularly of the all-important feature of the time lag of disruption. And even with air, the theory of a constant breakdown gradient, as modified by the conception of the energy distance, is satisfactory only within a certain range.

II. Air as Dielectric

The present practically universally accepted theory of a dielectric strength of air at and near atmospheric pressure, as most completely developed by Mr. F. W. Peek, Jr., is:

Air has a definite and constant "dielectric strength," at which it ceases to be an insulator and becomes a conductor, that is, breaks down electrically.

The dielectric strength of air is proportional to the air density, and is 30. kv. per cm. at normal air density of 0 deg. cent. and 76 cm. barometer.

The dielectric breakdown (or puncture) of air does not occur as soon as the voltage gradient in the dielectric field exceeds the dielectric strength at any point, but the voltage gradient in the field must exceed the dielectric strength over a finite distance, the so-called "energy distance."

The energy distance depends on the convergency of the electric field at the place where the breakdown occurs, and is the less, the more convergent the field.

The energy distance between parallel cylinders (wires) of radius R is $0.3 \sqrt{\delta R}$; between spheres of radius R it is, approximately; $0.54 \sqrt{\delta R}$, where δ = air density (with normal air density as unity).

Thus the breakdown gradient at the surface of two parallel cylinders of radius R is:

$$g_0 = 30 \delta \left(1 + \frac{0.3}{\sqrt{\delta R}} \right)$$

at the surface of spheres it is

$$g_0 = 30 \delta \left(1 + \frac{0.54}{\sqrt{\delta R}} \right)$$

For gaps of a length less than the energy distance, a higher breakdown gradient is required, the more so, the shorter the gap. The law is unknown.

The space in the dielectric field in which the dielectric strength is exceeded, becomes conducting, and, if adjacent to the terminals, becomes a part of the terminal. This changes the configuration of the dielectric field and if thereby the dielectric strength is exceeded in other parts of the dielectric field, these also break down and become conducting, until either the breakdown extends from terminal to terminal, the air gap punctures and short-circuits by a spark discharge (which tends to develop into an arc), and the current rises and the voltage drops to the short-circuit values of the supply source. Or the breakdown in the dielectric field limits itself, producing a new configuration of the dielectric field, containing conducting regions, in which the air is broken down and luminous by "corona," separated by insulating air spaces below the breakdown gradient. In this case the discharge current is limited to the small "corona current." A further increase of voltages then may extend the breakdown across the terminals and change the limited discharge into an unlimited spark discharge.

Between needle points, corona always precedes the spark discharge; between spheres at moderate distance (less than 3 to 4 times the radius of the spheres), spark discharge occurs without corona.

The disruptive discharge of single gaps in air, is instantaneous, that is, no time lag is produced in the spark gap, if no corona precedes the spark discharge, and the gap length is greater than the energy distance. When with rising voltage corona precedes the spark discharge, a time lag exists. With gaps of less than the energy distance, and multigaps, a time lag also seems to exist. The combination of resistance in series and capacity in shunt to an instantaneous spark gap gives the gap a time lag owing to the time required to charge the capacity by a current limited in value by the resistance. Without a capacity in shunt, an otherwise instantaneous sphere gap in series with a resistance lags by the time of charging the capacity of the spheres themselves, through the series resistance. For high values of resistance, this may become quite considerable, especially with large spheres.

This standard theory of dielectric strength of air at and near atmospheric pressure is fairly satisfactory for gaps ranging between the energy distance and a larger value where corona begins.

For gap lengths less than the energy distance, the standard theory does not apply.

For gaps in which corona precedes the spark discharge, the law does not seem to satisfactorily agree with experience. Between spheres, corona appears only at gap lengths materially larger than those in which it should appear according to the theory. Also the disruptive voltage at which spark discharge occurs between needle points, is materially lower than calculated. This may partly be accounted for as follows:

(a) The space filled by corona is not a perfect conductor, but has a finite resistance, which depends on the corona density, thus on the voltage, frequency, etc.

(b) It is practically an impossibility to calculate accurately the final dielectric field and its voltage gradients, as resulting from the partial short circuit by the corona, of regions of the initial dielectric field, even if the resistivity of the corona regions were neglected.

(c) The nature of the corona-filled space is that of an unstable third class conductor, which tends to produce local oscillations and other transients, and thereby rapid variations of the resultant field and premature breakdown. Incidentally, when high-frequency oscillations and other low-power transients of unknown origin appear in a system, it is advisable to look for the existence of corona somewhere in the circuit, as possible cause.

The theory of the dielectric strength of air at and near atmospheric pressure, outlined above, is based on the distribution of dielectric stresses and therefore depends on the configuration of the dielectric field. As the dielectric field is essentially determined by the shape of the terminals, the latter thus is of fundamental importance. At the same time, in the "conduction of gases in a vacuum" a theory has been developed, based on convection phenomena by carriers, the ions, and in this theory the configuration of the dielectric field and the shape of the terminals is practically not considered, and the two conceptions thus apparently are out of line with each other, though the phenomena of the Geisler tube and those of air at normal pressure should differ quantitatively only, by the different value of air density δ .

Approximately, and within a limited range, the voltage e required to break down a gap of length l at air density δ , is constant as long as the product $l\delta$ is constant, that is, for constant quantity of air within the gap. In other words, for different air densities δ , the gap length l at constant voltage e varies inversely proportional with the air density δ . The air densities in vacuum tubes usually vary from one thousandth to one millionth of normal air density and less, and even the longest vacuum tubes usually therefore correspond at atmospheric pressure to gaps of very small length, greatly within the energy distance. In other words, the phenomena of vacuum tube conduction correspond to the phenomena occurring in very small gaps at atmospheric pressure, where the conventional theory

does not apply, and the configuration of the field and the shape of the terminals become of lesser importance. Inversely, the voltage phenomena of the Geisler tube, may also appear in the dielectric strength of large gaps at atmospheric pressure, as terminal phenomena, though then secondary in magnitude to the gradient voltages of the dielectric field.

The conventional theory considers only the voltage gradient or intensity of the dielectric field as determining the dielectric strength, but not the direction, that is, assumes the same breakdown strength for either polarity of the impressed voltage. This resulted from the use of alternating voltages in determining the laws of the dielectric strength of air, due to high direct volt-

FIG. 1

age of considerable power being unavailable until recent years. It is very far from correct, however, and in an unsymmetrical field, the disruptive strength with the voltage in one direction, may be more than twice that with the voltage in opposite direction. As illustration, Fig. 1 shows the striking distances between a needle and a 12.5 cm. sphere, for various gap lengths. Curve I gives the results with the needle positive, curve II with the needle negative, and curve III with alternating voltage. As seen, I and II differ greatly, II being more than twice the voltage of I. The alternating curve approximates I, as is to be expected. In the voltage range between I and II, such an unsymmetrical gap rectifies.

Investigation shows that it is the form and intensity of the dielectric field at and near the positive terminal which has the greatest effect on the disruptive voltage of the air gap, while the field at and near the negative terminal is of secondary importance. Thus if at constant gap length the positive terminal is gradually changed in steps from a sharp point to a flat plate, while the negative terminal remains unchanged in form, the disruptive voltage changes correspondingly over a wide range. A corresponding change in the physical form of the negative terminal however, with the positive terminal remaining unchanged in form, varies the disruptive voltage relatively little.

In Fig. 1, curve I approaches the striking distance curve between needles, as modified by the different distribution of voltage gradients due to the large negative terminal, and curve II similarly approaches the striking distance curve between 12.5 cm. spheres.

This suggests the explanation that the disruptive discharge is due to carriers of current produced by the field at the positive terminals, the positive ions possibly.

Tests made at atmospheric pressure on very small gaps—down to fractions of microns—show that with decreasing gap length the voltage does not indefinitely decrease, but reaches a finite minimum value, of about 320 volts, and becomes apparently constant at this value. This would be the minimum voltage required to disrupt an air gap, no matter how small. It means that with decreasing gap length, the voltage gradient of the air film rises to very high values, and such thin air films have an extremely high dielectric strength; gradients of 6.2 million volts per cm. have been reached.

Inversely, with increasing gap length, the voltage increases with the gap length, and proportional thereto, from an initial value of about 320 volts. The increase with increasing gap length, however, is not at the rate of the dielectric strength of air, 30 kv. per cm., as might be expected, but is at approximately twice this rate; about 60 kv. per cm., up to voltages of about 4500. Then the increase of voltage with increasing gap length decreases and approaches the normal value of the breakdown strength, 30 kv. per cm.

The voltage e required to break down an air gap of length l and uniform dielectric field intensity thus would consist of

- (1) A constant voltage $e_1 = 320$ volts = 0.32 kv.
- (2) A voltage gradient g_2 of about 60 kv. per cm. over a short length $l_0 = 0.07$ cm., giving a constant voltage $e_2 = 60 l_0$ kv.
- (3) The voltage gradient of dielectric strength, $g_0 = 30$ kv. per cm., for the rest of the gap, $l - l_0$, or $g_3 = 30(l - l_0)$; thus giving a total voltage, approximately:

$$\begin{aligned} e &= e_1 + e_2 + e_3 \\ &= 0.32 + 60 l_0 + 30 l \\ \text{or, if } l < l_0, \text{ simply} \\ e &= 0.32 + 60 l \end{aligned}$$

In a non-uniform field, the breakdown would occur from the positive terminal up to the distance, to which the breakdown gradient $g_0 = 30$ extends, and this space is filled with corona.

In Appendix I is given a suggestion of the mechanism of the dielectric breakdown of air by carriers issuing from the positive terminal.

III. Liquid Dielectrics

Oil and similar materials (as petrolatum in the high-potential cable impregnation) are the most important liquid insulating materials and are depended upon for the insulation of the highest voltage electrical apparatus, the transmission power transformer. The fairly satisfactory agreement of the behavior of air as insulating material, with the theory of a definite dielectric strength, modified by the conception of the "energy distance" led to the application of the same theory to liquid dielectrics. Here, however, the agreement with experience is not satisfactory; and tests show that oil does not have a practically available definite dielectric strength, but successive tests made

Fig. 2

with all precautions with the same oil in the same gap (using such a large quantity of oil as to exclude the effect of deterioration) differ from each other by values many times greater than the possible errors of observation. The upper curve on Fig. 2 shows the deviation from average of 100 successive tests of the disruptive voltages of an oil gap, and the lower curve shows the corresponding results with an air gap. Plotting the number of times each deviation from average occurs, in A, as function of the value of deviation, gives a probability curve.

The most satisfactory explanation of the mechanism of the breakdown of oil and other liquids seems to be that based on the assumption of lack of homogeneity, namely that the breakdown of an oil gap is the result of materials of different conductivity or specific capacity being sucked into the gap by the dielectric field, or being produced in the gap by it, and so causing a distortion of the field, with local high densities, at which disruption begins. This can be visually shown by dropping a minute quantity of water or other foreign material into an horizontal

sphere gap in oil, at moderate voltage between the spheres, and observing the resultant motions and deformations. It is even somewhat questionable whether liquid dielectrics have a definite dielectric strength at all, or whether disruption does not always occur through gases produced from the dielectric by the electric stress. A discharge through oil seems always accompanied by the appearance of gas bubbles, and while the gas bubbles may not be the cause, but the result of the discharge, there are some differences in the shape of the striking distance curve of an oil gap from that of an air gap, which look as if the disruptive discharge in air is the result of the action of the dielectric field on the air, while the disruptive discharge in oil is the result of the action of the dielectric field on a material produced from the oil by the dielectric field, that is, the dielectric field produces dissociation or ionization of the oil, and the disruption occurs through the gases of ionization.

IV. Solid Dielectrics

The dielectric strength of solid dielectrics is often expressed by the disruptive voltage gradient in a uniform field, in kilovolts per cm., or per mil. Such an expression however, is meaningless, unless accompanied by a statement of the thickness of the dielectric, to which it applies, as the dielectric strength of solids varies with the thickness, sometimes by many hundred per cent. Besides this, the disruptive strength depends on the temperature, the duration and rate of the voltage application, the humidity, previous history of the sample, etc., and even with tests made under identically the same conditions, just as wide differences occur between successive tests of solid dielectrics, as shown by Fig. 2 to occur in liquids. The "disruptive strength of a solid dielectric" thus has only a limited meaning, and that, when the conditions are fully given.

Disruptive strength tests of solid dielectrics are usually made on sheets between metal plates as terminals, to produce a uniform dielectric field. This is open to the objection that at the edges of the terminals the field is not uniform. However, experience shows that puncture does not always occur at the edges of the terminal plates, but often inside, and by throwing out the tests in which the disruption takes place at the edge of the terminals, and averaging those in which the disruption occurs well inside of the terminals, fairly representative results are secured.

Two phenomena come into consideration in solid dielectrics: The electric conductivity and the dielectric losses in an alternating field.

The dielectric has an appreciable though usually very low conductivity. That is, under an impressed voltage, a slight current is conducted through it, causing a loss of power and thereby a heating of the dielectric. The power consumed by ohmic conduction in the dielectric usually is extremely small, at least at atmospheric temperature. The conductivity usually

increases very greatly with the temperature, often approximately exponentially, (for instance, increases ten-fold for every 25 deg. temperature rise, so that at high temperature the dielectric may become a good conductor). Often, the conductivity also increases with increasing voltage. In an alternating field, the resistance loss usually is very small compared with the other dielectric losses.

Under an alternating voltage, losses occur in the dielectric, more or less of the nature of a dielectric hysteresis. While probably mainly proportional to the frequency, some of these losses may increase faster than the frequency, some at a lesser rate, giving in the latter case a dielectric loss at zero frequency.

These dielectric losses may be represented by an energy current and an effective conductivity of dielectric hysteresis, and lead to a power factor of the dielectric. If the energy current of dielectric losses is proportional to the frequency and to the voltage, and the dielectric power loss therefore proportional to the frequency and the square of the voltage, then the power factor of the dielectric circuit is constant and independent of the frequency and the voltage. An increase of power factor with increasing voltage shows losses increasing faster than the square of the voltage, such as losses due to ionization of gas spaces inclosed in the dielectric; a decrease of power factor with increasing frequency shows losses increasing less than proportional to the frequency, or constant losses such as ohmic conduction losses.

The observation of the power factor thus is one means of judging the nature of the losses in the dielectric.

A dielectric of high disruptive strength in general has low conductivity and low dielectric losses, thus a low power factor in an alternating field; but the reverse is not necessarily the case, that is, a dielectric may have low conductivity or low power factor, and still be of poor disruptive strength.

It is doubtful whether a true dielectric strength of solid insulation exists, that is, a definite voltage gradient at which the dielectric is disrupted directly by the intensity of the dielectric field; or if it exists, it is so far beyond the disruptive strength observable, as to be of no practical consideration. That is, puncture of a solid dielectric probably in practice always occurs as the result of a more or less rapid progressive deterioration, far below the true dielectric strength, and the latter may be of moment only under direct lightning condition, for instance, in the puncture of a sheet of insulation by a powerful Leyden Jar discharge (giving the characteristic appearance of an internal explosion).

The mechanism of the breakdown of a dielectric under electric stress, may probably be any of a number of possibilities, thermal, mechanical, chemical, physical, etc.

MECHANISM OF THERMAL BREAKDOWN OF THE DIELECTRIC AS THIRD CLASS CONDUCTOR

Many, if not most of the dielectrics in reality are third class conductors, that is, have in some range of their voltampere characteristic such a high negative temperature coefficient of conductivity, that in temperature equilibrium the voltage decreases with increasing current.

Suppose a uniform sheet of solid dielectric is exposed to a constant direct voltage between two conducting terminals. Due to the slight conductivity of the dielectric, a current then flows through it at a uniform, though very low current density. This consumes electric energy, converting it into heat, and gives a slight temperature rise of the dielectric. Now, no material can be absolutely uniform and homogeneous, and thus in this sheet of dielectric there will be some spots of a slightly higher conductivity. However slight the difference, at such a spot the current density must be slightly greater, thus the energy consumption and the heat production slightly greater, giving locally a slightly higher temperature rise. However little this may be, if the conductivity of the dielectric increases very rapidly with increasing temperature, it will lead to a slightly higher current density, a correspondingly higher energy consumption and heat production and thus temperature rise, and so on. Two possibilities then exist, either the heat which can be conducted away from such a "hot spot" due to its temperature rise, is more than the heat produced by the increased conductivity due to the temperature rise. Then the temperature of the hot spot finally limits itself, and stable thermal conditions pertain. Or the heat which can be conducted away from the hot spot into the dielectric, by the temperature rise, is less than the heat produced in the dielectric by the increased conductivity due to the temperature rise. Then the conditions are unstable, that is, the temperature continuous to rise and the conductivity to increase indefinitely, until the energy concentration at the hot spot becomes destructive, and the dielectric is destroyed by "puncture."

The successive steps of this phenomenon have been observed by limiting the current density by suitable terminals and can be calculated from tests made on the conductivity of the dielectric at various temperatures and voltages.

As the energy consumption by the conduction current varies with the square of the voltage, there is thus a definite voltage—for a given set of conditions—at which instability is reached and puncture results, and this voltage is the "breakdown voltage," its voltage gradient the "dielectric strength" of the material under the conditions of test. This voltage depends upon the initial temperature, and considerably decreases with increasing temperature; at higher

temperature, a lesser temperature rise is necessary to reach unstable conditions, and at the higher initial temperature the phenomenon starts with a higher conductivity, that is, greater power consumption and heat production. The heat conductivity of the dielectric and of the terminals and other surrounding objects, and their ability to quickly absorbing heat, that is, their specific heat, are essential factors in determining the value of the puncture voltage. An essential factor also is the relation between temperature and conductivity of the dielectric, etc., so that the "dielectric strength" thereby determined, is very far from a constant for the material.

Suppose the "hot spot" is filamentary in shape. That is, the diameter of the spot of slightly higher conductivity (or temperature) at which the breakdown starts, is small compared with its length in the direction of the lines of force, so that heat conduction from it is essentially into the dielectric. Then a change of thickness of the dielectric will not affect the heat conduction, and in this case it follows that the disruptive voltage is proportional to the thickness of the dielectric, its dielectric strength independent of the thickness.

Suppose however the "hot spot" is plate-shaped, that is, its dimension parallel to the lines of force (from terminal to terminal) is small compared with its diameter parallel to the terminals, so that the heat conducted from it flows into the terminals. Then an increase of thickness of the dielectric gives an increase of heat to be conducted through a longer distance through the same area, thus instability is reached at a lower voltage gradient. In this case it is found that the puncture voltage is proportional to the square root of the thickness of the dielectric, and the dielectric strength inversely proportional to the square root of the thickness.

In general then, in dielectric breakdown by temperature instability, depending on the path of the heat conduction, the puncture voltage varies between the first and the 0.5th power of the thickness of the dielectric, and the dielectric strength or breakdown gradient varies between independence of the thickness, and the—0.5th power of the thickness of the dielectric.

This phenomenon of dielectric breakdown by thermal instability is the result of the increase of energy loss in the dielectric, with increasing temperature, and occurs wherever the losses greatly increase with the temperature. While its mechanism has been illustrated above on ohmic conduction in a direct-voltage field, the same phenomenon occurs in the same manner in an alternating field, and as the result of the specific losses of the nature of a dielectric hysteresis, as far as these losses increase with the temperature. The increase—and usually very rapid increase—of the power factor with the increase of temperature of most dielectrics shows that the losses in the dielectric in an alternating field, increase with the temperature, and

thermal instability leading to puncture at "hot spots" thus results.

MECHANISM OF DISRUPTION DUE TO MECHANICAL INSTABILITY

Suppose a dielectric encloses a particle of a higher conductivity or higher specific capacity. An electric field then exerts a mechanical force on this particle, which tends to elongate it in the direction of the electric field, and to compress it at right angles thereto, that is, tend to form it into a filament short-circuiting the dielectric field. With liquid dielectrics, this can be observed visually by dropping a little water into a horizontal sphere gap in a transparent oil. Each droplet, as it is sucked into the field between the spheres, lengthens into a filamentary conductor which bridges between the terminals, and then is destroyed with a flash by the heat of the current conducted by it. A similar phenomenon occurs with moisture in a solid dielectric, except that the puncture usually is permanent; occluded moisture moving under electrostatic forces through the pores of the solid dielectric, may form a conducting bridge between the terminals and by the heat of the current in the moisture filament start destruction of the dielectric. Or the moisture-thread may partially bridge between terminals and locally short-circuit the field, which will cause excessive dielectric stresses in the part of the gap in series with the moisture filament. In these over strained portions of the field, destruction starts by thermal or chemical instability, etc.

In impregnated insulation, where the impregnating material is liquid or viscous, motions of the impregnating material through the impregnated material may result from the mechanical forces caused by differences in specific capacity or conductivity of the materials, leading to a redistribution of the impregnating material. Conductivity and specific capacity here act in the same direction, in general. The differences in specific capacity of different dielectrics are however relatively small; rarely more than 1 in 6 in materials which are suitable for apparatus insulation; while the same constituent materials may differ in conductivity over an enormous range. The final effect of conductivity as compared to specific capacity is likely therefore, to be much greater. On the one hand, the mechanical forces due to differences in specific capacity appear instantaneously, and thus are present also in alternating fields. On the other hand the differences due to difference in conductivity appear gradual, being accompanied by the formation of local internal electrostatic charges, and may require seconds or even minutes for their completion. These local changes would not be present or only partly present in alternating fields, and the mechanical actions of alternating fields thus differ from those of continuous fields. This can conveniently be observed visually on sphere gaps in oil.

MECHANISM OF DISRUPTION BY CHEMICAL DETERIORATION

Suppose the dielectric contains a particle of higher specific capacity or higher conductivity. Let us assume, at first, this particle to be spherical in shape, and of relatively infinite specific capacity or conductivity, that is, short-circuiting the field (for instance, an oil of 10 megohms resistivity would fulfil this condition in a dielectric of 1000 megohms resistivity). Then the density of the lines of dielectric force inside of the spherical particle is three times that in the surrounding dielectric, and—at least temporarily, until a redistribution of internal charges has occurred—the density of the lines of dielectric force and thus the voltage gradient in the dielectric outside the poles of the spherical particle would be three times normal. It would be less than three times normal, if the specific capacity or conductivity of the spherical particle differs less than given above from the surrounding dielectric. But it would be greater if the particle is not a sphere, but more irregular in shape, and would assume much higher values at the edges and at points of the particle. Thus in the dielectric adjacent to edges or points of an enclosed particle of higher specific capacity or conductivity, very high-voltage gradients occur, and may be far beyond the dielectric strength of the material, and lead to local breakdown of the material by what may be called “electrostatic cutting edges.” With organic insulation, the effect usually would be carbonization by high local temperatures, a chemical change which in general increases the conductivity. The mechanical electrostatic forces brought about hereby are in the direction of the field, so that the shape of the product of chemical deterioration tends toward the form of a conducting needle, with excessive voltage gradients in front of it, gradually piercing the dielectric until final puncture occurs between the terminals. Thus in a laminated insulation consisting of very many layers, a foreign particle in one of the layers though originally forming only an insignificant part of the total thickness of the dielectric, may gradually but cumulatively, in the course of time, pierce and destroy the insulation by its electrostatic cutting edges, the average voltage gradients within the dielectric, being still very low compared with the tested “dielectric strength” of the material. The destruction will be the faster, the higher the local voltage gradient. This seems to be the main reason why such excessive margins are required in high-voltage insulation, to give reasonable length of life.

IONIZATION

The specific capacity of the common solid dielectrics is from 2 to 8 times that of air. Thus if air pockets are contained in the dielectric, the electric stress in the air is much higher than in the solid, and as the breakdown gradient of air is low, it breaks down with the formation of “corona,” giving heat and chemical

action, and such ionization due to enclosed air probably is a frequent cause of disruption. It is guarded against by excluding the air by impregnation with a material of higher dielectric strength and higher specific capacity, such as oil. It means however, that the process of impregnation to be effective must be perfect.

It is interesting to note that some of the mechanisms of breakdown, as thermal instability and mechanical forces, are reversible, that is, at the withdrawal of the voltage, the original condition may gradually return, leaving the dielectric undamaged, while the chemical deterioration by the electrostatic cutting edges or by ionization is irreversible, that is, what damage has been done is permanent and remains at the withdrawal of the voltage, and at the next application of voltage, the deterioration progresses further.

In non-homogeneous dielectrics, such as laminated insulation, due to the differences in the ratios of the respective specific capacities and the specific conductivities of the component dielectrics, gradual changes may occur in the distribution of the voltage gradients through the dielectric, with the formation of internal charges, which continue for some time, thus resulting in a corresponding change of the dielectric stresses.

V. Time Lag of Insulation

The two important properties of insulation are its dielectric strength and its time lag. The former means that there is a limit in the voltage gradient up to which an insulation can hold back the voltage, and when this voltage gradient, the “dielectric strength” or “disruptive strength” of the insulation, is reached, disruption occurs and the insulation ceases to insulate, becomes a conductor.

Experience shows the following condition: At least with very many insulations, the voltage at which disruption or breakdown occurs, depends on the time or duration of voltage application. The lower the voltage, the longer the time it has to be applied. There is a minimum voltage, which continuously applied, still just disrupts the insulation, and inversely, the higher the voltage, the shorter is the time during which it has to be applied.

This time, during which a given voltage has to be applied to cause disruption, is called the “time lag” of this voltage. The ratio of this particular voltage of brief application to the voltage which permanently applied breaks down the insulation, is called the “impulse ratio” of the time of voltage application.

Time lag bears to dielectric strength, in electrical engineering, a relation similar to the one between elasticity and mechanical strength in mechanical engineering; if it were not for elasticity, there would be no mechanical engineering. A pebble dropped on an armor plate would shatter it,—since theoretically, at the point of impact, without elasticity infinite mechanical forces would be produced.

So without the phenomenon of time lag, there would

be no electrical engineering, as there would be no possibility of insulation, since every insulation, even a low-voltage lighting circuit, is theoretically constantly exposed to transients of infinite voltage (though negligible energy), that is, far beyond its possible dielectric strength, by the inductive and capacity effects of any change of circuit conditions, and thus saved only by the time lag of its insulation.

Just as the relations between mechanical strength and elasticity give the wide variety of structural materials, on which the mechanical engineer depends, and which we denote by brittle, tough, ductile, elastic, rigid, flexible, yielding, etc., etc., so the relation of time lag to dielectric strength gives us insulating materials of widely different properties and correspondingly widely different uses—but our knowledge in this field is unfortunately still very limited.

To illustrate the importance of the time lag: Experience as well as calculation shows that in 2300-volt primary distribution circuits during thunder storms, potentials of short duration of the magnitude of hundred thousand volts are not infrequently produced by the setting free, by the lightning flash, of the bound charge of the atmospheric electrostatic field. The lightning transformers distributed over these circuits are not, and economically cannot be insulated to stand this voltage continuously. Hence, they must depend on the time lag of their oil insulation to stand the lightning voltage until it is dissipated or discharged by the lightning arrester. Inversely, the time lag of the lightning arrester must be so short, and its discharge rate so high, as to discharge the lightning voltage in a time less than the time lag of the transformer, bringing the voltage down to values safe for the transformer.

From the phenomenon of time lag it results that the rate of voltage application has a discriminating effect. Suppose two insulations are used in parallel, the one of lower dielectric strength but higher time lag than the other. (As for instance, the oil insulation of a transformer and the surface air insulation of its entrance bushings). At very rapid voltage application, the voltage may rise beyond the dielectric strength of the stronger insulation of shorter time lag, in less than the time lag of the weaker insulation, and the former thus punctures, while with a slower voltage application the weaker insulation of greater time lag would puncture. Thus under lightning conditions, the transformer bushings may flash over, short-circuit and blow the fuses without any damage to the transformer, while under high potential test the oil insulation may puncture far below the voltage at which the bushings flash over.

To illustrate the importance of this discriminating effect of rate of voltage rise: The insulation of high-voltage transmission lines depends on sectional or string insulators. With these, it is very desirable that in case of a failure the insulator disks should flash over rather than puncture. The transmission insulators

thus are designed for a puncture voltage much higher than the flashover voltage, and 60 cycles tests as well as high-frequency tests show such insulator strings to flash over and not to puncture. Nevertheless lightning punctures them not infrequently. The time lag of flashover is greater than that of puncture, due to the relatively high capacity of the insulator string. Therefore, under lightning conditions, that is, very rapid application of voltage of considerable energy, the voltage reaches puncture values in less than the time lag of flash over, while in low-frequency tests flashover limits the voltage, and in high-frequency tests the rate of voltage application is reduced, that is, the wave front flattened by the capacity of the insulator string, unless there is very great power back of the voltage, so as to maintain it against the short-circuiting effect of the capacity of the testing appliance (so-called "lightning generator").

TIME LAG OF SOLID AND LIQUID INSULATION

When the mechanism of the dielectric breakdown of the insulation consists of a cumulative thermal, mechanical or chemical effect, as discussed above, it inevitably involves a time lag, and usually a considerable one.

This time lag may be as short as a fraction of a second, such as occurs in the electrostatic field of an oil gap sucking in a moisture droplet, stretching it into a filamentary conductor, bridging between the electrodes and flashing over. In the formation of hot spots in solid insulation, it may take minutes and hours, until the process leads to the final disruption, and may extend to days and years in the chemical action of ionization, etc., so that here the time lag of the insulation breakdown gradually merges into the aging or deterioration of the insulation.

For instance, under overload a cable may get overheated and some hot spots form in the insulation and finally, after some hours, lead to a puncture. If however the load is taken off before the final breakdown, the cable cools and the hot spots disappear and leave the insulation undamaged, and we say that the cable has been saved by the time lag of insulation and no harm done by the temporary overload, because in this case of approaching thermal breakdown the process is reversible.

If however, under high-voltage test, ionization occurs in the cable and by chemical action begins to destroy the insulation, we also may say that the cable is saved by the time lag of chemical breakdown, if the over-voltage is taken off before failure has occurred. However, as this process is not reversible, some damage has been done, and at the next overvoltage further damage is done and adds itself, until final disruption occurs.

In some respect, we may thus consider the gradual and slow aging and deterioration of the insulation during the years of use, which limits its final life, as a progressive breakdown, and the entire life of the

to the dielectric field intensity g , and therefore in the time t acquire the velocity v , in a uniform field:

$$v = g t \quad (1)$$

In a non-uniform field, the velocity would be given by:

$$v = \int g dt \quad (2)$$

Let us assume that there is a critical velocity v_0 , at which these carriers produce additional carriers by collision with the atoms or molecules of the air or gas.

The time t_1 required to reach collision velocity v_0 then is,

$$t_1 = \frac{v_0}{g} \quad (3)$$

and the distance, within which this is reached:

$$l_1 = \frac{t_1 v_0}{2} = \frac{v_0^2}{2g} \quad (4)$$

thus:

$$l_1 g = \frac{v_0^2}{2} = \text{const.} \quad (5)$$

or, in a non-uniform field:

$$\int g dl = \frac{v^2}{2} = \text{const.} \quad (6)$$

This is of the dimension *voltage*. That is, a definite voltage,

$$e_0 = \frac{v_0^2}{2} \quad (7)$$

is required to raise the free conducting carriers of the air to the collision velocity v_0 , at which they produce additional carriers from the atoms or molecules.

The voltage e_0 may be considered as of the nature of a terminal drop, which must be present before the formation of conducting carriers can take place.

It then would be the minimum voltage, approached for minute air gaps:

$$e_0 = 320 \text{ volts.}$$

2. As the conductivity of the air rapidly disappears with the withdrawal of the dielectric field, these conducting carriers must be very short lived.

Let then g_0 be the voltage gradient, at which the rate of production of conducting particles equals their rate of decay, and the number of conducting particles, that is, the conductivity of the air, remains constant (whatever may be its value, whether high or low).

$$G = g - g_0 \quad (8)$$

then is the rate of increase of conducting particles, or the "ionizing force," and

$$\begin{aligned} c &= G l \\ &= (g - g_0) l \end{aligned} \quad (9)$$

or in general, in a non-uniform field:

$$c = \int_0^l (g - g_0) dl \quad (10)$$

is the total production of conducting particles in the distance l , or the *ionic density* or *conductivity* produced by the gradient g in the distance l .

If we assume that the conducting particles or carriers are produced from the gas molecules by collision, the ionic density or conductivity c must reach a finite maximum value, at which "complete ionization" of the gas has occurred, and the conductivity thus reached its maximum or "short circuit" value c_0 .

Dielectric breakdown thus would be characterized by

$$c_0 = (g - g_0) l_0 = \text{constant} = e_1 \quad (11)$$

or, in a non-uniform field

$$c_0 = \int_0^l (g - g_0) dl = \text{constant} = e_1 \quad (12)$$

This quantity e_1 is of the dimension of an e. m. f. and may be called the "conduction voltage."

To cause dielectric disruption of an air gap, there must thus be available a dielectric field giving

(a) A terminal drop $e_0 = 320$ volts.

(b) An excess gradient g , above the critical gradient g_0 (the so-called "dielectric strength of air"), extending over such a distance l_0 as to integrate to a definite voltage e_1 , required to produce complete ionization or maximum conductivity of the air.

(c) The normal or critical gradient g_0 , required to maintain the conductivity, and extending as far as the breakdown extends.

3. Applying this to the air gap between spherical electrodes:

With spherical electrodes of radius r , assuming first, that the other electrode is of such shape or so far away as not to distort the field, if we denote

g_r the gradient at the surface of the sphere of radius r .

r_0 the radius, at which the gradient has decreased to g_0

we have, at radius x ,

$$g_x = \left(\frac{r_0}{x} \right)^2 g_0 \quad (13)$$

and

$$\begin{aligned} c_0 &= \int_r^{r_0} (g - g_0) dx = g_0 \int_r^{r_0} \left\{ \left(\frac{r_0}{x} \right)^2 - 1 \right\} dx \\ &= g_0 \left(\frac{r_0^2}{r} + r - 2r_0 \right) = \frac{g_0}{r} (r_0 - r)^2 \end{aligned}$$

it follows, solving for r_0

$$r_0 = r \left\{ 1 + \sqrt{\frac{c_0}{g_0 r}} \right\} \quad (14)$$

$$= r \left\{ 1 + \frac{m}{\sqrt{r}} \right\}$$

and the voltage gradient at the surface of the electrode sphere is

$$g_r = g_0 \left(\frac{r_0}{r} \right)^2$$

$$= g_0 \left\{ 1 + \frac{m}{\sqrt{r}} \right\}^2 \quad (15)$$

or approximately

$$g_r = g_0 \left\{ 1 + \frac{2m}{\sqrt{r}} \right\} \quad (16)$$

where

$$m = \sqrt{\frac{c_0}{g_0}} \quad (17)$$

$g_0 = \delta g_{00}$, where δ = air density and g_{00} equals critical gradient at normal air density $\delta = 1$, at 0 deg. cent. and 76 cm. barometer.

It thus is

$$r_0 = r \left\{ 1 + \frac{m_0}{\sqrt{\delta r}} \right\} \quad (18)$$

$$g = g_{00} \delta \left\{ 1 + \frac{m_0}{\sqrt{\delta r}} \right\}^2 \quad (19)$$

$$= g_{00} \delta \left\{ 1 + \frac{2m_0}{\sqrt{\delta r}} \right\} \quad (20)$$

where

$$m_0 = \sqrt{\frac{c_0}{g_{00}}} \quad (21)$$

and c_0 is the (total) conduction or ionizing voltage, g_{00} the critical gradient at unit air density, and δ the air density. Equations (14), (16), (18) and (20) are the equations of energy distance and of surface gradient, given by Peek, and are here derived from the conception of the dielectric breakdown as a conductivity phenomenon.

4. With small gaps between plates or spheres of a diameter large compared with the gap length, the dielectric field and the gradient are uniform throughout the gap, and the maximum gradient, or gradient at the electrode surface, equal to the mean gradient throughout the gap.

$$g = e/l$$

and the conduction voltage required to produce maximum conductivity is by (11) given as

$$e_1 = (g - g_0) l \quad (11)$$

(a) Assume the gap length is so small, that the ionic density increases throughout the entire gap, that

is, the gap length l is less than the length l_0 , within which the density of conducting particles increases from the low density existing in the free air, to the maximum density, where maximum conduction is produced, and the dielectric gradient thereby has dropped to g_0 , so that no further increase of ionization occurs.

The conductivity throughout the gap then varies from the low initial value to the maximum value of gradient g_0 , and its average is half the maximum value, and the average gradient throughout the gap thus is twice the minimum value g_0 .

That is, in a short gap, the average gradient must be $2g_0$, and the voltage consumed by the gradient (which might be called "stream voltage," in distinction from the voltage e_0 of (7) or the "terminal drop") thus is:

$$e_1 = 2g_0 l \quad (22)$$

this gives as the total voltage consumed by the dielectric breakdown of a very small gap of length l ,

$$e = e_0 + e_1$$

$$= e_0 + 2g_0 l \quad (23)$$

b. Assume the gap length l to be greater than the ionizing distance l_0 , that is, the distance in which equation (1) produces maximum conductivity. Dielectric breakdown of the gap then requires the voltage

$$e_0 = (g - g_0) l_0$$

as the voltage producing the conducting stream, or the "terminal drop" (though not limited to the terminal alone).

$$e_1 = 2g_0 l_0$$

as the voltage consumed by the average gradient $2g_0$ in the distance l_0 , in which the conductivity is produced by (1)

$$e_2 = g_0 (l - l_0)$$

as the voltage consumed in the rest of the gap ($l - l_0$) by the gradient g_0 required to maintain conductivity.

The total voltage thus is,

$$e = e_0 + e_1 + e_2$$

$$= e_0 + 2g_0 l_0 + g_0 (l - l_0)$$

$$= e_0 + g_0 l_0 + g_0 l \quad (24)$$

$$= E_0 + g_0 l$$

where

$$E_0 = e_0 + g_0 l_0 \quad (25)$$

is the total excess voltage over that consumed by the critical gradient g_0 in the gap l .

c. Assume now that the gap is larger and the field is not uniform.

As g_0 is the minimum gradient of ionic conductivity, that is, the gradient required to maintain constant conductivity, the conductivity of the gap space can extend only up to the distance from the electrodes, within which the gradient g is greater than g_0 .

The dielectric breakdown thus extends up to the distance of the gradient g_0 , and within this distance l' , the voltage consumed must exceed the value of break-

down gradient g_0 times distance l' , by the total ionizing voltage E_0 of (25), that is, must be

$$e' + E_0 + g_0 l'$$

or, since

$$e' = \int_0^{l'} g dl$$

it is

$$E_0 = \int_0^{l'} (g - g_0) dl = e_0 + g_0 l_0 \quad (26)$$

that is:

The voltage c in paragraph 3, which gives the constant m in Peek's equation (14) etc., is not merely the excess voltage e_0 required to produce the conducting stream, but is the sum of this voltage plus the excess voltage $g_0 l_0$ required by the excess gradient in that part of the field, in which the conductivity has not yet reached full value.

$$E_0 = c \quad (27)$$

5. Consider now numerical values.

From test values of small gaps between large spheres and between a large sphere and a plate, we find,

$$\begin{aligned} e &= 320 + 59 l \\ &= e_0 + 2 g_0 l \end{aligned}$$

This gives

$$e_0 = 320 \text{ volts}$$

$2 g_0 = 59$ is in good agreement with $g_0 = 30$, as the temperature correction has not been applied.

For medium gaps, (case 4b,) the tests give,

$$e = 2370 + 30 l$$

Thus

$$E_0 = 2370 = c_0$$

This gives by (17)

$$m = \sqrt{\frac{2.370}{30}} = \sqrt{0.079} = 0.28$$

in good agreement with Peek's value: $m = 0.27$ or

$$g = g_0 \left\{ 1 + \frac{0.56}{\sqrt{r}} \right\}$$

while Peek gives

$$g = g_0 \left\{ 1 + \frac{0.54}{\sqrt{r}} \right\}$$

The limit l_0 between equation (23) and (24) is

$$e = e_0 + 2 g_0 l = 0.320 + 60 l_0$$

$$e = E_0 + g_0 l = 2.370 + 30 l_0$$

$$l_0 = 68 \times 10^{-3} \text{ cm.}$$

which is in close agreement with the experimental data given in the tables and figures, of $l_0 = 69$.

In Figs. 4, 5 and 6 are given numerous test values taken under various conditions, as indicated, with the theoretical curves shown by the drawn lines.

6. The polarity of the charge of the conducting particles or carriers, which give the dielectric breakdown of air gaps at atmospheric pressure, can be determined by the action of unsymmetrical gaps at direct voltage. Consider an unsymmetrical air gap such as that between a needle point and a plate, or between a small and a large sphere. In such a gap, with increasing applied voltage, the critical gradient g_0 is first reached and thereby the production of conducting particles

FIG. 4

started at that terminal, which has the greater curvature and thus the higher gradients, the point or small sphere. If then the polarity of this terminal is that of the conducting carriers, these move outwards away from the terminal, towards the opposite terminal, and thereby short circuit the gap and cause disruption as soon as the average gradient is sufficiently high to maintain the conducting stream across the gap. If

FIG. 5

however, the larger terminal—plate or large sphere—is of the polarity of the carriers, a higher voltage across the gap is required before the critical gradient is exceeded and the swarm of conducting carriers started at this larger terminal and disruptive discharge occurs. At the smaller terminal, in this case, the formation of conducting carriers has started already at lower voltage, but these carriers do not move away from the terminal and across the gap, and thus do not cause

break down, but move towards the terminal near which they started, and form a local corona in the space at and near this terminal.

Thus with unsymmetrical gaps, the direction of the polarity of the applied voltage should make a difference in the disruptive voltage, and this voltage be higher with the voltage in one direction, than with the voltage in the opposite direction. As the average gradient in the space in which the conducting particles are formed, was shown to be about twice the breakdown

FIG. 6

gradient of air, the disruptive voltage of such an unsymmetrical gap should be about twice as high with the voltage of the carriers on the large electrode, than with the voltage of the carriers in the opposite direction. Fig. 1 shows this, and also shows that the disruptive voltage is lower with the small terminal (the needle point in this case) positive.

It follows from this, that the conducting particles or carriers, which carry the disruptive discharge in air at atmospheric pressure, are *positively* charged, that is, they may be the *positive* ions, but cannot be the negative *electrons*.

7. Dielectric conduction thus may be either ionic, or electronic. The relation possibly is the following:

At atmospheric pressure the voltage required for ionic conduction, that is, disruptive discharge, is much lower than the voltage required for electronic conduction, and the conduction, that is, the disruptive discharge through air, is ionic, that is, by positive carriers. With decreasing air pressure, the voltage required for ionic conduction decreases, approximately proportional to the air pressure, and the conduction thus remains ionic. At some low pressures a minimum value of voltage (or rather voltage gradient) is reached. Then, with further decrease of air pressure, the voltage of ionic conduction again increases, due to the decrease of carriers, and finally passes beyond the voltage of electronic conduction. The phenomenon then changes its character, ionic conduction ceases and electronic conduction begins. At high vacuua, the conduction thus is electronic.

There is a difference between ionic and electronic conduction: Ionic conduction permits practically

unlimited current, and when it begins, thus short-circuits the gap and drops the voltage. Electronic conduction however is limited in current, and when it occurs, the voltages can be maintained and still further raised. At such high vacuua, where the voltage of ionic conduction has risen beyond that of electronic conduction, and the conduction become electronic, the voltage can be raised beyond the value of ionic conduction through the traces of residual gases, and then ionic conduction again begins and "short-circuits" the electron tube, thus limiting electronic conduction. Therefore a practically perfect vacuum is needed for pure electronic conduction in the modern high-power electron tube.

On the other side, with pressures higher than atmospheric, the disruptive voltage increases with increasing pressure, and approximately proportional thereto, as shown by experiment. It may be expected then, that at some high pressures the voltage of ionic conduction increases beyond that of electronic conduction, and the latter limits the increase of disruptive strength of gases at high pressures. While this field has been little investigated, experiments indicate that the dielectric gradients of air and gases with increasing pressures reach a limiting value somewhere at 1000 kv. per cm.

Discussion

R. W. Sorensen: My first point is in connection with the statement that we use our insulations under stresses which rarely exceed the breakdown voltage of air, though tests show a strength of 10 to 20 times that of air for many of the insulations used. This plea for a more strenuous use of insulating materials is

FIG. 1—ARCING POTENTIAL VS. GAP LENGTH

Between Needle and Sphere, 12.5 cm. dia.

Curve I—Direct Current, Sphere Negative

" II— " " " Positive

" III—Alternating Current, Maximum Values.

interesting in the light of a request in another paper given this morning, in which the author recommends a decrease in the test voltage applied to transformers with one terminal grounded.

In Fig. 1 of the paper the curves show the interesting fact that a given potential will cause spark over between a point and a sphere for much greater spacing when the sphere is negative, than will be the case with the needle points negative and the sphere positive. The results shown in Fig. 3 have been duplicated by Messrs. Otis and Mendenhall, two students at California Institute of Technology as shown by the curves in Fig. 1 accompanying this discussion. In making these tests the high-

voltage alternating current was rectified by means of a two-segment commutator driven by a two-pole synchronous motor.

The a-c. curve is very much like that obtained by Hayden and Steinmetz, but the d-c. curves differ in shape because of the pulsating current obtained with the commutator, whereas Hayden and Steinmetz had very steady current delivered by a four kenetron rectifier. An explanation of the dip in these curves would be very interesting.

In John S. Townsend's "Ionization of Gases by Collision" is found this statement "When the point is negative, the strong field is near the negative electrode, so that the potential required to produce a discharge is less than when the point is positive." Also in "Conduction of Electricity through Gases," 1906 edition, by J. J. Thompson on page 498 we find this statement ".....this minimum potential depends upon the sharpness of the point, the pressure and nature of the gas, and the sign of the electrification of the point, being less if the point is negatively than if it is positively electrified." Hence we have from these authorities statements which, at first reading, appear quite contrary to those given in this paper.

There is, however, some confusion as to the definition of the term "spark discharge," in the texts referred to the term does not seem to apply to an arc current and the voltage required to cause it, but means the point at which a leak discharge only and not a complete arc over occurs between the electrodes. In fact in one treatise on the subject of ionization this definition appears: "Sparking potential may be defined as the potential which is required to maintain a very small current in the gas."

Dr. Millikan has explained the Hayden-Steinmetz results on the basis of the increased difficulty experienced in extending the ionization envelope with negative points, as compared to that phenomena for positive points, hence the required higher potentials for a breakdown over a given distance.

In discussing the mechanism of "thermal breakdown of dielectrics" the paper follows the work of Mr. Wagner as published in the JOURNAL for December 1922, but Wagner does not deduce the same law. Also some tests we have made in our laboratory do not conform the deduction that puncture voltage is proportional to the square root of the thickness of dielectric.

To emphasize "time lag" is indeed worth while as our experience shows it an important factor in making an analysis of voltage stresses on insulations, and indicates that an intensive study should be made of the laws which govern it. It may be of interest to note here that in testing thousands of porcelain insulators I have found that very few which stand a potential test at minimum are over voltage for fifteen seconds, fail when the potential is applied for a longer time. In testing apparatus insulated with organic insulating materials very often potentials apparently harmless when applied for short periods will cause breakdown when applied for longer periods of time.

At the bottom of the last page: "It follows from this, that the conducting particles or carriers, which carry the disruptive discharge in air at atmospheric pressure, are positively charged, that is, they may be the positive ions, but cannot be the negative electrons."

If an atom is ionized and you have your positive ions turned loose what becomes of the negative ions, where do they go?

Then follows: "At atmospheric pressure the voltage required for ionic conduction, that is, disruptive discharge, is

much lower than the voltage required for electronic conduction." This is explained further on in the paper. If you have a perfect vacuum, as stated, how would you have the pure electronic conduction? I presume tubes in which there are heated filaments have been used.

C. P. Steinmetz: The paper deals with a subject which has assumed, in the last year, a still greater importance than it had before, that is, the problem of high-voltage insulation and mechanical breakdowns.

This is such a vast field and so much work has and is being done, and can be done, that the paper must necessarily be only a general part of the preliminary announcement of the results and investigations, with a more complete record of results to be announced at some future occasion.

There is, however, one feature which begins to get clear, namely, that our conception of insulation and of breakdown of insulation again begins to change and to be subjected to multiplication. To members in the early days, insulation was merely a boundary bar. We knew, by experience, that a tenth of an inch of insulation of a conductor would protect it against 2300 volts. Then, when it came to higher voltages we realized that there is something occurring within the boundary bar, of importance, and it is not merely the material, but there is a dielectric field with potential radius and other things within the boundary bars which require consideration and study, and which we are studying.

Now, it seems that our views are just beginning again to get a multiplication with respect to at least the failure of insulation and the mechanism of breakdowns. It seems to be clear that the mechanism of breakdowns, under the failure of insulation on high voltage is a phenomena of instability. In other words, it is not that insulation fails, that dielectric breaks down, when electric stresses are beyond limits and value, but it is said that under conditions very much lower than those gradients in lightning conditions of instability occur which gradually brings about the multiplication and changes leading ultimately to a breakdown of insulation. It is, therefore, a condition of instability of constants of material which instability brings about, largely upon lesser changes, which leads either to destruction or breakdown. Therefore, the mere reduction or stress on the insulation is not a factor which saves breakdowns, but that the new problem of insulation seems to assume the shape of arranging of designs in the dielectric field of insulation, so as to get the condition of stability and not instability. That is the future which seems to impress itself upon us. The more we study the problems of insulation we find that it is not existing stresses that cause this, but largely it is the result of stability, or instability.

Now, that is not only true in solids, but probably in the air. In this respect we could point out the same idea that the discharge makes its own gradient. Now, you have the same conception there, that it is the discharge which is taking place in the dielectric field about conditions which are unstable. We all know that if we had 2,000,000 volts spread over, I don't know how many thousand inches, there could be a gradient that would be so low there would be no puncture and for that discharge under such conditions. By the discharge making its own gradient there would be produced a dielectric condition of instability which would finally lead to self-destruction.

Waterwheel Generators and Synchronous Condensers for Long Transmission Lines

BY M. W. SMITH

Associate, A. I. E. E.
Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa.

Review of the Subject.—It is the intention of this paper to bring out some of the special conditions which affect the operation and design of machinery for long transmission lines and the discussion is confined largely to waterwheel generators and synchronous condensers.

Under the subject of generators, the following points are discussed: Leading current drawn by transmission lines and its effect upon the stability and mechanical design of generators; characteristic curves of generators designed for operation at leading power factor; special winding connections which increase the capacity of generators for leading power factor operation for temporary periods without increasing their weight and cost; description of general construction and ventilation of a 28,000-kv-a. vertical waterwheel generator.

The following points are discussed with reference to synchronous condensers: Operation at leading and lagging power factor and how it affects the stability cost and weight of the machines; special winding connections and their effect on stability; general mechanical construction with particular reference to damper

winding design and the use of sheet steel end bells; the importance of losses and a curve showing values it is possible to obtain on machines with the latest improvements in design; starting kv-a. and how it may be minimized by the use of oil pressure in the bearings.

WHILE the design of waterwheel-driven generators and synchronous condensers for long transmission lines is, in general, the same as for other applications, there are often special conditions imposed on machinery for long transmission lines which make the design special and of greater cost and, in the case of large high speed units, often difficult. A better knowledge of these operating and design difficulties by both operating and designing engineers might enable them to modify the conditions in such a manner as to obtain a lower cost and better operating installation as a whole. Some of the special conditions applying to the design of machinery for long transmission systems are discussed in this paper with this idea in view.

LEADING CURRENT AND STABILITY OF GENERATORS

The effect of the leading current taken by a long transmission line upon a generator is shown by curves in Fig. 1. Curves 1, 2 and 3 represent the saturation curves for no-load, full-load, 0 per cent power factor lag and full-load 0 per cent power factor lead, respectively. The shape of curve 3 below the point *c* is of little practical value and is out of the range of practical operation. Assuming that an external power factor of 0 per cent lead could be maintained and no losses in the circuit the curve 3 would extend down to the point *e* and have a shape similar to curve 2. This assumption, of course, never exists. It would mean condenser capacity approaching infinity and no resistance. In actual practise the resistance and losses in the

circuit would tend to give curve 3 a shape indicated by *a d f*. However, this means that the machine must produce torque and that its power factor is not 0. With such low excitation as indicated by the point *d*

FIG. 1—REPRESENTATIVE SATURATION CURVES

even a salient pole generator cannot supply the required torque for the losses of the machine and line and will “slip a pole” or “pull out”. Therefore, in practical operation curve 3 cannot follow either the shape *a d e* or *a d f* below some point such as *c*. If in practise

it is attempted to operate the machine on curve 3 below point *c*, the generator will slip a pole as stated above and the excitation which was negative will become positive with respect to the voltage on transmission line (since it is reversed) and the voltage will rise from the value *c* to the value *g*. This, of course, is a dangerous condition and care must be taken in the design of generators which must supply high values of leading current to prevent the necessity of the field excitation being reduced to such low values that the generators will not have sufficient synchronizing power or stability. It is not considered good practise to go below zero excitation even on salient pole machines where the irregularity of the magnetic circuit permits the development of torque even at reversed excitation. On machines with uniform reluctance of the magnetic circuit in the rotor, such as steam turbine generators, stable operation cannot be had at any reversed field excitation. The term "stability" is rather general, but it is used here to refer to the ability of synchronous apparatus to remain in synchronism without hunting or pulling out of step.

EFFECT ON MECHANICAL DESIGN

To increase the stability of generators, supplying leading current the field, strength must be increased with respect to that of the armature. In other words, the design of the machine must be such that the effect of the leading current in the armature on the field will be minimized. This means increasing the ampere-turns on the field or decreasing the ampere-turns on the armature or a combination of both. Any of these methods results in a heavier and higher cost machine than normal, but the latter procedure or method is usually more economical. Not only is the weight and size of the machine increased as a whole, but the rotor parts become abnormally large in proportion to the whole machine. This means a more expensive rotor construction to withstand the high stresses encountered at the overspeed condition. On large high speed units this may become quite serious. After the limit of axial length as determined by ventilation has been reached, the only other alternative to meet abnormal line charging conditions is to increase the diameter and hence peripheral speed. Therefore, it is evident that special line charging conditions may become a limiting feature in the mechanical as well as in the electrical design.

Difficult conditions of this nature were met in the design of three large high-speed generators recently built for the Southern California Edison Company. So far as the writer knows, these generators are the largest waterwheel machines ever built to run at so high a speed. They have 50-cycle ratings of 28,000 kv-a. and 33,500 kv-a. at guaranteed temperature rises (by detector) of 60 deg. cent. and 90 deg. cent., respectively, at 428 rev. per min., and they have 60-cycle ratings of 31,300 kv-a. and 37,500 kv-a. at guaranteed temperature rises

of 60 deg. cent. and 90 deg. cent. respectively at 514 rev. per min. They are required to meet an overspeed of 85 per cent at either frequency. At the 60-cycle overspeed (951 rev. per min.) the peripheral speed of the rotor is nearly 28,000 feet, or over 5 miles per minute. This is unusually high for a salient pole machine (although quite common in cylindrical

FIG. 2—PLATE SPIDER FOR 28,000 KV-A. VERTICAL WATER-WHEEL GENERATOR

rotors of steam turbine driven generators) and a very careful design of the pole and spider proportions was necessary in order to equalize the rotor stresses and work the material in the most effective manner. The rotor spider is built of rolled steel plates, approxi-

FIG. 3—ROTOR OF 8125 KV-A. 6600-VOLT, 50-CYCLE, 600-REV. PER MIN. WATERWHEEL GENERATOR

mately $2\frac{1}{2}$ inches thick carried on a through shaft. A photograph of the spider is shown in Fig. 2. The poles are built of $1/16$ -inch rolled steel punchings which are riveted and bolted together between cast steel end plates. This built-up construction of the rotor spider insures material with uniformity and reliability which is unquestioned. The construction

of the rotor is similar to that shown in Fig. 3, except that two coil braces were necessary between poles on account of the high speed and great length of the field poles and coils.

FIG. 4

FIG. 4A

The field coils are made of copper strap formed on edge. The bulge or swell at the corners caused by the bending process was pressed out by means of a hydraulic press. In this operation steel plates were placed between turns as shown in Fig. 5 to prevent the skewing of the coils. After being smoothed up by filing where necessary the individual turns were thoroughly coated

with an air drying shellac and permitted to dry. Two insulating strips of asbestos each coated on one side with shellac were then placed between turns and the coil heated to near a red heat (by circulating current) in order to drive out all solvent and volatile matter. During this process the coil was held in shape by heavy metal sizing plates, pressed to size and allowed to cool. Particular attention was paid to the cell insulation between the coil and pole. It is made of several thicknesses of 10-mil flexible and hand built mica

FIG. 5—PRESSING OUT THE SWELL OR BULGE AT THE CORNERS OF A STRAP FIELD COIL

FIG. 5A—ASSEMBLING OF COIL INSULATION ON STRAP WOUND FIELD COIL

sheets. These sheets were cut wide enough to cover the inside of the coil and to be turned down over the top and bottom edges as shown in Fig. 5A. The mica is the darker material extending above the coil and is reinforced all around by one thickness of heavy asbestos cloth which is indicated by the light portion of the material extending above the coil. Both the asbestos cloth and mica are turned down over the top and bottom edges of the coil, but the

asbestos cloth was made sufficiently long to be turned back under and between the mica and the top and bottom of the coil. The cell was then given a heavy coat of bakelite and moulded to the coil while heated and held in place under pressure with metal plates. In this process the bakelite becomes hard and forms a solid moulded insulation around the coil. Furthermore, with the asbestos cloth turned back under the ends of the mica cell no raw edges are exposed. When the coils were assembled on the poles they were further protected by micarta washers at the top and bottom.

The drawings in Figs. 4 and 4A show a cross-section and plan view of the machine with exciter and Kingsbury thrust bearing, and a photograph of one unit without the air housing is shown in Fig. 6. The general construction of the machine is of conventional

FIG. 6—28,000 KV-A., 11,000-VOLT, 3-PHASE, 50-60 CYCLE, 428-514 REV. PER MIN. VERTICAL WATERWHEEL GENERATOR

design. The lower guide-bearing bracket is insulated from the generator frame to prevent the circulation of bearing currents through the guide and thrust bearings. The lower end plate, supporting the lower finger and core punchings, is cast integral with the frame. This construction facilitates building and pressing the core.

It was necessary that all the cooling air (for both top and bottom of the machine) be brought in at the base of the generator. On low-speed machines which permit the use of open-type spiders through which the air for the upper part of the generators may be drawn,—this condition causes no difficulty. However, on machines such as these where the size of the rotor and the stresses make it advisable to use a solid plate construction, the cooling air obviously cannot be brought up through the rotating part. A special

air housing as indicated in Figs. 4 and 4A has been used in this case for conveying the cooling air to the top of the machine and for collecting and discharging the hot air from the frame. The upper part of the housing is attached to and has the same slope as the upper bracket arms. Although the individual chambers of the air housing are eccentric with respect to the generator, the outer contour is circular (except where the outer discharge duct is attached at *D*) and concentric with the generator. This gives a symmetrical appearance and does not detract from the appearance of the machine. The cooling air for the bottom half of the unit is drawn directly from the pit, while the air for the top half is drawn in at openings in the floor up through chamber *A* and discharged into the opening or chamber between bracket arms. Holes are provided in the webs of the bracket arms through which any unequal discharge of air into this space between arms can be equalized. The air goes directly into the machine through the fans from this chamber. The air from both the top and bottom of the machine, is then forced through the vent ducts in the core and out the holes in the frame to the discharge chamber *B* and thence through the discharge *D* to the outside of the building through ducts.

CHARACTERISTIC CURVES

Two of these generators were completely assembled and set up for tests in the factory, and are about the largest units ever to receive a complete factory test. With two units assembled, it was possible to obtain temperature tests at normal voltage current and frequency at 0 per cent power factor by over-exciting one machine and under-exciting the other, the losses being supplied from the factory testing equipment. The temperature rise on the stator of the over-excited unit was within 45 deg. cent., by either of the three methods of measurement as defined by the A. I. E. E. Rules. Complete segregated losses and characteristic curves were also taken.

The characteristic no-load and load saturation curves obtained from these tests are shown in Fig. 7. These generators were designed to carry 1680 amperes at 0 per cent power factor leading and 8910 volts at 50 cycles without becoming self-excited. This is 14 per cent more than the normal current of 1470 amperes and 81 per cent of the normal voltage of 11,000. They were also designed so that with a constant separate d-c. excitation corresponding to 2000 volts no-load, they would not be self-exciting above 8910 volts when delivering 1400 amperes 0 per cent power factor leading. Both of these conditions are unusually severe. Curve 3 shows the former condition and curve 5 the latter, and it may be seen from these curves that both conditions were met with a reasonable margin. The condition shown by curve 5 is the more severe and is, of course, the determining one.

If the generator had to operate at leading power factor only, it would be quite easy to make the machine stable without exceeding normal costs and weights. However, it is the lagging power factor operation that imposes the severe condition when the machine is especially proportioned for leading power factor conditions. It can readily be seen from the curves in Fig. 7 that anything that is done to make the leading power factor operation more stable, such as increasing the air gap or the normal induction and saturation,

FIG. 7—TEST CURVES ON 28,000-KV-A., 11,000-VOLT, 3-PHASE 50-CYCLE, VERTICAL WATERWHEEL GENERATOR

will increase the demand on the field winding at lagging power factor operation. This means an increase in the field temperature, or an increase in the field copper, or an increase in the size of the machine, or a combination of these.

SPECIAL CONDITIONS AND WINDING CONNECTIONS

Ordinarily, the leading power factor operation is encountered only at short and infrequent intervals when a transmission line is unloaded and the power factor becomes lagging when the load is on. However, in the case of a line built for a large ultimate load but that has a small initial load and generating capacity the power factor even at maximum kw. load of the generator may be leading. This means that the generator must be designed for a very stable operation at leading power factor and must also be able to take care of the lagging power factor operation in the future when the ultimate load builds up on the line. For the machine to deliver power under leading power operation requires that it be designed with more stability than when merely charging the line to insure that it will not pull out of step on account of the torque it must develop. Therefore, a unit for this

class of service may become unduly large and expensive. In cases like this the use of a machine of normal design with some special connection of the armature winding, such as an inter-connected star, during the period of light load on the line is suggested. In this scheme, each leg of the ordinary star winding is opened at the mid-point and each half of each leg is connected in series with half of another leg which has a phase relation of 120 degrees with respect to it. Diagrams of this connection are shown in Fig. 8. Diagram (a) represents the standard star connection, diagram (b) represents the interconnected star with the neutral leads unchanged, and diagram (c) represents the interconnected star with the main leads unchanged. This is equivalent to reducing the armature conductors so that the voltage generated for a given flux will be 86.7 per cent of that for the straight star connection. Therefore, to get the same voltage, the field strength must be increased while the demagnetizing effect of the armature is decreased. The reactance is practically unchanged. So long as the power factor remains leading this expedient increases the stability of the machine without any extra duty on the field because of the inherently small field excitation required under such conditions. However, when the load on line increases to the extent that the power-factor becomes sufficiently low and lagging to overload the field with the machine operating at the high induction the armature must be reconnected for straight star and the machine operated under the normal lagging condition for which it was designed. With the lagging power factor there is, of course, no occasion or necessity for increased stability.

Such an expedient as the above scheme might, in some cases, be used on generators when charging the

FIG. 8—INTERCONNECTED STAR

line on starting up the system, even though the normal operation be at lagging power factor. For instance, assume there are several generators on a system and it is necessary that each machine be able to charge the line. Instead of increasing the size of the machines to make them inherently of such proportions as to be able to charge the line it might be possible to use machines of normal or of less abnormal design by bringing out the leads on the machines to a panel in such a way as to permit the connection shown in diagram (c) Fig. 8 during the period prior to the building

up of the load. After the load built up to the limit of the field capacity of this one machine, one or more of the other machines could be put on the line to carry the load while the first machine was disconnected from the line and the armature connection changed to the normal star connection. This machine could then be put back on the line, if desired. The feasibility of this method of operation will depend on local conditions. If the occasions for charging the line were very seldom and if the leads were brought out of the machine to a panel with a switching arrangement that would permit a quick change in connections, it is possible that it would be more economical and satisfactory in some cases to use this or some other special connection than to increase the size and cost of the generator to meet the special and infrequent line charging condition. Connecting the winding in inter-

FIG. 9—SHORT-CIRCUIT LOSS CURVES ON 1080-KV-A., 2400-VOLT, 3-PHASE, 60-CYCLE, A-C. MOTOR

connected star increases the line charging capacity of a normal machine about 30 per cent.

Care must be taken in the use of special connections of the winding such as interconnected star to insure the proper distribution and relation of the armature reaction set-up by the current in the armature winding. With the ordinary connection shown in diagram (b) or (c), Fig. 8, the armature reaction is not evenly distributed around the machine. This is equivalent to a resultant single-phase action and gives a negative sequence component to the rotation of the armature m. m. f. This results in excessive losses in the pole faces and damper winding, if any is used. However, by means of a special connection for interconnected star the desired result can be obtained with very little increase in losses. In this special connection the phase groups are split and the interconnection between phases made every pole. It results in a much more even and uniform distribution of the armature m. m. f.

than does the usual interconnected star and hence does not produce the bad effects found in the latter connection. This difference in the distribution of the armature m. m. f. for the straight star, the usual interconnected star, and the special interconnected star can be readily seen by plotting the armature reaction or m. m. f. for the several conditions. The m. m. f. for the usual interconnected star is irregular in shape for a given pole and varies in shape and magnitude from pole to pole, while the shape of the m. m. f. for the special interconnected star is very similar to that of the straight star. This analysis is also borne out by actual test results of short-circuit loss on a 1080-kv-a., 900-rev. per min., 2400-volt, 60-cycle machine with the usual and special interconnected star windings as shown in Fig. 9 by curves 1 and 2, respectively. Curve 3 shows the short-circuit loss for a straight star connection. It is readily seen from these curves that there is quite an extra loss for the usual interconnected star and that there is very little additional loss over the straight star for the special interconnected star. The only objection to the special interconnected star is that the number of changes in connections is greater than for the usual interconnected star by the ratio of the number of poles in a given machine. Therefore, machines which are to operate for long periods with interconnected star and then changed permanently to the straight star should have the special connection, while those which operate only for short periods with interconnected star and require that the changes in connection be made quickly, and often, should have the simpler connection. This extra loss for short periods would not be serious and the standard connection would permit the 9 leads to be brought out of the machine to a panel for rapid connection as referred to above.

OVERSPEED AND FLYWHEEL EFFECT

A reasonable overspeed is, of course, necessary for any waterwheel generator. However, it is often possible to influence it considerably by the design of the waterwheel and it should be kept as low as the economical design of the waterwheel will permit. Unusually, high overspeed, especially in the case of large high speed machines, often necessitates difficult and expensive mechanical construction and may even require a reduction in the normal running speed.

There seems to be a tendency to base the hydraulic design on a standard speed regulation and corresponding flywheel effect, regardless of the magnitude of the probable load changes. In the large units and stations usually involved in long transmission systems sudden load changes seldom amount to any considerable percentage of the connected generator rating. Under such conditions a larger percentage regulation (with 100 per cent load change) can be permitted than in the case of smaller systems in which sudden load changes may be a large percentage of the connected

generator rating. It appears to the writer that sufficient consideration is not given to actual operating conditions and that over conservative values of flywheel effect are sometimes specified on units which actually operate with very small changes in load. Flywheel effect, of course, does not become a factor in the generator design unless it exceeds the value determined by normal design. Abnormal flywheel effect always means increased cost. Either a separate flywheel must be furnished, the weight of the spider increased or the diameter of the machine increased. Even if the increased flywheel effect can be obtained at an increased diameter without increased weight, the larger diameter machine is generally more expensive. Also if the rotor weight is increased on a given diameter the mechanical parts, especially in the case of a vertical unit, must be made heavier and more expensive. In the case of large high speed units and where it is not possible to get the required flywheel effect by increasing the spider weight of a normal machine nor permissible to use a separate flywheel and it becomes necessary to increase the diameter, the stresses may increase to the extent that special and expensive construction or material may become necessary.

SYNCHRONOUS CONDENSERS

The great increase in the size and length of transmission systems in recent years has greatly increased the demand for, and importance of, synchronous condensers for correcting power factor and regulating and stabilizing the voltage of the lines.

LEADING AND LAGGING OPERATION

The majority of condensers are designed primarily for leading power factor or over-excited operation. However, on long lines where the leading current drawn by the line may be sufficient to increase the receiver voltage at light loads the condenser may be called upon to operate at a lagging power factor or under-excited, in order to maintain the normal receiver voltage. The effect of lagging current on a condenser normally designed for leading power factor operation is similar to that of leading current on a generator normally designed for lagging power factor operation and previously referred to. Anything that is done to a normal machine without increasing its weight or cost, to improve its stability under lagging power factor operation increases the duty on the field at the leading power factor condition. A condenser may be made with normal proportions and at normal costs to operate at full kv-a. leading or at full kv-a. lagging, but not at both. A machine designed to operate at both leading and lagging power factor (above a normal amount) must have increased proportions and cost. A normal condenser designed for leading power factor operation can carry about 50 per cent, of its rated capacity lagging. Although it is possible to operate condensers of salient pole

construction at considerable reversed excitation (about 50 per cent of no-load excitation) and get still more lagging capacity it is not considered good practise to operate below zero excitation on account of possible instability. With excitations below zero the machine is likely to become unstable and drop out of step during minor line disturbances.

SPECIAL CONNECTIONS AND STABILITY

The special armature connections referred to in the discussion of generators might also be used to increase the stability of condensers at lagging power factor operation in the case of a line operating at a small initial load requiring lagging condenser capacity and that will have a large ultimate load requiring leading condenser capacity. This would require that the special connection be used initially and that the machine be reconnected, straight star, for the ultimate and normal condition. Although lagging capacity

FIG. 10—14,285 Kv-A., 6600-VOLT, 3-PHASE, 60-CYCLE, 450-REV. PER MIN. WATERWHEEL GENERATOR

increases the cost of a condenser which normally operates at leading power factor it increases the stability of the machine and is quite desirable at extreme overloads on the system when the regulation limit or pull-out point of the line is approached.

CONSTRUCTION

Synchronous condensers are usually built at the highest economical speed and resemble horizontal water wheel generators in general appearances and construction. They are usually designed for very little (about 25 per cent) overspeed as under usual conditions no overspeed need be anticipated. However, occasionally manufacturers are called upon to proportion the machines to meet the overspeed of the generators to which the condensers will be connected. In such cases the condensers are usually on isolated lines or in the power station with the generator. A 15,000-kv-a., 6600-volt, 3-phase, 450-rev. per min. synchronous condenser being built for the City of Seattle is required to meet such a condition. The condenser will be the same as the generator shown in Fig. 10 except for the frame and bearings.

A new type of damper winding is employed on account of the unusual overspeed of this condenser which is described later.

DAMPER WINDINGS

In large condensers, the damper winding constitutes one of the most difficult design problems and has given considerable trouble in condensers in operation. The early design employed a complete ring without joints (on account of stress conditions) with bars bolted to the rings. This design is satisfactory in smaller

FIG. 11—PARTIALLY ASSEMBLED, 4-POLE ROTOR, SHOWING WELDED DAMPER CONSTRUCTION

FIG. 12—ROTOR OF 5000 KV-A., 11,000-VOLT, 60-CYCLE, 720-REV. PER MIN. SYNCHRONOUS CONDENSER WITH WELDED DAMPER WINDING

units and when the current density at the joint between bar and ring can be moderate. In larger units some trouble has been experienced due to burning between the bars and end rings and this has led to the development of design with welded joints. Welding the bars to a continuous end ring is not a wholly satisfactory solution on account of the impossibility of removing a pole or field coil without destroying the damper winding. Bars cannot be welded to a sectional end ring (except for moderate stress conditions) on account of the effect of the welding heat on the

strength of the end ring segments. A construction has been worked out that has the advantage of the welded joint and the strength of the continuous end ring without the disadvantages mentioned above. The construction is shown in Figs. 11, 12 and 12A. The bars are welded to a copper segment of angle section and these segments are bolted to the continuous copper ring. This ring is rolled copper strap with a brazed scarf joint located opposite one of the poles. The ring is on the edge and hence has maximum mechanical strength as well as ample contact surface at the various sections to which it is bolted.

This construction has proved quite satisfactory and is generally applicable to high-speed condensers. Machines with this damper construction have been run at very considerable overspeed in factory tests. It is believed that this design constitutes a distinct advance in damper winding construction and removes one of the limits that previously existed in the design of large high-speed condensers.

FIG. 12A—ANOTHER VIEW OF ROTOR IN FIG. 12

END BELLS

As the necessity for locating condenser substations in residential and business districts increases, the question of noise becomes of increasing seriousness. With the high speed to which it is necessary to go to obtain the most economical design, the moderate and large condensers are inherently noisy even though the fans and other projecting parts may be specially proportioned to minimize the noise. Therefore, where noise is objectionable, it is advisable to totally enclose the condenser so as to contain and suppress the noise within the machine. To further suppress or muffle the noise, the enclosing parts, such as the frame and end bells, should be designed so that ducts leading to the outside of the building may be attached for bringing in the cooling air and discharging the hot air. Even in uninhabited or mill districts where noise will not be objected to by the surrounding community it is often advisable and profitable to enclose the condensers to provide additional comfort for the station operators

and attendants. Enclosing has sometimes been objected to in the past on account of additional weight and difficulty of handling the heavy cast iron end bells. However, this objection is largely eliminated by the use of sheet steel end bells. With the improvements in their design in recent years sheet steel end bells do not detract from the appearance of machines on which they are used and on account of their decreased cost and weight and the ease of handling their use is

FIG. 13—5000-KV-A., 11,000-VOLT, 3-PHASE, 60-CYCLE, 720-REV. PER MIN., SYNCHRONOUS CONDENSER WITH SHEET STEEL END BELLS

strongly recommended. Fig. 13 shows a totally enclosed 5000-kv-a., 11,000-volt, 720-rev. per min. condenser with totally enclosed frame and double sheet steel end bells. The frame has a rectangular opening at both top and bottom and the depth of the frame is such that either opening may be closed and all the hot air carried around the frame and discharged at the other opening through ducts, if any are provided.

FIG. 14—SYNCHRONOUS CONDENSER LOSSES

The outer sheet steel end bells are arranged so that ducts may be readily attached. Even on machines which are semi-enclosed and do not have the outer end bells, the use of sheet steel for the inner bells is recommended for reasons given above.

LOSSES

In the case of generators there is usually very little doubt as to their necessity. If a certain load is to be furnished the required generator capacity is rather definite. However, in the case of condensers the

required capacity is not so definite and their economical necessity is often debatable. Condensers have, therefore, had to justify their use by results and in the process great importance has been placed on low losses. It has, therefore, been necessary to reduce them to a minimum. This has been made possible by the use of improved core plate material, improved fan design and refinements in general design. The curve in Fig. 14 shows the low losses it is possible to obtain on synchronous condensers designed for 11,000 volts or less and with all modern improvements and refinements in design. Guarantees will usually be about 10 or 15 per cent above this curve. As an example, the segregated full-load losses for the two 20,000-kv-a. 11,000-volt, 3-phase, 60-cycle, 600-rev. per min. condensers built for the Pacific Gas and Electric Company are given below.

A photograph of the two machines is shown in Fig. 15. They are installed on the Mount Shasta system and are designed for a lagging capacity of 12,000 kv-a. Fig. 16 is a photograph of the stator of one of the units showing the armature winding and coil bracing. The connections between armature coils and groups were transposed in such a manner as to reduce the eddy current loss to a low value. This is partially responsible for the fact that the kw. losses on this unit were reduced to 2 per cent of its kv-a. rating. A photograph of the rotor of one of the units showing the coil bracing, fans, etc. is shown in Fig. 17. The shaft has a forged half coupling to permit its possible use as part of a frequency changer set in the future.

STARTING KV-A.

By the use of oil pressure in the bearings during starting and with improvements in damper design it is possible to start synchronous condensers of 5000

FIG. 16—STATOR OF 20,000 KV-A. SYNCHRONOUS CONDENSER

FIG. 17—ROTOR OF 20,000-KV-A. SYNCHRONOUS CONDENSER

FIG. 18—TWO-CYLINDER OIL PRESSURE PUMP AND MOTOR

kv-a. capacity and over on 15 per cent of normal kv-a. To obtain such low starting kv-a., however, requires a very low starting voltage, and unless low starting kv-a. is extremely important, it is advisable to increase the starting kv-a. to 25 or 30 per cent and obtain more margin in starting voltage, reduce the

difference in the starting and running voltage, and reduce the time required to reach synchronism.

Tests on one of the 20,000-kv-a. condensers referred to above showed that it would start on approximately 2800 kv-a., at 19 per cent voltage and come up to speed in three minutes. However, at the minimum auto-transformer starting voltage tap, of approximately 27 per cent voltage, the machine takes approximately 6000 kv-a. and comes up to speed in a little over one minute.

The latest equipment for furnishing the oil pressure during starting consists of a small two cylinder pump driven by a one horse power motor. The pressure usually required for starting varies from 400 to 800 lb. per sq. in. However, the equipment is capable of furnishing a sufficient quantity of oil at 1000 to 1200 lb. per sq. in. when necessary. A photograph of the pump is shown in Fig. 18.

Discussion

E. B. Shand: It is desired to draw attention to the conditions of line charging by an a-c. generator. One method which has been frequently used to determine this effect consists in taking the voltage characteristics of the generator when excited by the armature current directly from the no-load saturation and the short-circuit saturation curves. By plotting the volt-ampere characteristics for the capacity effect of the external circuit, the intersection of the two curves will give the value to which the terminal voltage will rise, with the field un-excited. This method involves quite an appreciable error, due to the fact that when the generator is excited from the field, the voltage is generated only by the flux in the magnetic circuit of the armature, but when excited from the armature an additional voltage is generated due to the leakage fluxes which are not present in the other case. It is evident, therefore, that the relation between voltage and ampere turns will differ under the two conditions of excitation.

To evaluate the effect of capacity loads in a more accurate manner, the actual effect of ampere turn relation between the armature and the field should be used in place of the modified relation as obtained directly from the short-circuit saturation curve. This can be done by separating the total effect of the armature current into armature reactance and armature demagnetization by the standard method; the real ratio of ampere turns will then be expressed by the component of demagnetization. For instance, in Fig. 7 of Mr. Smith's paper the short-circuit saturation curve (the intersection of the zero per cent power factor curve with the axis of field current) indicates that 1470 armature amperes corresponds to 220 field amperes. The true ratio, as expressed by the component of demagnetization, is approximately 145 field amperes. The same main flux and saturation will be produced by either 145 field amperes for 1470 armature amperes. The additional component of voltage for the same latter current, and due to the armature leakage fluxes will be approximately 2200 volts. These fluxes are largely in air paths and therefore, are practically independent of saturation. The terminal voltage of the generator under the conditions assumed, may be expressed as the voltage taken from the no-load saturation curve corresponding to $(I_f K + I_a)$ field amperes, plus $I_a \times x_a$,

where I_f = actual field current.

I_a = armature current.

x_a = armature leakage reactance.

K = relation between armature current and field current as expressed by the component of demagnetization.²

1. This constant K may be calculated directly from the design constants of a machine when these are available.

Fig. 1 gives the general construction for determining the voltage when a generator is connected to an open-circuiting transmission line or similar circuit with a high capacity effect. The line characteristic curve is merely the relation between the terminal voltage and the leading reactive current in the external circuit. Curve (2) is curve (1) less the armature reactance drop. The intersection of (2) with no load saturation curve furnishes the point of operation required. The actual terminal voltage will be the point (P).

FIG. 1

FIG. 2

Fig. 1 of Mr. Smith's paper gives two alternatives for the load saturation for zero per cent leading power factor at low voltages. Although of little practical importance, it may be of slight interest to investigate this point by means of the type of diagram described above. This diagram will be modified slightly to represent a condition of adjusting the d-c. excitation so that on varying the capacity of the external circuit, the armature

current will be maintained constant. In Fig. 2, therefore, $K I_a$ will be constant while I_f will be assumed a variable, as well as the slope of the line characteristic curve. As the external capacity increases as indicated by the decrease slope of the line characteristic, the d-c. excitation must decrease and eventually reverse. When curve (2) coincides with the saturation curve, stability will cease so that with reversed excitation, the whole zero per cent power factor curve must be considered hypothetical, this, of course, neglecting the effect of salient pole construction. Under this condition of instability, the voltage will naturally drop to zero and build up in the opposite direction which is indicated by the relative positions of the two curves at the intersection. Assuming, however, that the voltage could be stabilized by some means, it will be seen that the load saturation curve must approach the point e , which represents the condition of an infinite capacity of the external circuit.

By rotating this diagram through 180 deg. it may be seen that the point e' may be considered as the equivalent of f' under the condition that the reverse excitation had been employed in taking the load saturation curve at zero per cent lagging power factor. It can, therefore, be considered that the points corresponding to short circuit and to an infinite capacity may approach either of the points e or f , depending upon the direction of excitation. In the case of the circuit of high capacity, however, the operating condition is absolutely unstable and not possible. This seems to represent the relations involved rather than the curve $d f$ of Mr. Smith's figure.

It might be suggested that there is probably only one method to actually obtain from test the values for the part of the curve which is unstable. By coupling two generators together so that their voltages are exactly in phase and consequently, that they can exchange no power by driving the machines from a separate source and properly adjusting their excitations the complete curve can be obtained for either condition of reactance or capacity, and moreover, the two curves will be continuous at the points e and f . The necessary stability is, of course, acquired through the mechanical interconnection of the two machines.

M. W. Smith: Although the criticism in the first paragraph of Mr. Shand's discussion may apply to the usual method, it is not applicable in this particular case. In determining the voltage obtained at the terminals of the generator when delivering 0 per cent, leading power factor current, the effect of both the armature re-action and armature reactance were taken into account. Furthermore, in Fig. 7, the two abscissas coordinates for "Armature Amperes" and "Field Amperes" are not interchangeable as apparently assumed by Mr. Shand, i. e., they do not apply to the same curves. The abscissa for "Armature Amperes" applies only to curve five. Curve five, shows the values of terminal voltage, that will be obtained with various values of 0 per cent leading power factor current in the armature, with a constant d-c. excitation, and the effect of the armature reactance, as well as, the magnetizing effect of the armature, was included. The abscissa "Field Amperes" applies only to curves 1, 2, 3, and 4.

I wish to correct Mr. Shand's impression, that Fig. 1, gives two alternatives for the 0 per cent leading power factor curve at low voltage. As stated in the paper, if 0 per cent leading power factor could be maintained, the curve would extend to "e" at 0 voltage. It is further stated that it is not practicable to maintain 0 per cent power at low voltages on account of the increasing effect of the resistance in the circuit as the voltage is decreased and that in actual operation the machine would tend to follow the portion of the curve shown by $d.f.$ The portion $d.f.$ is, therefore, not a 0 per cent power factor curve, but represents the tendency of the machine to change over to points on higher leading and finally lagging power factor curves.

Both Mr. Shand and I agree that it is not practicable to operate generators at such low voltages and further discussion on this academic point is hardly justified.

Methods of Voltage Control of Long High-Voltage Lines by the Use of Synchronous Condenser

BY JOHN A. KOONTZ, Jr.

Member, A. I. E. E.
Great Western Power Co., San Francisco, Cal.

Review of the Subject.—The following points are covered in this paper:

Inherent characteristics of high-voltage lines and high-voltage transformers.

Effect of low power factor load on high-voltage lines as to limiting

capacity and uses of condenser for increasing line output and obtaining good voltage control.

Characteristics which must be met by generators, condensers and regulating equipment in order to control properly voltage over all operating conditions.

THE long high-voltage transmission line is inherently very poor as regards voltage regulation.

The inductive reactance is high, due to the wide spacing of wires required for the high voltage, or to the long spans that are necessary to reduce the cost of structures and insulation. Transformers must always be considered with the line when voltage regulation is concerned, and they must be designed with high reactance for the large power systems so that they can withstand the short-circuit stresses without mechanical damage, and reduce the short-circuit current to a value to give them sufficient heat storage that they will not be destroyed during system trouble. The wire must have a large diameter to avoid corona loss, but in general, this conducting material of the large cables is utilized to advantage in keeping the energy loss at a low figure. These cables, however, subjected to a high voltage, cause heavy charging currents to flow.

With these points in mind, namely, a system of high reactance, which at no-load carries a heavy charging or leading current, it is readily seen that the voltage generated by the flow of this current through the inductive reactance is added to the impressed voltage and thus the receiver voltage on the long transmission line is higher at no-load than the generator voltage.

The amount of this rise in receiver voltage at no-load will naturally depend on the design of the line and connected transformers, but with present 100-kv. systems this value may be as much as 8 per cent above the generator voltage, and the highest voltage lines met with may have an increase in voltage of almost double this amount under no-load conditions.

The load met with in practise is almost universally of a lagging nature. When this load with its lagging current is carried by the transmission line, we meet with the reverse conditions to that of an empty line with charging current, as the e. m. f. generated in this high reactance system when carrying lagging current, opposes the generator voltage, and the drop between generator and receiver ends of the line becomes quite excessive at low power factor and heavy load.

To show this effect of power factor on transformers and line capacities, figures from an actual curve will probably best serve the purpose. These results cover conditions as obtained on 190 miles of 160-kv., three-phase circuit. When maintaining the same generator voltage and a constant receiver voltage, we could transmit over such a line:

At unity	power factor	60,000 kw.		
At 90 per cent	"	35,000	"	(current lagging)
At 80 per cent	"	28,000	"	"
At 70 per cent	"	21,000	"	"

From these figures it is seen that by change of power factor we can readily control the voltage to suit load conditions, and this is the method used on long lines, for in the first place it is an economic necessity to provide ample synchronous condenser equipment in order that the lines and transformer equipment may operate at near unity power factor, and it is a simple matter and of relatively small expense to provide the necessary regulator equipment in order that the voltage on the receiver system may be held constant and the power factor shifted to suit load conditions. The ordinary regulator of the Tirrill type is well suited for such work if the equipment is of the so-called broad range type such that it will control the field current of synchronous condenser or generator from practically zero to a value well above normal.

In some transmission systems where the ohmic resistance is low and the reactance high, it is possible to operate with equal and constant voltage at both ends of the line, but in most cases it is necessary to operate with the generator voltage higher than the receiver. The amount naturally depends on the size and length of line. In general this generator voltage should exceed the receiver voltage by at least the resistance drop of the load current in the connecting lines, and sometimes more than this value, depending on the power factor of the load that must be handled over the line.

In order to reduce the line losses, particularly at light load, line drop compensators can be used on the generator voltage regulators to advantage, as by proper setting of these power house regulators, they will increase the generator voltage as the load increases to take care of the line drop, and at light-load or

no-load the voltage will be automatically lowered so that the receiver condensers will not be called upon to supply such large amounts of lagging line current at light loads. These line drop compensators will not only increase light-load losses but will also permit of use, in general, of condensers which are of slightly less cost, as a condenser will probably only have to supply one half or less of its rating in lagging line current at no-load conditions.

In order that satisfactory voltage control may be had in connection with any high-voltage lines, the apparatus must be specially designed to suit conditions.

The generator design must be such that the units will carry charging current without becoming self-exciting, or such that under all operating conditions, these units will require positive field excitation to give their normal voltage at normal frequency. When practicable, these generators should be of such size and so designed that one unit will charge a transmission line. This will not always be possible in connection with the extremely high-voltage lines, but where a single unit cannot be used, the station, or certain groups of machines in the station, should be designed to take care of line charging and testing, so that this may be handled with dispatch. One disadvantage in using more than a single machine for testing purposes is that when these units are operating at very low values of field current they have low synchronizing torque, and it is sometimes difficult to keep a number of units in step.

The synchronous condenser should be selected so that they will furnish their maximum kv-a. of lagging line current with field excitation above the residual voltage of their exciters. Condensers that are operated from the secondaries of transformers or tertiary windings of auto-transformers where power is not supplied from the same winding or from the condenser bus, should be carefully selected for operation with their respective transformer designs, so that the voltage variation obtained, due to power factor changes through the transformers, will not effect the condenser output, as it must be borne in mind that the condenser will have to furnish its highest voltage at a time when it is operating with its heaviest field current, or when furnishing leading line current, while on the other hand, when furnishing lagging line current and extremely low fields, the condenser will in turn be operating at well below normal voltage, which may effect the kv-a. output of the machine or reduce the field excitation to such value that it is difficult or impossible to obtain stable regulator operation. This variation in voltage in modern transformer design, may easily amount to 15 per cent.

Automatic voltage regulators are difficult to adjust to control the voltage of long lines under no-load conditions and obtain stable operation. This is due to the extremely low values of exciter voltage required on the generator and condenser fields and to the

fact that quite a portion of the excitation is supplied by the leading current of the line, and the regulator is hence only controlling a portion of the total excitation.

This condition can be greatly improved by installing proper relays so that at suitable exciter voltage the condenser field rheostats and generator field rheostats are gradually cut into the circuit before this low-exciter voltage is reached. This resistance acts as a governor, tends to reduce surging and permits the exciter to operate at a higher voltage.

To obtain the low-exciter voltages necessary it requires very high resistance in the exciter fields over which the regulator contacts must operate if speed is obtained under no-load or line charging conditions. When using this large amount of resistance, very sluggish and poor regulator operation is obtained under heavy load conditions, so at load conditions it is necessary to shift the amount of resistance in the exciter field and make sure that all resistance is cut out of the generator and condenser fields. This can be taken care of by utilizing a proper type relay such that it will not only cut in the resistance on light load conditions, but will cut out this resistance in generator and condenser fields when the load increases to the proper value, an additional relay should be used connecting a resistance in shunt with the exciter field rheostat under heavy load conditions. Thus, by suitable adjustment of this relay, it can be made to cut in or out of the exciter field at suitable values in order to obtain the most stable operating conditions.

Voltage regulation of long lines is thus taken care of mainly by power factor control. The synchronous condenser not only serves to correct the power factor and in many cases reduce line losses, but it also gives a steadying effect on the system, which is difficult or impossible to obtain by any other method of voltage control. Short lines can be operated without condenser equipment, but it is difficult to obtain good voltage regulation by generator regulators alone when the load power factor is poor. For satisfactory operation of long lines it is essential that automatic voltage regulators be used at both generating stations and on the condensers at the receiving stations, and in general line drop compensators can be used to advantage in connection with the generator regulators.

Discussion

A. W. Copley: In amplification of Mr. Koontz's paper and carrying out the thought a little farther, it may be pointed out that there is a very definite power limit on a transmission line on which the values of generator and receiver voltage are fixed. The addition of synchronous condenser capacity beyond a certain limit does no good as far as increasing the capacity of the line is concerned. For instance, on a 200-mile line with 200 kv. maintained at both ends, the addition of synchronous condenser capacity beyond the point which allows a load of about 220,000 kw. at the receiver end, does not increase the capacity

for transmitting power. The power limit of such a line being in the neighborhood of 220,000 kw., it can be seen that, at least on projected lines, the limit is being approached. It is, however, possible to increase the power limit of the line by making, in effect, two lines in series. For instance, on a 400-mile line, with synchronous condenser capacity at the receiver end, the limit of capacity is around 120,000 or 125,000 kw. By breaking the line in two parts of 200 miles each, the power limit of the upper end of the line is about 220,000 kw. and with that power delivered to the middle of the line, the balance of it again has the capacity of 220,000 kw. minus the losses, which bring the delivered power down to about 200,000 kw. That is, by the introduction of condenser capacity in the middle as well as at the receiver end, the line capacity is increased from 125,000 to 200,000 kw.

One other point mentioned by Mr. Koontz which is of much importance, is the method used for the control of the exciter voltage at times when lagging current is being taken by the generator or condenser. When the line is being charged and no load being carried, the condenser must be operated with a very light field. The same holds true of the generator field under the same conditions. With the ordinary generator voltage regulator, the voltage across the generator or condenser field can be controlled only down to about the residual voltage of the exciter. By cutting resistance directly in the field of the condenser or generator the voltage across the field can be reduced still further and it is now possible to do this automatically by means of a face plate regulator which is operated as an auxiliary to the usual generator voltage regulator. Such a regulator has been applied on the generators of the Big Creek No. 3 Plant of the Southern California Edison Company. It allows the lowering of the voltage across the generator field to something like ten per cent of the residual voltage of the exciter and thus there is obtained a considerable increase in the lagging current capacity of the machines while under the control of the regulator.

R. J. C. Wood: I didn't quite understand what Mr. Koontz said about the generator voltage being low under certain conditions of operation, when the load was low. We have made calculations on the Big Creek System 250 miles long—that line, with 100,000 kw. per circuit, transmitted from Big Creek No. 3 plant, including the effects of the transformers on the line, which take certain magnetizing currents. It develops that the variation of the voltage on the generator will be very slight between zero load and full load. As I remember the figures the 11,000-volt machine requires slightly under 11,000 volts at zero load and in the neighborhood of 11,500 or 11,600 at full load. So, the variation at the generator is slight and the demands on the regulator will not be heavy.

About what Mr. Copley said relative to putting synchronous

condensers in the middle of the line, that, of course, gives you a new lease of life. You get power at the end of the first section of the line at a certain voltage and at power factor desired and start all over again in the next section of the line. The method has its limitations and would not be used on a comparatively short line.

The calculations for the Big Creek 250-mile line indicated that there was no advantage in putting condensers in the middle of that line. The installations of a synchronous condenser at the middle point causes a loss of, roughly speaking, one-half of its capacity. A great many of these calculations are often made for the line only and the effects of transformers are not taken into consideration. This should be done, as illustrated by a test we made when we were first getting ready to energize the line at 220 kv. One of the preliminary steps was to test the transformers and equipment of the Big Creek No. 8 Plant. We had generators and transformers at the Big Creek No. 8 Plant, a 220-kv. line about 105 miles in length, from Big Creek No. 8 to Vestal, and in addition auto transformers at Big Creek No. 1, No. 2 and also at Vestal, if I remember rightly. The result was that we got about 600 amperes on the generator at considerably less than full voltage and when we were up to full voltage on the line only 300 amperes, on account of the large amount of magnetizing current taken by the transformers on the line, so that you have a very good regulator in the magnetizing current of transformers; if the voltage tends to increase greatly on account of loss of load, the magnetizing current will increase rapidly and neutralize the charging current on the line and prevent excessive voltages. Magnetizing current may be taken at about 4 per cent of full-load current at normal voltage; at 110 per cent voltage it will be about 12 per cent, and at higher voltage—the manufacturers conceal what it is going to be. They need not conceal it; for our particular purpose it is a good thing to have.

J. A. Koontz: The statement, that there is a wide variation in voltage at the generating station, should refer to the exciter voltage. The generating voltage usually only varies some 8 or 10 per cent depending on how the lines are operated. On the lines of the Great Western Power system, this variation amounts to 10 per cent. The impression I intended to convey was that synchronous condensers have to operate over a rather wide range of terminal voltage, particularly when they are operated from high-reactance transformer windings which supply no other load. The condensers require minimum field excitation when the machine is supplying the minimum terminal voltage, and maximum field excitation at maximum terminal voltage, hence extreme exciter voltage variation. I have a case in mind where the condensers deliver only 9800 volts at minimum field and 12,200 volts under maximum field conditions. It is this change in machine terminal voltage, together with the magnetizing or de-magnetizing effect of the armature, which necessitates extreme field ranges and makes difficult regulator operation.

Economic Considerations of the Power Factor Control of Long High-Voltage Lines

BY A. V. JOSLIN

Associate, A. I. E. E.
Pacific Gas & Electric Company

Review of the Subject:—In the early days of the electric industry when transmission lines were short, power factor control was not considered necessary. At the present time, with transmission lines of 200 miles and more, and with loads whose power factor is very poor owing to the universal use of the induction motor, power factor control is being forced upon the transmission engineer as a necessity if power is to be transmitted economically.

By taking a few typical examples of transmission lines, the effect of power factor upon efficiency of transmission is shown very clearly.

The most economical line power factor for any ordinary commercial transmission line is shown to vary by a comparatively small per cent and to be slightly less than unity. At the same time there appears a very wide range of load delivered over a line without an undue rise in cost of transmission.

It is quite generally accepted that some degree of power factor correction is advisable over long high-voltage lines but the amount of this correction has been considered a special problem to be worked out for each particular line.

By constructing curves of kilowatt capacity and capital cost at various power factors for several typical lines, the writer has endeavored to show that the power factor for lowest transmission cost varies through a

copper conductor, 100-kv. at receiving end, 10 per cent drop in voltage, 5 per cent transformer reactance at receiver end. Cost per mile, \$15,000.

c. 50 miles, 2 circuit tower line, 250,000-cir. mil. copper conductor, 100-kv. at receiving end, 5 per cent drop in voltage, 5 per cent transformer reactance at receiver end. Cost per mile, \$15,000.

Figs. 1, 2 and 3 each has a curve showing the kw. capacity of the different lines as the power factor at the

FIG. 1—COST AND CAPACITY CURVES—LINE A 200 MILES, 200 Kw. 500,000 CIR. MILS COPPER, 10 PER CENT VOLTAGE DROP

narrow range.

The lines taken as typical are the following:

a. 200 miles, 2 circuit tower line, 500,000-cir. mil copper conductor, 200-kv. at receiving end, 10 per cent drop in voltage, 5 per cent transformer reactance at receiver end. Cost per mile, \$35,000.

b. 100 miles, 2 circuit tower line, 250,000-cir. mil

FIG. 2
COST AND CAPACITY CURVES—LINE "b"
100 MILES 100 KW 250,000 C.M. COPPER 10% VOLTAGE DROP

FIG. 2—COST AND CAPACITY CURVES—LINE B 100 MILES, 100 Kw., 250,000 CIR. MIL COPPER, 10 PER CENT VOLTAGE DROP

receiving end varies. It will be noticed that the kw. capacity rises very rapidly around unity power factor.

Fig. 4 shows curves of capital invested per kw. delivered over line a. Curve marked "Line Cost" shows capital investment in line only. Curve marked "Condenser Cost" shows capital investment in synchronous condensers required to bring the load power factor, assumed to be 80 per cent, to the line power factor which

is required for transmitting the load at the designated voltage drop.

"Condenser Cost" covers condensers installed on transformers necessarily in use for other purposes, and includes condenser losses at 3 per cent and at 4 mils per kw-hr. and depreciation at 3 per cent all capitalized at 6 per cent per annum. Itemized as follows:

Synchronous condenser installed per kv-a. = \$9.00
 Power required to operate at 3 per cent
 loss for one year = $0.03 \times 8760 =$
 262.8 kw-hr. 262.8 kw-hr. at \$0.004 = \$1.05
 Depreciation at 3 per cent on \$7.00 = .21

Cost of operating power and depreciation \$1.26
 Capitalized at 6 per cent per annum = 21.00

Total condenser cost per kw. delivered = \$30.00
 Line and condenser cost curve is the sum of these two curves.

Line loss cost curve shows the $C^2 R$ line losses per kw-hr. capitalized at 6 per cent per annum.

Total cost curve is the sum of all the above costs.

Two of these curves, total cost and line and conden-

FIG. 3—COST AND CAPACITY CURVES—LINE C 50 MILES, 100 KW., 250,000 CIR. MIL COPPER, 5 PER CENT VOLTAGE DROP

ser costs are shown in Fig. 1 plotted to line power factor as abscissas in place of kw. delivered.

Total cost curve shows that, for a minimum transmission cost on this line, the line power factor should be about 97 per cent lagging.

Similar curves are shown in Figs. 2 and 3 for lines b and c. They indicate that for minimum transmission costs the line power factors should be about 95 per cent and 91 per cent lagging respectively.

Fig. 5 shows curves of line b at two different line

drops; 0 per cent, and 15 per cent, which indicate the marked effect these differences have on the most economical line power factor.

Fig. 1 has a second cost curve with line losses excluded for a load power factor of 70 per cent. Comparing it with the 80 per cent load power factor show that the load power factor has a very slight effect on the most economical line power factor.

An increase in the size of conductor chosen will decrease the line loss cost curve and increase the line cost curve to a less degree; the net result being to

FIG. 4—COST CURVES PER KW. DELIVERED—LINE A 200 MILES, 200 KW., 500,000 CIR. MIL COPPER, 10 PER CENT VOLTAGE DROP, 80 PER CENT LOAD POWER FACTOR.

raise the economical line power factor. This increase of the power factor is small compared to the corresponding increase of conductor required to produce it.

A smaller assumed cost of power will reduce the line loss cost curve and also the condenser cost curve, thus increasing the economical line power factor. A larger allowable voltage drop over the line will have a marked influence in raising the economical line power factor by reducing the condenser capacity required to deliver a stated amount of power.

Some of the smaller factors such as attendance for operating condensers have been neglected as well as the advantage gained by voltage regulation obtained by use of the condensers, which displaces regulation by induction regulators or other regulators with their attendant losses. Also the saving in generator size and losses due to the use of condensers has been neglected.

The foregoing considerations have all been based on a 100 per cent load factor which unfortunately is not often met with. However, by taking a load which will

give the average losses of the real load the above considerations will apply very closely. The condenser capacity required would be enough greater to maintain the proper voltage at the peak load. The condenser losses would be only slightly greater. The condenser cost would be materially increased but this is roughly only about one third of the "condenser cost."

While the economy of transmission changes very rapidly with a small change in line power factor it changes very slowly over a wide range of kw. delivered, on both sides of the minimum cost point. This can be clearly seen in the "total cost curve," Fig. 4.

A change of load delivered from 125,000 kw. to 225,000, *i. e.* from 91 per cent power factor to unity means only a change in capital cost per kw. delivered of \$4.50. Assuming an interest depreciation and operation charge of 12 per cent this means 54 cents per

FIG. 5—COST AND CAPACITY CURVES—LINE B

8760 kw-hr. or about 0.06 mil. per kw-hr. which is a very small per cent of the total cost of a kw-hr.

It is a very happy circumstance that there is this wide range of load over which the transmission cost is near the minimum. It means that considerable increase of load can be allowed for when designing a new line without sacrificing present economy. Likewise the load on an existing line can be taken care of economically up to the point where it will justify an additional line.

CONCLUSION

On long high-voltage transmission lines it is economy to install synchronous condensers to correct the line power factor very close to unity and if it is necessary to correct slightly more than this on account of voltage regulation the economy of the transmission line will not be greatly effected.

Discussion

F. G. Baum: Our vision of the future transmission system of the United States is a 220,000 volt system, at least for most of the country, and for most of the time that we will be here.

In the states east of the Mississippi River, the average transmission line distance will be around 250 or 300 miles. That is not a long transmission. In our Western country, however, we are already up to that distance, both in the north end and the south end of the state. In not very many years the southern part of the state will probably have to go over to the Colorado for its power, which means a 500-mile transmission, and the northern part of the state will have to go up to the Columbia Basin, which means again approximately a 500-mile transmission.

If we consider a circuit of 500 miles and apply voltage at one end, as shown in the paper by Mr. Peek a year ago, approximately 110-kv. at one end of the line will give you approximately 220-kv. at the other. Of course, you cannot have such a line and have it safe. So, we must have some way of holding the voltage down or stabilizing the line.

If we have the charging current at one end of the line and the capacity current is traveling 500 miles, then in that capacity current travel of 500 miles it passes over 500 miles of reactance and that is what raises the voltage of the lines.

Let us look at what are the natural characteristics of a 220,000-volt line. Let us say we have a 600,000 circular mil. copper line of any length and let us apply a load on one end of the line. I don't care whether the line is 500 miles long or 1000 miles long. Let us take the load at unity power factor and see what the characteristics are. Now increase that load gradually and take a voltage measurement along the line, when you reach a load of 120,000-kw. at 220,000 volts, you will have what we call a constant potential and a constant power factor transmission line. That is, all points of that transmission line will be at the same potential and at unity power factor. That is, there is a load for that line that when it approximates at 120,000 kw. for a 220-kv. line which makes that line a constant potential line; that I call the natural capacity of that transmission line. Of course, we can not hold the load at 120,000 kw. at all times. Suppose we trip out the switches at the end of that transmission line, then the voltage is approximately double due to the rise in voltage caused by the charging current; it would be worse than that because the charging current itself will come back to your generators and increase the excitation, and the voltage limit is unstable. We cannot have such a transmission line for satisfactory operation. In order to vary the load on that transmission line (let us again say it is 500 miles long), we locate synchronous condensers at the end and at one or two other points, depending on the location of the large loads in the large cities, etc. We may then vary the lagging or leading kv. of those condensers. Say we want a smaller load than 120,000 kv-a.; we change the condition by drawing some lagging current on those condensers and we may go entirely down to zero load, providing we make the charge kv-a. of a given section of the line come from the condensers connected to that section. That is, the charging kv-a. of the line is circulated merely through the condenser and does not travel through the entire transmission line. (I believe Prof. Ryan also showed that in a new way at that special meeting last year). When you want a higher load than 120,000 kv-a. over that line you raise the supply leading kv-a. or take it from the line wherever, or whichever way you want, and you get an economical capacity around 120,000 to 160,000 kw. and an overloading capacity of around 200,000 kv-a.

What would be the advantage of such a system? The generators would all be standard and would be uniform. That is, the excitation, in place of varying from, say, 100 amperes up to 300 amperes from no load to full load for 80% power factor, would vary from 100 to 200 amperes for unity power factor.

The generator designers would have an easier job and some of the men I have talked to hope to see that day in order to relieve them of the trouble of designing from 80 to 100% power factor. Also, the transformers along such a line would be all of one voltage and standard and there would be no necessity for voltage taps. In operating such a system with those condensers tied to it, there would be a stabilizing effect produced by the condensers. The transformers would help to stabilize the line. But, a rising voltage without the condensers on the transmission line, tends to produce a further rising voltage and, therefore, produce instability; whereas with the condensers, the condensers react, and have a tendency to lower the voltage and to cause the line to operate just in the opposite way, giving you a stabilized transmission system. And, it is such a transmission system as I have in mind to cover the country.

Mr. Joslin has shown in his paper the economic value of the condensers for 220 kw. transmission.

This is also shown on pages 15 and 18 of the Atlas of U. S. A.

Electric Power Industry. The addition of the condensers does not materially increase the cost of the transmission, but the addition gives a safe line, and a line that may be extended as far as economy dictates. With the condensers we also obtain increased capacity so that the cost per kw. for transmission is reduced.

I especially urge electrical engineers to study the characteristics of the constant potential 220 kv. transmission with condensers for voltage control. I think they will find that this gives a system of transmission commensurate with the needs of the industry at this time.

J. P. Jollyman: It is fortunate that the engineer, taking advantage of the information that Mr. Joslin has presented, can say in some cases, "Spending a half-million dollars for synchronous condensers will do more good than spending it for additional transmission circuits."

I think the economic phase of the problem has not been emphasized enough in the past.

Performance of Auto Transformers with Tertiaries Under Short-Circuit Conditions

Review of the Subject.—The problem of operating many of the present day transformers designed and built to function in sizes and under conditions unheard of only a few years ago, is now of prime importance to many of the larger power companies.

A statement of one type of the operating troubles encountered in the larger sizes is discussed in this paper and data taken as far as practicable under operating conditions is given.

From experience so far gained it is thought that both the auto-transformer and the grounded neutral system are here to stay and such problems as they present merit considerable investigation under actual working conditions.

The present paper presents rather than solves one type of trouble encountered.

* * * * *

IN July, 1914, the California Railroad Commission published the first report of the Joint Committee on Inductive Interference.

In 1918 General Order No. 52 superseded General Order No. 39, following the final report of the same committee. In this order under which California public utilities now operate is the following clause, "no star-connected transformers or auto transformers shall be employed with a grounded neutral on the side connected to a three-phase power circuit involved in a normal parallel, unless low-impedance, delta-connected secondary or tertiary windings or equivalent means are used for suppressing the triple harmonic components of the residual voltages and currents introduced by the transformers".

In complying with this order, and to reduce the cost on a winding used solely to suppress the effects of causes which could not be removed, most companies have used tertiary windings of capacity less than the rating of the transformers, that is, the current-carrying capacity of the tertiary winding has been reduced by reducing its copper cross-section.

Presented at the Pacific Coast Convention of the A. I. E. E., Del Monte, Cal., October 2-5, 1923.

At the same time most of the major companies using high-tension systems in California have adopted a permanently grounded neutral on the high-tension circuit and a considerable number of the later-built transformers have been auto transformers, designed specifically to operate only with one terminal of the high-voltage winding grounded.

In present designs some of the tertiaries have a current density 20 per cent higher than the primary of the same transformer for the nameplate rating. This relatively high resistance further increases the tertiary temperatures under short-circuit conditions. Having this condition in mind it becomes an operating problem of when and how to protect the tertiary winding against destructive overheating during line short circuits.

Tertiary windings are used, in addition to the prevention of inductive interference, for:

1. Providing a path for the flow of third harmonic current, necessary for the proper magnetization of the core for a sine wave e. m. f. across the main windings.
2. Stabilizing the neutral and providing a sufficient flow of current in the line or windings at times of

single-phase short-circuit conditions to give proper operation of relays and circuit-breakers.

3. Providing a winding for load connections or a synchronous condenser.

In practise the size of the tertiary is fixed by the short-circuit kv-a. rather than the third harmonic

radiation of heat takes place, consequently the copper must store its $I^2 R$ losses by thermal capacity during this period.

There is given later a curve for determining approximately the relations of size of copper, current, temperature, and time for this condition.

For short-circuit conditions, the size of the tertiary

FIG. 1

Rating

Primary: 1500 kv-a., 40,000 volts

Secondary: 1500 kv-a., 6680 volts

Tertiary: 300 kv-a., 2340 volts

Impedance: Primary and Secondary: 5.7 per cent at 1500 kv-a.

Impedance: Primary and Tertiary: 20 per cent at 1500 kv-a.

component of magnetizing current, *i. e.*, this winding must carry the short-circuit kv-a. long enough to allow circuit opening devices to operate. The time required to open the circuit is usually short, of the order of 5 seconds or less, and therefore very little

FIG. 4

FIG. 5

For rating of transformer, see Fig. 1

FIG. 6

For rating of transformer, see Fig. 1

is determined by the value of short-circuit current that it is desirable for protective reasons and the duration of the heavy current.

From 300 per cent to 400 per cent of normal current is usually desired for operation of protective relays and this abnormal current requires a tertiary winding constructed to have from 25 to 30 per cent of the capacity of the main transformer windings.

the several voltages and currents read as shown in the following figures.

Fig. 1 shows a ground on the high-tension with the neutral ungrounded tertiary closed.

Fig. 2 shows the tertiary open.

Fig. 3 shows the neutral grounded tertiary open.

Fig. 4 tertiary closed.

Figures 8, 9 and 10 and 11 show conditions in auto transformers with a tertiary.

cent of full voltage is required to circulate full current through the high-voltage winding. For this test one high-voltage winding was short-circuited and gradually increasing 3-phase voltage applied, measuring the current in the tertiary and short-circuited high-voltage winding. For 300 per cent high-voltage current there will flow approximately $14\frac{1}{2}$ times normal current in the tertiary.

Fig. 13 gives a curve for the heating of the transformer windings neglecting radiation and using the 60 deg. cent. resistance of copper. From the study of

FIG. 13

FIG. 14

Volts to ground on top; volts across tertiary on bottom; tertiary current in center

These figures are self explanatory and indicate clearly what takes place on short-circuit conditions. Not all of the connections are used in practise, but from a study of the diagrams given in the several figures an idea can be gained as to what happens in practise.

Fig. 12 gives a curve from a bank of transformers in which the tertiary has a rating of 20 per cent of the transformer rating, and an impedance such that, with the tertiary short-circuited, from 15 to 20 per

FIG. 15

Volts to ground on top; volts across tertiary on bottom; tertiary current in center

this and similar data it was decided to install, on a bank of three 12,000-kv-a., 110-kv., 60-kv., Y-connected auto transformers a 13,800-volt tertiary having a capacity of 4000 kv-a. in each, of 13 per cent impedance and a relay in the tertiary to open it in case of sustained overload.

Later a 12,500-kv-a., 13,200-volt synchronous condenser was so connected as to operate on this tertiary that when the tertiary switch opened it cleared the condenser by means of its main running switch. This developed considerable trouble in the tertiary switch

FIG. 16

Volts to ground on top; volts across tertiary on bottom; tertiary current in center

and winding apparently from high voltage so that a series of short-circuit tests were made on the bank and oscillographic records taken of the tertiary current and voltage.

By using a comparatively long 100-kv. line with a limited amount of available power it was possible to short-circuit the 60-kv. side of one auto transformer to ground.

Fig. 14 gives a curve of the voltage from one condenser lead i.e. one corner of the delta to ground together with the tertiary current when one phase of the 60-kv. was grounded.

are to operate as they have in the past to clear trouble selectively in about two seconds.

In the original scheme where the tertiary opened and tripped the synchronous condenser all of the switches were opened during the first $\frac{1}{2}$ second after a short circuit occurred, that is on the definite time portion of the induction type relay curve.

It seems advisable to delay the action until the high-current values had subsided to more nearly a steady state and then clear the bank of transformers completely as a last resort. On banks of transformers in which the tertiary impedance is in the order of 20 per cent and the current-carrying capacity 25 per cent or above, with a primary impedance of 5 per cent it is thought that the tertiary will withstand for a short time any overload that the primary can withstand.

Such combinations, unless supplying condensers, can be and usually are treated as delta banks and only the over-all transformer protection used.

Some banks of transformers have neither 20 per cent impedance between high tension and tertiary nor 25 per cent tertiary current capacity and these installations present a difficult problem in operation.

Important information on the subject of tertiary windings may be found in the following articles:

"Harmonics in Transformer Magnetizing Currents" by Mr. J. F. Peters, TRANSACTIONS A. I. E. E. 1915.

"Tertiary Windings in Transformers, their Effects on Short-Circuit Current" by Mr. J. F. Peters, Electric JOURNAL, Nov. 1919.

"Transformers for Interconnecting High-Voltage Transmission Systems; for Feeding Synchronous Condensers from a Tertiary Winding" by Mr. J. F. Peters and Mr. M. E. Skinner, June 1921, JOURNAL of A. I. E. E.

Discussion

L. F. Blume: The subject of the paper by Messrs. Mini, Moore and Wilkins involves many interesting problems because the transformer connection to which the authors mostly refer is a mongrel which has inherited its peculiarities from three distinct sources. For, in this one transformer connection are combined the various aspects of (a) an auto transformer, (b), the Y connection, and (c) the 3-winding transformer. I will point out briefly for purposes of emphasis, a few of the salient characteristics of only one of them, namely, the 3-winding transformer.

Wherever transformation of power is desired between three circuits, the practise of using three windings of different voltages is growing on account of the resulting economy, not only in first cost, but also in operation. By using one transformer bank rather than two, double transformation of power is avoided and the total amount of transformer kv-a. for a given service is correspondingly reduced. A particularly interesting and important illustration is in high-voltage transmission where synchronous condensers are used for power factor control, in which case the synchronous condenser sometimes is neutralizing the lagging reactive current of the low-voltage system and at other times it is neutralizing the leading charging current of the high-voltage line. The joining together in one bank, of the trans-

mission line, the low-voltage circuit and synchronous condenser for the purpose of transforming directly from any one circuit to another by one transformation is the unique function of the three-winding transformer.

In addition to this, however, it is also being frequently used where the Y-Y connection is primarily desired, the third winding being added merely to correct the inherent weakness of the Y-Y connection. These inherent weaknesses resulting sometimes in abnormal voltages either in the connection or in the line, or sometimes in interference with parallel telephone lines and also in various operating difficulties, may be grouped under the rather broad generalization of neutral instability. This use of the tertiary delta in itself, is good evidence of the superiority of the Y-delta connection, for by the addition of the delta the stable characteristics of the Y-delta connection is secured. It is desirable to point out in this connection that if the tertiary winding is not needed for loading purposes the Y-delta connection is simpler and cheaper, and therefore, the only legitimate reason for adding the third winding is found in those cases where the system conditions are such that a Y connection for both the primary and secondary windings is essential.

Thus it is seen that the 3-winding transformer is being employed for two distinct reasons, the one being based on economy both in first cost and operation; and the other being for the purpose of securing specific improvements in operating characteristics. The one purpose may be called the economical use, and the other, the non-economical use of the 3-winding transformer.

However, whatever may be the reason for the use of the three windings, the majority of them are connected in Y-Y delta, with the delta tertiary having a capacity considerably less than the rating of the main windings. In these cases the size of the tertiary winding may not be determined by the load which it is to deliver, but rather by other characteristics such as the short-circuit current. For example, a short circuit from line to neutral on either of the high or low-voltage circuits results in a short-circuit current circulating in the delta limited only by the internal reactance of the tertiary winding. In this case the controlling factors in design as pointed out by the authors, are the amount and duration of the short-circuit current.

It may be well to add that when a tertiary winding is to be designed for a given short circuit and for a given length of time, these other terms, kv-a. rating and reactance become superfluous and are arbitrary.

Where the tertiary windings constitute an important protective link in a system, it is highly desirable that they be sufficiently liberally designed so as to possess an ample margin of safety from the point of view of the mechanical forces and the thermal effects resulting from short-circuit currents. The certainty that the over loading of tertiary windings will be much more frequent by short circuits and also of longer duration than in ordinary transformer windings is an additional reason for a conservative policy. Moreover in most instances a larger tertiary costs comparatively little more than a small tertiary. For example, comparing a 50 per cent with a 25 per cent capacity tertiary winding, the former involves only 5 or 6 per cent increase in transformer cost.

To determine the short-circuit and regulation performance of a three-winding transformer it is essential to have a clear conception of the manner in which the reactance between the windings affects the current division, regulation and short-circuit currents. The determination of these characteristics may prove to be very perplexing and unnecessarily complicated unless the fundamental relations are clearly understood. These relations, however, are fortunately quite simple.

In a two-winding transformer the internal impedance is usually expressed in terms of one value. The leakage reactance between primary and secondary, and the resistances of the two windings are lumped into one and thus one value of impedance is

sufficient to express the voltage consumed internally by the transformer. From time to time academic discussions arise concerning how much of the reactance belongs to the primary and how much to the secondary but no practical use is served in attempting to make this distinction and no matter how the reactance is assumed to be divided between high-voltage and low-voltage windings, the performance of the transformer remains unchanged. Therefore, it is common practise to use only one value to express the impedance of a two-winding transformer. The reason that this may be done is because the high and low-voltage currents are equivalent and in phase.

On the other hand in 3-winding transformers the current flowing in one winding is not necessarily equivalent to, nor in phase with, a current in one of the other windings, and for that reason resistances and reactances cannot be so simply expressed. It is convenient, and in fact necessary, to consider that every winding possesses a reactance belonging to itself just as distinctly as its resistance, and that they are connected together in the equivalent circuit in Y. Having segregated in this manner the impedances into a primary, a secondary and a tertiary value, regulation drop can be calculated for each one separately by using the ordinary formula for regulation, and also by means of the simplest algebra, current division for any condition of loading or of short-circuit condition can be readily determined.

Thus there are two new problems introduced by the 3-winding transformer. First, the determination of the size of the tertiary winding may not be obtained in the ordinary manner but by one or more of the unique functions which it is called upon to perform. Second, the three windings are so related to each other that impedance and regulation cannot be so simply expressed as in ordinary transformers, although by means of a simple equivalent circuit, equivalent impedance values can be determined for each winding and these values used in the ordinary formulas to obtain regulation or current division for any given condition.

A. Boyajian: There is an implied recommendation in the paper by Messrs. Mini, Moore and Wilkins that tertiary windings should have larger capacity or larger margin of safety; a suggestion which deserves serious consideration, especially in view of the relatively small cost that it involves.

Relative Cost of Tertiary Windings: In three-winding transformers a larger tertiary costs only a trifle more than a small tertiary. For instance, a transformer with a 50 per cent tertiary winding has a total kv. rating which is only about ten per cent larger and a cost which is only about five or six per cent greater than a similar transformer which has only a 25 per cent capacity tertiary. That is, the capacity of the tertiary winding can be doubled with only a five or six per cent increase in the cost of the transformer. Although it seems to be common practise to rate tertiary windings in the neighborhood of 25 per cent (excepting those which have to carry large loads normally), I happen to know that in a number of cases a manufacturer furnished tertiary windings with capacities much in excess of the capacity specified in the contract, simply because the additional expense involved was very small while the greater security to the transformer resulting therefrom was very large.

Tertiary windings cut a somewhat larger figure in the case of auto transformers than in transformers on account of the fact that the economy in the primary and secondary circuits accomplished by their auto-transformer connection does not apply to the independent tertiary winding. For instance, in a two-to-one auto-transformer, the cost of fifty per cent capacity tertiary may be about 10 per cent more than that of a 25 per cent capacity tertiary. But even in this case the extra cost is small, the capacity of the tertiary being doubled with only about 10 per cent increase in cost.

In as much as a tertiary winding is an important protective link in a system, its capacity should be specified liberally, though not wastefully, and this naturally raises the question as to what is the proper capacity for tertiary windings.

Factors Controlling Tertiary Capacity: The authors have properly recognized that the tertiary capacity and the tertiary reactance are interdependent and that when one is given the other is fixed thereby. The reactance in this case can of course only mean the net equivalent reactance as effective in the limitation of the short-circuit current. In other words, the capacity of the tertiary winding is determined by its short-circuit load. I wish to point out, however, that the *duration* of the short-circuit load is just as important a factor as the *magnitude* of the short-circuit load in the determination of the necessary tertiary capacity. This point probably can be best brought out by a comparison as follows:

Transformers are as a rule guaranteed for a two-second duration of short circuit. If we arbitrarily assume 5 per cent reactance as an average conservative lower limit of reactance for convenience in this illustration, it means that the conductor can carry twenty times its rated current for two seconds without exceeding a certain permissible temperature rise. From the standpoint of temperature rise based on heat storage, we have the following approximate equivalents:

20 times normal current for 2 seconds.					
= 14	"	"	"	4	"
= 11.5	"	"	"	6	"
= 10	"	"	"	8	"
= 7.8	"	"	"	10	"

That is, a normal transformer winding will carry 7.8 times (call it 8 times) normal rated current for 10 seconds, on a conservative basis.

If the duration is assumed fixed, the capacity of the tertiary varies directly as the current. Based on the 10 seconds time for tertiary relay operation assumed by the authors we have the following table of values:

Duration of short-circuit assumed 10 seconds.

Short-Circuit Current	Tertiary Capacity in Per cent of Primary
8 times normal primary	100
6 "	75%
5 "	62%
4 "	50%
3 "	37%

This table shows that if a tertiary winding which is to carry four times rated primary current for 10 seconds is to have the same margin of safety in temperature rise as a 5 per cent reactance transformer designed to operate at normal conservative densities, it must have about 50 per cent of the capacity of the primary. Otherwise, it will have a smaller margin of safety.

It may also be interesting to note a table of tertiary capacities for various currents for a shorter duration, say 6 seconds.

Duration of short circuit 6 seconds.

Tertiary Short-Circuit Load	Tertiary Capacity in Per cent of Primary
11.5 × normal primary	100%
10 "	87%
8 "	70%
6 "	52%
4 "	35%
3 "	26%

It is not the object of this discussion to recommend any particular tertiary capacity nor the magnitude or duration of the short-circuit currents, but to indicate how the relative merit of tertiary capacity can be estimated in terms of customary values applying to the major windings and to emphasize the wisdom of specifying tertiary capacities ungrudgingly in view of the very small additional cost involved.

A further circumstance that makes a conservative policy towards tertiary windings desirable is the certainty that short-circuits which will load-up tertiary windings to their full capacity will be much more frequent than short-circuits which will load up the major windings to their full capacity. In other words, line-to-ground short-circuits are bound to be much more frequent than line-to-line short-circuits, and, hence, tertiary windings will have their ordeal oftener than the major windings.

Relation of Reactance to Short-Circuit Currents and Tertiary Capacity. Reactance in connection with tertiary windings usually means the reactance between the tertiary and the primary circuits. This reactance, however, does not directly and completely determine the short-circuit currents of the tertiary winding for all the various possible system connections and location of short-circuit. These are so varied that time would not permit their discussion now, but in any practical case, it is necessary to consider the various possible conditions, especially two of them, *viz.*, (a), the condition for the sake of which the tertiary winding is to be provided, together with, (b), the condition which imposes the severest duty on the tertiary winding. For instance, in a system grounded at a number of points for purposes of selective relay operation, a short-circuit across the terminals of the tertiary winding is likely to be a much more severe load to it than a line to ground short-circuit on the primary or secondary lines. In such an instance, if it is not absolutely necessary that the tertiary should furnish a load normally, it would be better policy not to bring out tertiary leads and thus avoid the extra risk that would otherwise be incurred.

Test Data: The authors present a number of interesting test data in curves and vector diagrams. All of these could have been predicted accurately by calculation, and the following comments may be interesting and helpful in their interpretation.

1. Figs. 1 and 2 of the authors are the experimental verification of two theorems or principles, *viz.*:

(a) Y-delta (or delta-Y) connected transformers operate equally well on unsymmetrical as well as symmetrical line voltages, that is, lack of balance or symmetry in the line voltages does not produce any circulating current in the delta.

(b) The leg voltages of a Y-connected bank of three similar transformers are equal to two-thirds of the corresponding median of the triangle of line voltages. On the side of the vertical leg the median of the line voltages is $244/2$, that is, 122 volts, and $2/3$ of this, that is, 81 volts, should appear across that leg. The observed voltage is 80 volts, which may be considered as a complete commercial check. The fact that the observed voltage on the delta side on the corresponding leg is 4.7 volts proves by ratio that the observed voltage on the Y side must have been nearer 81 volts than 80.

2. In Fig. 3 excitation is applied only to the lower two legs (V_1, V_2). The vertical leg is short-circuited, but this short circuit does not affect the circuit in any way because the delta is open. The phenomena are capable of prediction by very elementary considerations, but presumably the authors included this in their tests for comparison with the case of Fig. 4.

3. Fig. 4 is the same as Fig. 3 except that the delta is closed. The vertical leg is disconnected from the generating system (note the break in the upper transmission line) and is short-circuited. The object of this line-break was no doubt to prevent a direct dead short circuit on the left hand bank of transformers at the generating end, because the break does not influence the phenomena of the righthand bank (the bank under test) in any way. The formula for the short-circuit current in this case is:

$$I_c = \frac{\% E}{3 \times \% I Z} \times \text{rated current}$$

An interesting fact about the short-circuit current of this case is that if the step-up transformers were not grounded, only the step-down bank being grounded, (in which case the upper line break would be dispensed with) the coil currents in the

short-circuited step-down bank would be three times as large as the figures given above. This is a good illustration of the influence of system connection and number of neutral grounds on the short-circuit currents.

The voltages on the delta side by ratio from the primary Y side would be 14 volts. The short circuit current being only one third of that corresponding to a short-circuit on a unit as a single-phase unit, the voltage on the delta side of the short-circuited leg will be one third of the excitation, namely, one third of 14 volts, or, 4.7 volts. The measured value is 4 volts, and the small discrepancy may probably be accounted for by reading the voltmeter very low in the scale, as would be the case if the scale was of the order of 50 volts or more. The voltages on the other legs would be 12.3 volts, the measured value being 12 volts which may be considered a sufficiently close check.

4. Fig. 5 is the verification of the simple statement that if one leg of a Y-Y bank is short-circuited, the other two legs take up the full line voltage in open-delta. The corner of the tertiary delta winding is open, at which point 41 volts, which is 1.73 times the voltage of the excited legs, is observed, being the vector sum of the two excited legs with a 60 deg. angle, as the authors have indicated in the vector diagram. When the open corner of the tertiary delta is closed, this voltage is short-circuited and we have the case shown in Fig. 6.

5. The calculation of the currents in Fig. 6 would require a knowledge of the impedance between the tertiary and the secondary. This is not given, but in as much as the currents are given, it is possible to reason back from them to the value of this reactance which figures out to be about 13.5 per cent and which we may apply to the solution of other cases, as for instance the case of Fig. 7.

6. In Fig. 7 short-circuit current could be furnished with the upper transmission line on open circuit, that is, the vertical leg not taking any part whatever. Short-circuit current could also be furnished with the lower two transmission lines on open circuit, that is, the lower two legs not taking any part whatever. This means that we have in effect two sources in parallel furnishing current to the short circuit. What the actual short-circuit current will be and how it will distribute itself in the network may be calculated as follows:

Let us call the upper vertical leg, on primary side, circuit A; the lower two legs together, B; and the line-to-neutral circuit on the secondary side, C.

When the upper leg circuit (A) alone is excited, lower legs (circuit B) being disconnected, the impedance effective from A to C is

$$\% I X_{ac} = \% I X_{ps} = 5.7 \text{ per cent}$$

When the upper leg (circuit A) is disconnected, and the lower legs (circuit B) alone furnishes the load in C, the effective impedance is

$$\% I X_{bc} = 2 \times \% I X_{pt} + \% I X_{st} = 53.5 \text{ per cent}$$

Evidently, the impedance from A to C being about one-tenth of that from B to C, we can say as a first approximation that the former will furnish 10 times as much kv-a. into the short circuit as the latter. Since the voltage of the former is twice that of the latter, its current will be five times as much to make its kv-a. ten times as much. Considering the test data we find that the current in circuit A (vertical leg) is 3.78 amperes, and that in circuit B (lower two legs) is 8 amperes total, the ratio being about five to one. The effective impedance of the two circuits A and B in parallel for the circuit C will be approximately

$$\% I Z_c = \frac{1}{1/5.7 + 1/53.5} = 5.2 \text{ per cent}$$

$$I_c = \frac{\% \text{ Excitation}}{\% I Z_c} \times \text{Rated current} \\ = 0.6/5.2 \times 225 = 26 \text{ amperes.}$$

The observed current is 24 amperes, about 8 per cent lower,

which may perhaps be accounted for partly by the impedances introduced into the circuit by the meters, leads and grounds, and partly by the approximateness of the data on which the calculation is based.

The exact calculation of problems like this involves some methods into a discussion of which we cannot enter now but which will be found described in a paper entitled "Theory of Three-circuit Transformers" to be published in a forthcoming issue of the JOURNAL of the Institute.

8. Of the tests with auto-transformers, Fig. 10 is of particular interest illustrating the reason for and wisdom of the two simple general maxims for the operation of auto transformers, viz.: "If the system is grounded, ground the neutral of the

auto-transformer; if the system is isolated, isolate the neutral of the auto-transformer." In Fig. 10, the delta is open, so that the unit is acting as a straight Y auto-transformer, and it is found that if the system is grounded and the auto-transformer is isolated, a line ground on the secondary over-excites that leg in the ratio $E_1/(E_1 - E_2)$ and shifts the neutral. In this case, the low voltage being 50 per cent of the high voltage, this ratio was 2. If the low voltage had been 90 per cent of the high voltage, this ratio would be 10, that is, the leg whose line is grounded would be overexcited 10 times. This would of course overexcite the other legs also. If the primary is the low-voltage side, a high-voltage line ground not only overexcites but also reverses the voltage of the corresponding leg.

Transformers for High-Voltage Systems

BY A. W. COPLEY

Associate, A. I. E. E.

Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

Review of the Subject.—The designs of transformers for 220-kv. systems do not represent radical departures from designs which have become standard for lower voltages. The solidly grounded neutral system is used and advantage is taken of this to use graded insulation and reduced voltage test. Auto-transformers

are used to connect between the 220-kv. system and existing high voltages and are connected star-star with delta tertiary. The tertiary may or may not be used to supply synchronous condensers but it is not used for the supply of power load.

* * * * *

WHEN considering the use of extra high voltages for the transmission of electrical energy, the apparatus that first claimed the attention of the engineers consisted of transformers, switches and line insulators. Other apparatus, such as generators and synchronous condensers, have generally been considered as being unaffected or only slightly affected in their design because of their application in connection with high-voltage transmission. The problem of transformer design for 220,000-volt operation has been met and solved, however, without the encountering of any unforeseen difficulties or complications.

The application of transformers to 220,000-volt service has brought about a change in the generally prevailing ideas in regard to transformer construction in that the considerable savings obtained by the use of graded insulation on the 220,000-volt transformers has centered attention on similar savings which could be accomplished on transformers for the more moderate voltages. Except for this point, design problems on the 220,000-volt transformers have not been appreciably different from those which had been previously met in standard high-voltage transformers and design. The same types of design have been used, transformers of both the shell and core forms having been built and are now in operation on 220,000-volt circuits. The quality of insulating materials and the insulating oil have not been affected by the advent of the high-voltage. The same types of terminal bushings and the same principles of design have been followed.

Presented at the Pacific Coast Convention of the A. I. E. E., Del Monte, Cal., October 2-5, 1923.

It was universally recognized among engineers that a solidly grounded neutral should be used on the 220,000-volt system. This point being established, it became desirable to take advantage of the savings that could be effected in transformer manufacture by using only one high-voltage terminal and by grading the insulation from the maximum at the line end to a minimum at the neutral end of the high-voltage winding. Such grading of the insulation does not, however, affect the providing of extra insulation between turns or the turns immediately adjacent to the ends of the winding, and such extra insulation has been provided, both at the line end and at the ground end. This practise has been followed in recognition of the fact that surges or steep wave front potentials might be experienced at either end of the winding even when one end is connected solidly to ground.

In carrying out the design of the transformer for use on a system on which the neutral is solidly and permanently grounded, it has seemed to be possible and desirable to recognize the lower electrical stresses to which a transformer so applied would be subjected when compared with a transformer applied on a system in which the neutral is not necessarily permanently grounded. It should, therefore, be possible to reduce the insulation test to which the transformer is subjected.

It is evident that it would be impracticable to apply the voltage test specified in the Institute Rules between the whole winding and ground because of the grading of the insulation. The logical method of applying the insulation test is to ground the neutral end of the winding on the transformer core and to

induce the test voltage in the winding. This gives the maximum voltage test at the line end and graduates it to zero at the neutral end. The dielectric test for a transformer as specified by the Institute Rules is two times the line-to-line voltage plus 1000 volts. The maximum operating voltage which might obtain on a transformer used on a line without solid grounding of the neutral would occur when one line became grounded and would, therefore, amount to the line-to-line potential.

The voltage test specified by the Institute gives a factor of safety of two on this voltage or, in other words, gives a margin equal to line-to-line voltage above the maximum normal obtainable voltage. When a transformer is used on a solidly grounded neutral system and is provided with graded insulation, the practise has been followed of testing with this same margin but as the maximum normally obtainable voltage in such a case is only the line-to-neutral value, the test given is the line-to-neutral value plus the line-to-line value or 2.73 times the line-to-neutral voltage.

As has been suggested, the attention brought to the graded-insulation, single-terminal transformer, by its use on 220,000-volt circuits, has brought about similar arrangements for more moderate voltages and recently transformers for 165,000-volt systems and also for lower voltages have been constructed on this principle. The savings accomplished are larger and more important on the very high-voltage transformers, but there is also a very real saving on transformers built for lower voltage operation.

On the transmission systems now arranged for 220,000-volt operation, special conditions have called for the use of auto-transformers connected to the high-voltage line. The Southern California Edison Company had been operating their Big Creek lines at 150,000 volts and the two original Big Creek plants and the Eagle Rock step-down substation were provided with transformers and switching equipment to give or to utilize this potential. It was considered economy, therefore, to allow this 150,000-volt apparatus to stand and to obtain the 220,000-volt potential by auto-transformation. This necessitated star-star connection between the two voltages and the use of tertiary windings to supply the third harmonic component of magnetizing current and to provide a comparatively low impedance path for the flow of the unbalanced current demanded in the case of a ground on the star-connected system. The importance of maintaining this tertiary winding in service under all exigencies was considered by the engineers of the Southern California Edison Company to be enough to warrant the exclusion from this winding of any other load such as low-voltage local distribution or synchronous condenser current.

The newer Big Creek power plants and the new Laguna Bell substation, near Los Angeles, are equipped

with two-coil transformers connected in star on the high-voltage, and delta on the low-voltage side as no intermediate 150,000-volt potential is required.

The Pacific Gas & Electric Company have had a 100,000-volt system in use in the San Francisco district for many years and it was planned to bring the power from Pit River into the district and to transmit it to the 100,000-volt system already in existence. Thus transformation from 220,000 volts to 100,000 volts became necessary and auto-transformers provide the most economical means of making such transformation. These auto-transformers are located at the Vaca substation. They are connected star-star and provided with a delta tertiary winding which cares for the third harmonic component of magnetizing current, unbalanced ground current in case of line faults, and at the same time supplies the synchronous condensers used for line regulation.

It is not practicable to use the tertiary winding for supplying local distribution and at the same time synchronous condenser current if the field of the synchronous machine is varied in such a manner as to give a constant potential on the high-voltage side of the transformer. This prohibition is on account of the voltage variation which must obtain on the tertiary winding under this condition.

Discussion

E. A. Smith: It would be quite interesting if Mr. Copley would give some more information on these 220,000-volt circuit breakers, such as the necessary data on the rupturing capacity, size of tanks, amount of oil, the grade and the insulating factors, what sort of contacts used and the depth of contacts under the oil.

Also the general tests and curves covering all the characteristics of flashover and safe operating limits.

R. W. Sorensen: Mr. Copley's paper sums up nicely the present-day accomplishments toward the consummation of the 220,000-volt, 1100-mile California bus-bar system as proposed at the 1919 Pacific Coast Convention held in Los Angeles. At that time I hardly thought the plan presented would in any way be realized in less than a decade.

In paragraph two, Mr. Copley speaks of graded insulation being used. Descriptive articles I have read and a rather casual inspection of some of these transformers I have seen out of the tank did not indicate to me a truly graded insulation. To my way of thinking, the term "graded insulation" means a tapering insulation. I am under the impression that, with the exception of the end turn insulation, the insulation between turns is uniform throughout the winding. Also I did not find grading between high-tension windings and core legs. What I have understood is that the large insulation barriers used in the more familiar types of construction, between coils and yokes have been left out, a condition made possible by a plan of construction which permits a single high-voltage lead to be brought out from the center of the coil stacks. This form of construction is not original with the 220,000-volt transformers, as it was first made known by the W. J. Wooldridge patents, so old they have expired, and afterwards used in the Fortescue plans for stress distribution, published about ten years ago. In practise, it has been tried out on many voltages for several years. It is not a scheme necessary for engineering reasons, but is largely one of economy, determined not only by the voltage, but also the

rating of the apparatus. I think it would be a mistake to create the impression that transformers for this voltage can be built only with one insulated lead and a solidly grounded winding.

This brings us to a point in paragraph three. I rather doubt the advisability of saying engineers are universally of the opinion that 220,000-volt systems should be provided with solidly grounded neutrals only. As such a system grows it may be necessary to use Peterson coils, or a resistance of some type in the neutral of 220,000-volt systems and also for systems for other voltages, even though we have by long practise become accustomed to the use of solidly grounded neutrals on the Pacific Coast.

It seems to me ample provision for giving single terminal transformers a voltage test made in Rule 6362 of the A. I. E. E. Standards which reads, "Under certain conditions it is permissible to test transformers by inducing the required voltage in their windings in place of suing a separate transformer. By 'required voltage' is meant a voltage such that the line end of the winding shall receive a test to ground equal to that required by the general rules."

Further, the Standardization Rules call for a specific test for three-phase work of two times line voltage, because many years of practise show this to be desirable. This of course gives a ratio of transformer test voltage to transformer working voltage of 3.46 in a Y connection and of 2.00 for a delta connection. Also, Rule 6321 (e) specifically states that single-phase systems permanently grounded used for more than 300 volts shall be tested at 2.73 times circuit voltage plus 100 volts. If this difference is unwarranted, the matter should be corrected by a change in the Standardization Rules and not by an avoidance thereof.

The economy and also the difficulties encountered in the use of auto-transformers are well known. Therefore, to avoid most of these difficulties auto-transformers, when Y-Y as they usually are, are provided with tertiary windings. The capacity of the tertiary winding is determined by its ability to take care of short circuits. The tertiary winding by providing a path for the third harmonic component of the exciting current, stabilizes the neutral, and should a ground occur on the system it provides a path through which current can flow until a balance is obtained; but if there were no tertiary winding there would be no current flow, as indicated in the seventh line from the bottom of column one of the 2nd page of Mr. Copley's paper. For my part I can see no particular reason to assume the tertiary

more immune from trouble when left idle than when used to supply power, as power load, or to a synchronous condenser, providing proper precautions are taken against faulty connections and overload. Of course, if there is a large leakage reactance factor between tertiary and secondary winding of the transformer, the secondary voltage could not be expected to stay constant if the regulator were set to regulate on the tertiary or the primary, but I see no reason why a condenser can not be supplied with power by the tertiary and yet be made to regulate either the secondary or primary voltage as desired.

A. W. Copley: Professor Sorensen is correct in his statement that the insulation between turns in a transformer with "graded insulation" is uniform throughout the body of the winding except for the end turn padding. The grading is, however, accomplished in the insulation from coils to ground as it is the potential from coils to iron that varies from zero at the ground end to a maximum at the line end of the winding. In shell type construction the grading is done in the group insulation.

The fundamental reason for grading is economic and its justification is the fact that with one end of the winding solidly grounded there is no necessity for taking up space by also insulating this end for full voltage. For the same reason there is no necessity for a high-voltage bushing on the ground end of the winding. The only systems now operating at 220 kv. use the solidly grounded neutral and I have yet to hear engineers seriously propose to operate at such voltages with neutrals either free or grounded through resistance or reactance.

As to the test voltage value for transformers having graded insulation, I explained in my paper the reason for the acceptance of a value of 2.73 times the voltage from line to neutral. Although this is a lower value than is called for by a strict interpretation of the Institute Standards, I believe it is justified and consistent with the values used on transformers with straight insulation which might be used on free neutral systems. The present standards take no cognizance of the graded insulation transformer in the test values given.

The desirability of taking load from transformer tertiaries in addition to the condenser current is largely a question of voltage regulation. The condenser may be used to regulate the voltage on any one winding but not on two simultaneously. In most instances it is desired to regulate the secondary voltage and in these cases the tertiary voltage will generally vary over so wide a range as to make it unsatisfactory for supplying load.

Applications of Long Distance Telephony on the Pacific Coast

BY H. W. HITCHCOCK

Associate, A. I. E. E.

Engineering Department, Pacific Telephone & Telegraph Company, San Francisco, Cal.

Review of the Subject.—This paper deals with the general problem of providing long distance telephone service on the Pacific Coast. A description of the present toll plant is given and the applications which have been made of recent developments in telephone practise are illustrated. Reference is made to the extensive use which has been made of carrier telephone and telegraph systems, and the many special problems, such as the loading of long toll entrance cables, which these systems introduce, are pointed out.

The service to Catalina Island is described to illustrate the changes which are taking place in the communication art. This service was first provided by means of a radio link to which a privacy system was later added. This radio system was later replaced by two submarine cables between the island and the mainland. The mechanical and electrical characteristics of these cables are given, together with a description of the work of laying, which was done principally by the government cable ship, "Dellwood."

WITHIN the last few years the extensive and systematic research which has been carried on by the Bell Telephone System has resulted in developments in the art of long-distance telephony

of facilities whereby the telephone service rendered the public has been greatly extended and improved. Many of these new developments have been ably described in Mr. Osborne's paper, and in others recently presented

FIG. 1

which are indeed remarkable and have placed at the disposal of the Bell companies an ever increasing variety

Presented at the Pacific Coast Convention of the A. I. E. E., Del Monte, Cal., October 2-5, 1923.

before the Institute. It is the purpose of this paper to point out the extensive use which has been made of these newest facilities on the Pacific Coast and how the various elements have been combined under the par-

ticular conditions encountered here to form a coherent toll plant.

To illustrate this, the accompanying map has been prepared. Backbone routes extend north from San Diego through Los Angeles, San Francisco, Portland and Seattle, to the international boundary where connection is made with the British Columbia Telephone Company's lines to Vancouver. Contact with the territory to the east is effected by leads to Phoenix, Salt Lake, Boise and Butte. The heavy lines on the map represent leads on which carrier systems are in operation. The medium weight lines represent other main leads not so equipped at present, while the light

built up circuit exceeds the limit which has been set, repeaters are inserted at the intermediate points to preserve the necessary over-all efficiency.

To illustrate the manner in which the several types of circuits may be combined, let us assume a connection established between Avalon on Catalina Island and Deer Park, Washington, a tributary of Spokane. The circuit arrangement together with the comparative power level at all points when the Avalon party is speaking is shown in Fig. 2. Starting from the Avalon end we encounter in succession, a deep sea submarine cable, a long loaded toll cable, the 25-kilocycle channel of a carrier telephone system operating over No. 12

AVALON - DEER PARK CIRCUIT DIAGRAM

FIG. 2

lines represent some of the more important branches. Toll cables are represented by the short heavy lines in the immediate vicinity of the larger cities. Future carrier facilities for which plans are actively under way are indicated by heavy dots on medium width lines. Various types of repeaters are also shown.

In any telephone connection regardless of its length the aim is to maintain a satisfactory equivalent or standard of efficiency. All direct circuits between the large cities and towns are designed to be well within this equivalent. Where no direct connection exists, two or more circuits joining intermediate points are connected together. When the equivalent of such a

N. B. S. gage wire (173 pounds per wire mile), a trans-bay lead-covered submarine cable, the 10-kilocycle channel of a carrier system operating over No. 8 B. w. g. wire (435 pounds per wire mile), a No. 8 gage open-wire phantom and a No. 12 gage open-wire circuit. Two through line voice frequency repeaters and seven carrier-frequency repeaters are employed. Voice-frequency cord circuit repeaters are inserted at Los Angeles to connect a toll cable with a carrier system, at San Francisco to join two carrier channels, and at Portland to connect a carrier channel with an open-wire phantom circuit.

In addition to the various types of circuits and am-

plifiers involved in this connection the power relations are also of interest. Consider for example the conditions at a time when the power delivered to the line in question by the Avalon telephone is 1000 microwatts. The over-all circuit efficiency is about 0.4 per cent (25 mile equivalent) so that four microwatts are delivered to the Deer Park instrument. Were the cord circuit repeaters omitted the power transmitted would be reduced to 0.02 microwatts. Should all the repeaters including those in the carrier systems be omitted, the received power would be 1.3×10^{-16} microwatts.

Not only is it necessary to maintain a certain over-all efficiency, but also is it required that the power be kept within certain upper and lower limits at all points along the way. Should the voice currents become too great, overloading of the repeater tubes accompanied by distortion of the speech waves will occur. If the current becomes too weak, the circuit will be noisy or experience excessive crosstalk from other lines. These upper and lower limits make it necessary to amplify the current at regular and fairly frequent intervals as

already been made of carrier systems. This is due largely to the fact that the great distances which separate the main centers of population are sufficient to justify the large cost of carrier terminal and intermediate repeater equipment, because of the resulting saving in line wires. Fig. 3 shows the systems now in use and those upon which work is progressing. At the present time, there are in operation 6400 channel miles (10,300 km.) of carrier telephone and 18,500 miles

FIG. 4—TERMINAL EQUIPMENT OF TWO CARRIER TELEPHONE SYSTEMS AT OAKLAND

FIG. 3

is done in the circuit shown. Were all the amplification to be effected at the receiving end, the noise and crosstalk would completely drown out the speech current. In case the amplification were all applied at the sending end the speech input power would have to be about thirty billion kilowatts. Such a mode of operation is of course impossible.

One of the most noteworthy things about the Pacific Company's toll plant is the extensive use which has

(29,800 km.) of carrier telegraph. These figures will soon be raised to 8600 miles (13,800 km.) and 32,300 miles (52,000 km.) respectively. All of the eight San Francisco-Los Angeles circuits now are carrier channels as are the four San Francisco-Portland circuits. It may be of interest to note that when the carrier systems now contemplated are completed it is expected that it will be possible to talk by carrier alone for practically the entire distance from Avalon to Spokane, which is more than sixteen hundred miles (2600 km.).

Among the special problems which the use of the new facilities presents is that of bringing the toll circuits into San Francisco. Those which enter from the north and east must cross the bay in submarine cables which are too long to be operated on a non-loaded basis. Fortunately, Goat Island provides an intermediate loading point between Oakland and San Francisco for the circuits from the east, although the minimum spacing which is obtained in this way is 12,000 feet (3660 meters), or more than twice the spacing which is used normally with cables associated with open wire. Special coils have been developed to meet this condition and are used on all the existing submarine toll entrance cables, since the provision of submarine loading coils would not have been as economical.

Although lines loaded in this special manner are satisfactory for voice frequency circuits, they cannot be used for carrier systems. It has therefore been

necessary to make Oakland the carrier terminal point for all such systems operating over wires which approach the bay from the east, although the individual channels, both telephone and telegraph, are extended across the bay to San Francisco and terminated there.

Another special problem incident to the use of carrier systems is the loading of long toll entrance cables. Two of these, each about nine miles (14.5 km.) in length, occur in this territory. One extends from the Los Angeles office north to Cahuenga Pass and provides entrance facilities for both the coast and valley leads. This cable will soon be extended to Simi junction, an increase of three miles (5 km.). The second cable

FIG. 5

extends from Oakland to San Leandro and serves the valley circuits to Los Angeles. Both of these cables have been loaded at frequent intervals with special coils so as to render them suitable for use with carrier systems. A third cable 12.5 miles (20 km.) in length extending south from Seattle will also be loaded for carrier operation in the near future. Such loading is quite expensive and has an important bearing on the question of carrier circuit economy.

One of the most difficult problems encountered in this territory is to anticipate and provide for the rapid increase in the long distance or toll business. The extent of this growth is shown on Fig. 5, which gives the total toll circuit mileage for the last ten years.

For comparison the increase in population for this period is also shown. In order to care for this increase in business, extensions to the plant are constantly being made. Mention has already been made of the several carrier projects now under way. Toll cables are to be placed between Seattle and Tacoma, between San Francisco and San Jose and between Los Angeles and Long Beach to supplement those now in use. A cable

FIG. 6

is soon to connect Los Angeles with Anaheim and other Orange County points while another is now being designed for use between San Francisco and Sacramento.

New open-wire circuits are constantly being added to the plant. A group of No. 8 gage wires (435 pounds per wire mile) is being strung between San Francisco and Los Angeles by way of the coast. These wires are being specially transposed to facilitate carrier operation

FIG. 7

and together with those already in place will provide facilities for several new carrier systems over this route. The new No. 8 gage circuits from Los Angeles to Denver will furnish a new and much needed outlet for eastern business and will also materially reduce the possibility of total interruption to service between the coast and eastern points.

No better illustration of the rapid advance in the

art of communication or the application of new methods to the telephone toll plant can be found than that provided in our territory by the service to Catalina Island.

In 1920 commercial telephone communication was established between Pebble Beach on Catalina Island and Long Beach by means of a two-way radio system. At the two ends the connection was extended to Avalon and Los Angeles respectively by means of wire circuits. Soon after this a telegraph channel for handling commercial messages was added. This is the first and

Catalina talked to Havana by way of the radio and the newly completed Key West-Havana submarine telephone cable,—a total distance of about 5500 miles (8800 km.).

One objection to the radio circuit was the lack of secrecy, and the recent increase in the use of radio sets for the reception of broadcasting rendered this increasingly troublesome. In order to obviate this difficulty a privacy device which was recently developed by the Bell System was installed on this circuit. This privacy system although it in no way impaired the

FIG. 8—LOCATION OF SOUTH CATALINA ISLAND CABLE

perhaps the only instance in which radio has been used as an integral part of a telephone toll system and operated under the same severe requirements as are imposed on the wire circuits.

From the time of its installation, this circuit handled a tremendous volume of business. That it was quite efficient is proved by the fact that it was used in frequent demonstrations such, for example, as the one in 1921 when a conversation was held by way of the transcontinental telephone line between Catalina and the S. S. Gloucester one hundred miles (160 km.) off the Atlantic coast; and again in the same year when

quality or volume of the speech over the radio circuit, rendered it unintelligible to anyone listening with a radio receiving set of the usual type.

The radio system recently was replaced by two deep sea cables between Avalon and the mainland. The license of the radio "talk bridge" expired on August 1st and the Department of Commerce requested that its operation be discontinued, making its wave lengths available for broadcasting.

The capacity of the ether for radio messages is distinctly limited and when such services as broadcasting, ship-to-shore telegraphy and telephony, radio

compasses, etc., which can be handled only by radio, have been accommodated, the available wave lengths of the ether are about exhausted. Consequently, the change from radio to cable in a case like Catalina Island, where the cable is not only feasible but more economical than radio, was for the good of the service, especially as the large volume of business which developed made it necessary to provide additional facilities.

The submarine cables were manufactured by the Western Electric Company at Hawthorne, Illinois, and in their design have been incorporated many of the most recent developments in submarine cable construction. The approximate position of these two cables is shown in Fig. 8. At the Avalon end they

FIG. 9

terminate directly in the new central office located about 800 feet (240 meters) from the shore. At the San Pedro end a small concrete hut was erected at the base of the breakwater in which to terminate the cable and house the special terminal equipment. This was selected as a landing point as the water in the cove formed by the shore and the breakwater is comparatively quiet and at this point a small sandy beach has been formed. At all other points in the neighborhood of Point Fermin the shore is very rocky and steep and the water quite rough. The distance between Point Fermin and Avalon is about twenty-three nautical miles (6087 feet or 1856 meters per nautical mile). At the center of the channel the water reaches a depth of slightly over 3000 feet (900 meters). For the greater part of the distance the cables were laid

about two miles (3.2 km.) apart. This separation was maintained so as to give greater insurance against simultaneous interruption and to render it easier to pick up one cable without disturbing the other.

The cables themselves are of the deep sea type. Such a cable provides but a single physical circuit formed by the central insulated conductor as one side and the sea water, armor wires, and copper tapes, all in parallel, as the other side. The details of construction are shown in Fig. 9. In shallow water near

FIG. 10—CABLE BARGE AT AVALON

the shore where there is danger of injury from anchors or abrasion due to tide and wave movement, large armor wires are employed. In deep water where these dangers are largely absent, the armor is formed of smaller wires having a high tensile strength. Such armoring provides a light and flexible yet strong cable, suitable for withstanding the severe strains encountered in laying or picking up the cable in deep water. For the cable lying in water having a depth of between 600 and 1800 feet, (180 and 550 meters) an intermediate

FIG. 11—U. S. CABLE SHIP "DELLWOOD"

type of armoring employing medium size wires was used.

The first part of each cable to be laid was the 2.5 mile (4 km.) shore end section on the Avalon side. This was done from a barge equipped with a large power-driven reel upon which the cable was first wound. At the Avalon end the barge was anchored near shore and the end of the cable pulled up through the underground ducts and into the office by means of a tractor. Following this the barge was towed out to sea, the

cable being unwound from the reel. Prior to the laying, marker buoys had been placed to indicate approximately the location of the ends of these shore end sections. To the end of the cable a section of chain and a long rope was attached, the other end of which was made fast to a buoy.

The main portion of the cable was laid by the government cable ship "Dellwood." This ship, which has a length of 330 feet, (100 meters) is well provided with the usual cable handling equipment.

In laying the main portion of the cable the ship was first anchored about half a mile (about 1 km.) off the San Pedro shore opposite the cable hut and the end of the cable pulled ashore with the aid of the barge, tug, and other small craft. The ship then started on its course paying out first the shore end, then the intermediate and finally the deep sea cable, all of which had previously been spliced together. On reaching the 1800-foot (550 meter) depth line on the Avalon side, the ship was stopped, the remainder of the deep-sea cable cut off and the end spliced to the intermediate type. Laying was resumed until the buoy fastened to the shore end was reached. The ship was again stopped, and the end of the cable previously laid was hoisted on board. The intermediate cable was then cut and spliced to the shore end, after which the com-

depth of water encountered, the performance of this cable will be watched with great interest as it marks

FIG. 13

an important forward step in the development of submarine cable manufacture in this country.

While this discussion has covered only a few of the outstanding applications of long distance telephony on the Pacific Coast, it will serve to indicate the way in which some of the most recent advances in the art constantly developed by the Bell System have been employed. It is by means of such recently developed instrumentalities that the people of the Pacific Coast now are able to talk to all sections of the United States, bringing the inhabitants of this

FIG. 12

pleted cable was dropped overboard. Both cables were laid in essentially the same manner.

As the balance of the circuit from the cable hut to Los Angeles had been provided in advance, it was possible to communicate between the ship and shore points as soon as the end of the cable was brought into the hut and the connection established there.

While the cable was being laid, a number of conversations were held between company officials on board the ship and persons in and around Los Angeles and San Francisco. As soon as the final core splice was made communication was established between Avalon and Los Angeles and two hours later a conversation was held with American Telephone and Telegraph officials in New York.

At present each cable provides one d-c. telegraph and one voice-frequency telephone circuit, the circuit arrangement being shown in Fig. 12. Figs. 13 and 14 show the impedance and attenuation respectively of the East Cable.

Although not imposing as regards total length or

broad country into an intimate contact that cannot fail to be of great commercial and social benefit.

Group Operation of Systems Having Different Frequencies

BY E. R. STAUFFACHER and H. J. BRIGGS

Associate A. I. E. E.

Both of the Southern California Edison Co.

Associate A. I. E. E.

Review of the Subject.—The group operation of high-tension transmission systems having different frequencies has been successfully accomplished in Southern California during the past seven years. Some of the outstanding advantages of power interchange are emphasized and the value of the frequency changer for this purpose is shown.

The metering of the interchanged power and the method of loading

a frequency-changer offer somewhat unusual problems. With a liberal field design a synchronous frequency changer is of value as a means of power factor correction.

Certain troubles with the starting winding and the bearings of some of the machines have developed as a result of severe operating conditions but the frequency-changer has proved to be a reliable and satisfactory means of interchange of power between large systems.

GROUP operation of systems having different frequencies each of which is composed of a network of high-tension transmission lines has been successfully accomplished during the past seven years in Southern California. Frequency changers for this purpose have proved to be a reliable and rugged piece of equipment and have shown their value not only as a means of interchange of power, but also as a means of power factor correction when necessary.

The position of the Southern California Edison Company is unique in that it is, with one exception, entirely surrounded with systems operating at a different frequency. The above company interchanges power with the San Joaquin Light and Power Company (60 cycles) on the north; the Southern Sierras Power Company (60 cycles) on the east; and the San Diego Consolidated Gas and Electric Company (60 cycles) on the south. In addition to this there is an interchange of power between the systems of the City of Los Angeles and the Southern California Edison Company, but without the necessity of frequency changers as both systems operate at fifty cycles. To be more specific concerning the location and size of the various frequency changes, these data are given in the table "A".

The advantages of interchange of power between adjacent systems need not be gone into detail here. It is sufficient to summarize them as: (a) A means of disposing of large blocks of hydroelectric energy during off-peak hours which otherwise might be wasted; (b) a means of obtaining hydroelectric power and thus overcoming the necessity of generating power by means of the more expensive steam plants, with the further advantage that the steam plants can be held in reserve for emergencies; (c) when the hydroelectric systems concerned cover a wide area, as is the case in Southern California, a deficiency of snow-fall or of rain-fall, in one section is not serious when power can be obtained from a system where the power is obtained from a widely separated watershed; (d) three or more systems can attain greater operating economies when, by means of fre-

quency changers and intermediate transmission networks, one system not directly connected with another can obtain power through the lines of the intermediate system; (e) a ready means of exchanging power in case of a breakdown of a major generating plant of any of the systems so inter-connected.

To give an idea of the value of group operation of a number of systems through frequency changers, table "B" has been prepared showing the amount of power interchanged during the past year.

FREQUENCY CHANGER AT CAPISTRANO SUBSTATION
5,000 kv-a., 50-60 cycles.

From a study of this table the flexibility of frequency changers as a means of interchanging power is well shown. In addition to delivering power from one company to another, the equipment can obviously be utilized as a means of delivering power to a third company.

It may be of interest to outline the method of metering when power is to be transmitted in either direction through a frequency changer. The scheme generally used is to have both sides of the machine equipped with a polyphase curve drawing wattmeter and two polyphase integrating watthour meters. Each of the integrating instruments is equipped with a ratchet mechanism so arranged that one instrument will meter energy only when power is flowing towards the frequency changer while the other will register only when power is flowing from the machine. By this combination the power delivered to either company is accurately recorded and the losses in the frequency

changer throughout the month are definitely determined. The losses in the machine can, of course, be borne by either of the parties according to the terms of the contract, but the method usually followed is to bill the receiving company for one-half of the losses. Since the installation of the original frequency changer set in Southern California this method of metering has been used with satisfaction to all parties concerned.

The method of loading up a frequency changer has apparently not always been thoroughly understood. There has been some question as to whether the operator at the substation where the machine is located had control over loading, whether either of the systems concerned had to lower or raise their system voltage or if any adjustment in the frequency was necessary. After a frequency changer is in operation and synchronized with both systems and it is desired to load up the machine the system which is to supply the energy calls on its governing plant to pick up load. This plant opens the nozzles or wicket gates of the generator which is governing or "taking the swings" as it is termed, and in doing so the generator attempts to

speed up the system to which it is connected and in doing so it picks up more load. The frequency changer in turn tends to speed up and in so doing it picks up load from the receiving system, or in other words, delivers power from the system which contained the governing plant. Due to the increase in current at the generating plant and at the frequency changer substation some slight adjustment of the voltage is necessary either by manual or by automatic means but this is a comparatively minor operation in picking up load.

The motor end of a frequency changer can, in addition to driving the generator end, be utilized for power factor correction. The adaptability of a synchronous motor for this purpose is well known, which feature is quite valuable on systems having a larger induction motor load and a network of comparatively long high-tension transmission lines. If it is contemplated using either end of a frequency changer set for power factor correction, care should be taken to specify a liberal design of the field winding. There have been a number of instances where the usefulness of a frequency changer for power factor correction has been limited because the field winding was not designed for a great amount of over-excitation.

Some of the major considerations to be made when the installation of a frequency changer is contemplated are:

- What will be its size in relation to the generating capacities of the two systems concerned, and will the set be required to furnish energy in either direction?
- What will be its location in regard to the principal generating plants of both systems?
- Voltage and frequency of each system?
- Rating of each unit? The specification for one of the frequency changers listed elsewhere in this paper calls for the following:

"Each unit will have a maximum continuous capacity when operating as a generator of 5000 kw., 0.8 power factor or 6250 kv-a. with a 50 per cent maximum momentary overload. When operating as a synchronous motor, each unit will be required to operate at 0.8 power factor leading, corresponding output

of the set being 5000 kw., 0.8 power factor. The temperature rise corresponding to the above conditions shall not exceed 50 degrees centigrade on either unit."

(e) Method of excitation, whether provided with individual exciters direct-connected, or if excitation will be provided from a motor-generator set or both, and whether an automatic voltage regulator such as a Tirrill is to be provided.

(f) *Efficiency.* If the set is to be operated con-

FREQUENCY CHANGER AT VESTAL SUBSTATION
15,000 kv-a., 15,000 volts, 50-60 cycles.

tinuously, the losses should be capitalized. For this reason the efficiency of the set for $\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$ and full loads should be specified, both for unity and some certain power factor leading for the motor and for unity and some lagging for the generator.

(g) *Starting Device.* Shall the set be capable of starting from either end and how will the starting be accomplished?

The experience of the Southern California Edison Company with frequency changers has been quite satisfactory during its seven years experience with such apparatus. There have been minor troubles, however, the chief of which have centered around the starting bars on the squirrel-cage winding and with the bearings.

After the first 5000-kv-a. machine had been in operation for about four years under conditions of rather severe service, it was necessary to take the machine out of service for approximately one month for the purpose of straightening the shaft. There has also been trouble with the motor bars coming loose. The original bars were replaced with bars of Monel metal. This change resulted in a different performance of the frequency changer on starting, in that the starting torque was much greater and the starting current was less, but there was more difficulty in falling into step than had been the case with the original bars.

It has also been an open question whether the trouble with the starting bars and the end rings of the frequency changer was due to the fault of the manufacturer or the result of the treatment of the machine. It must be realized that the excessive number of times of starting and stopping such a set as this will entail

heavy duty on the squirrel-cage winding with the constant result of heating and expansion which will cause trouble later.

The largest machine on the system of the Southern California Edison Company (15,000 kv-a.) is a four-bearing machine and is equipped to use oil pressure in the bearings at the time of starting. Originally this machine was lined up so nicely that after the oil pressure had been applied it was possible for one man to move the rotor by applying his weight. There has been some trouble with the bearings, however, due to the fact that the conduits used for the bearing thermostat wiring accidentally short-circuited the insulating pad in the end bearings. After the bearing trouble occurred the conduit was removed and examined and evidence was found of considerable current flowing. This current flow was the result of accidentally short-circuiting the insulating pad which completed the circuit for the flow of circulating currents in the frame and shaft of the machine. The conduit was pitted and practically welded to the frame and base of the machine. There was evidence of pitting in the bearing and without doubt the circulating current

EFFICIENCY CURVES OF FREQUENCY CHANGER SET AT CAPISTRANO

was the cause of the bearing failure. Needless to say precaution has been used to eliminate the recurrence of such trouble by the same cause.

In regard to the protection of the frequency changer, time limit overload relays have been used on both ends so that in case of trouble on either system the frequency changer is disconnected on the side of the system in trouble. Power directional relays can be used to good advantage for this purpose. In addition to this it is necessary to provide some means of protection against

internal trouble of the frequency changer and this has been provided for at Vestal by means of two sets of power directional relays so wired that their contacts are closed when power is going towards the frequency changer. In addition to this the contacts on each set of relays are wired in series, so arranged that the tripping circuit will kick out the switches on both sides of the frequency changer. Under these conditions it can be seen that power will flow towards the frequency changer from both sides in case of a severe ground developing in the machine, and it is hoped that by this means to keep the damage to the machine windings and laminations down to a minimum.

In conclusion it may be stated that the frequency changer has proved to be a very satisfactory means of interchange of power, and that it should cause no trouble provided it is of the proper size in relation to the two systems which it connects.

Discussion

L. M. Klauber: There are two points upon which I should like to comment from the standpoint of a smaller company engaged in interconnection with a larger.

Mr. Stauffacher has told you of the smoothness of operation of frequency changes used in interconnection. On the contrary operation is not always so simple for the smaller company.

One point I might mention is that of governing. Steam turbines appear to be equipped with governors which are inherently more sensitive than those on the hydraulic machines. Therefore, a smaller system with steam turbines tied to a large system, principally hydro, through frequency changers tends to either feed into the large system or take from it a violently fluctuating block of power. For this reason it is necessary when our system is tied to that of the Southern California Edison Co., to change the degree of sensitiveness of the governors on our steam turbines. This has proved quite a problem. A method was finally devised whereby this might be done with entire satisfaction in a practical way, but unfortunately it is a method that

is frowned upon by the manufacturers of the turbines. Yet, so far they have been unable to offer any other practicable solution. Our method is to place on one of the operating rods of the governor a device which we call a "load steadier" which works by friction on the governor shaft. It works, as I say, with entire satisfaction and it is so arranged that the load on the turbine may be varied from the switchboard in the usual way. It may be instantly released if desired.

Recently, we have tried a second means of governing. We fix the turbine load for a certain specific amount by partially closing the hand throttle so it cannot carry more than that amount with all the governor valves wide open. The result is a decreased efficiency, approximately 2 per cent below the other method of governing, but it is thought by some to be safer. We operated for approximately a month, alternating between the two methods in order to determine the relative efficiency of each. This matter of control of governor sensitiveness is a point to which the manufacturers should give some attention.

Another matter is that of load control, which, again is somewhat difficult. Without frequent telephone communication it is difficult to carry the load at a maximum and yet within the capacity of the frequency changer. It, therefore, becomes necessary for the operators to do considerable guessing, in which they ultimately become quite expert, for if load is being taken from the line between the generating station and the frequency changing station, it is obvious they must make calculations of the load which is being taken off along the way, so that the ultimate load which reaches the frequency changer is not beyond the capacity of the machine.

P. M. Downing: My experience has been that where you attempt to operate turbines in parallel with a large hydro-electric system you must of necessity make your governors more sluggish; otherwise, your steam turbine will one moment have no load and the next moment it will be overloaded. That is not due entirely to changes of frequency on the larger system, but due to the inherent differences in governing between a steam turbine and a water power governor.

O. B. Coldwell: Our company has two frequencies, 33 $\frac{1}{3}$ and 60 cycles. There are frequency changers in operation tying the two systems together. We have been for several years past doing away with the 33-cycle apparatus. To a considerable extent this has been accomplished by remodeling 33-cycle machinery for 60-cycle operation.

Recent Developments in Carrier-Current Communication

BY LEONARD F. FULLER

Member, A. I. E. E.

Radio Engineering Department, General Electric Co., Schenectady, N. Y.

Review of the Subject.—Carrier-current communication over transmission lines has been developed to a point where its practicability and value are thoroughly established.

This paper discusses several recent developments in apparatus and methods of operation.

Carrier-frequency energy flow along the line is discussed briefly to give a mental picture of the electromagnetic and electrostatic conditions existing.

Standard 50 and 250-watt apparatus are shown in the illustrations and described briefly.

Energy Transfer and Flow.	(480 w.)
Station Apparatus.	(390 w.)
Summary.	(80 w.)

CARRIER-current communication over transmission lines is being adopted rapidly not only as an auxiliary to existing wire telephones, but as the only means of direct communication for some recently constructed lines.

As our accumulated experience has increased the desirable frequencies and the range of sets of various powers over lines and networks of different types have become fairly well established.

Field experience to date has shown the practicability of transmitting carrier current over power systems with reliability and certainty. The method has been proved basically sound.

RECENT DEVELOPMENTS

The next steps in development are improvements in the apparatus, both mechanical and electrical, including those features which give greater operating convenience and flexibility.

Remote control of the apparatus is an example. Early sets were designed for control distances up to 250 ft., which is sufficient for the usual conditions encountered when the operator and apparatus are in the same building, but remote control attachments now available increase this distance to several miles. Thus a dispatcher in a city office building can control the carrier-current set miles away in an outlying suburban substation.

A modification of the foregoing is to retain the control of the carrier set at the station at which it is installed, but to have it arranged so the operator at the station can plug in the voice control on any one of a number of the company's wire phone lines. Such an arrangement allows distant stations to communicate directly with anyone in the main office.

Calling is accomplished on existing carrier-current channels either by one or more gong bells operated by a local relay, or by means of a loud speaker which permits direct voice or howler calling. This method is employed in the Great Western Power Company and Pacific Gas and Electric Company equipments, while

the relay and call bell method has been generally employed in eastern installations.

Each method has its inherent advantages and disadvantages. The loud speaker cuts the time for short dispatching orders almost in half when operators are constantly within hearing distance. In such cases calling and answering calls are dispensed with. The dispatcher gives an order and the station to which it was directed repeats it. The Great Western Power Company has used this method for over a year and the Pacific Gas and Electric Company has also found it satisfactory.

If there are several carrier sets on a system, which intercommunicate frequently, it is often annoying and generally undesirable to have a loud speaker talking when its station is not concerned with the conversation. In one installation there was an objection to the loud speaker, not because of undesired conversations which did not exist in this case, but because of the line and electric storm noises which were reproduced. Relay and gong bell ringing is necessary in such cases.

Selective ringing is a further refinement which may be employed when code ringing of the gong bell would cause annoying and unnecessary disturbance at several stations of which only one was desired.

Time limit attachments are often furnished with the calling relay system to prevent electric storms and other high-frequency disturbances from ringing the gong bell. Code ringing is possible with such attachments, since the time limit feature is automatically inoperative after the first signal which must be a long dash. It may be followed by any desired dot and dash combination.

An excellent calling system is a relay with time limit attachments arranged to connect a loud speaker in circuit at the end of the long dash above mentioned. A gong bell may be added if desired. In this way the loud speaker does not reproduce undesired noises, but comes into service automatically for any speech or code calling.

A selector system may be added to such a combination. In this case the loud speaker is connected in circuit only when its station is called, but after being connected, the message may follow immediately if desired, with the resultant saving in time.

We are thus able to utilize the desirable features of the loud speaker system and remove those considered detrimental.

The calling relays are quite reliable when equipped with the time limit feature. They require very little energy and will operate with less than is required for satisfactory speech. Thus we can ring over any line over which we can talk.

All our installations are simplex. That is, the operator throws a tumbler switch or operates a foot pedal to connect the apparatus for talking or listening. This method has met with success wherever installed. It rarely takes an operator more than the first day to become used to the scheme of things.

The writer once saw a laborer working about a station called to the carrier phone set to receive a personal message from a man he had known in the army who happened to be visiting the station at the other end of the line. After operating the talk-listen button for him for the first few sentences no more assistance was required and the conversation proceeded vigorously.

This was a case where men who had not talked with each other for two years and who had never seen a carrier phone set before, found simplex operation so easy that they carried on an animated conversation over a 200-mile line for some time.

Duplex operation, except over short distances with sets of very low power, complicates the apparatus and decreases its reliability out of all proportion to the slight advantage gained. The users of this equipment are mainly station operators who soon grow accustomed to the man at the other end of the line and the semi-routine character of a large portion of the traffic handled.

Telegraphy is a valuable adjunct which may be added to carrier-current sets. It may be by either interrupted or continuous waves. The latter are preferable in emergency work because they will permit telegraphic communication under extremely severe line conditions.

The writer has received continuous wave telegraph signals at Pit River from the Vaca-Dixon substation 202 miles distant with all 6 line conductors grounded at several points although telephony and interrupted wave telegraphy were altogether out of the question, not a sound being heard in the phones.

For communicating over very noisy lines and during bad electrical storms interrupted waves may be used, but continuous wave heterodyne reception is probably preferable.

In starting telegraphy on an existing carrier-current telephone channel it is preferable to begin with a list of code signals for the common orders and use these frequently while the operating personnel are learning the telegraph code.

A speed of only 5 words per minute is of great value in emergencies when all other forms of communication may have failed. Most men can learn to send and receive at this speed without great difficulty. The

higher speeds used in commercial telegraphy are learned easily and well only by rather young men.

ENERGY TRANSFER AND FLOW

Irrespective of the use to which the carrier-current energy is put at the receiving station, the method of transferring it to and from the line is the same.

At the transmitting station a carrier-frequency current is fed into the line. This results in a potential difference either between all line conductors and earth or between conductors. To date commercial installations have utilized the former method.

The electrostatic field due to this potential difference expands or travels down the line toward the receiving station at a velocity depending upon line constants. Usually this is not far below that of light in free space.

If the carrier frequency is 30,000 cycles per second, a half cycle will last $1/60,000$ second and the static field of one half-cycle will have extended for about 3 miles along the line before the reversal of polarity due to a succeeding half-cycle commences.

If our eyes could see electrostatic fields and we stood at any point along the line, while these things were occurring, we would see nearly three miles of field slide by at about the speed of light, with the line positive with respect to earth, followed by an equal length in which the polarities were reversed.

If the line is short enough to allow the static field to travel to the receiving station while it is still being formed at the transmitter, the load drawn by the receiver will effect the power output of the transmitter. That is, the input impedance of the line will be varied by the receiver or load impedance.

This phenomenon, which is always observed at power frequencies on lines of present day length, is rarely observed at carrier frequencies. The lines are obviously too long to permit it.

Thus the energy delivered to the line at the sending station becomes wholly detached from the transmitter and is either partly absorbed by the receiver or frittered away entirely in line losses.

The most common method of charging the line at the transmitter is to erect a "coupling wire" in the vicinity of the line conductors. When this is raised to a given carrier-frequency voltage with respect to earth the conductors assume a potential corresponding to their relative positions in the static field.

Various types of coupling condensers have also been employed with mica, porcelain, and other dielectrics. Such condensers are connected between the carrier-current transmitter and the line, the current passing through them charging the line with respect to earth.

At the receiving station various arrangements capable of extracting energy from the electrostatic field may be used. Coupling wires, large wire loops, coupling condensers and combinations of them may be employed. At the present time the coupling wire method is preferable for both transmitting and receiving, due not only

to its reliability, simplicity and ease of inspection, but also to its low first cost.

FIG. 1—TRANSMITTER-RECEIVER FOR 50-WATT CARRIER-CURRENT TELEPHONE
The calling relays are mounted on the section at the right.

FIG. 2—250-WATT CARRIER-CURRENT TRANSMITTER
Having master oscillator, power amplifier, voice amplifier and modulator tubes.

STATION APPARATUS

The sending and receiving station apparatus is

much like that used in commercial radio communication with such modifications as are desirable for power system use.

Fig. 1 shows a typical carrier-current equipment having a power output of 50 watts. The transmitter is mounted at the left, the receiver at the right.

Power is supplied to the transmitting vacuum tubes at 1000 volts d-c. by a small motor generator driven by the station a-c. or d-c. supply as determined by local conditions. The receiving tubes are operated from storage batteries in the customary way.

FIG. 3—250-WATT CARRIER-CURRENT RECEIVER
Showing tuning adjustments and calling relays.

This equipment is used for telephony over the shorter lines. Its actual range depends upon the arrangement of the system. Transformers, taps, cables and associated low-voltage lines all affect the situation. Field experience has accumulated to such an extent however, that the analysis of such networks is now readily accomplished.

More powerful sets of 250 and 500 watts carrier frequency power output are built for the longer and more difficult lines. Communication by the 500-watt

Pit River set of the Pacific Gas and Electric Company has been received over 410 miles of line.

These equipments are built in several units.

The 250-watt set comprises:

(1) A power panel on which the motor generator starter, switches, fuses and instruments are mounted.

(2) The transmitting apparatus, cabinet housing all necessary vacuum tubes, instruments, coils, relays etc.

(3) The receiver cabinet.

(4) The motor generator.

(5) The operator's desk phone set and a loud speaker when used.

Figs. 2 and 3 show portions of this equipment.

Both the 250 and 500-watt sets are of the master oscillator type, that is, the carrier-frequency currents are generated by a small tube used to excite a larger one. The output of this power amplifier is modulated in accordance with the voice by another or modulating tube and then delivered to the coupling wire.

This method gives a substantially constant carrier frequency irrespective of line conditions and maintains a better voice quality than is possible with self-exciting tubes when forced to operate under adverse conditions.

The sets of the Great Western Power Company and Pacific Gas and Electric Company are not of the mechanical form shown in Figs. 2 and 3 having been developed in cooperation with the power companies prior to the design of the present standard equipments.

SUMMARY

In this paper I have attempted to outline briefly and without irrelevant technical or descriptive detail, the outstanding features of carrier-current work on transmission systems as we know it today.

Our present technique has the background of the older radio communication. Active commercial experience on high-voltage lines has been of shorter duration, but amply sufficient to prove the method technically and economically sound, and to demonstrate a few of the many uses the future will find for it.

Some Experiences with a 202-Mile Carrier-Current Telephone

BY E. A. CRELLIN

Member, A. I. E. E.

Pacific Gas & Electric Company, San Francisco, Calif.

ON April 11th, 1923, the Pacific Gas and Electric Company placed in operation a carrier-current telephone system between Pit River Power House No. 1 and Vaca-Dixon substation. This system utilizes the twin-circuit 220,000-volt transmission lines between the two points for a conducting medium and is for use primarily by the operating department in directing the operation of the power houses in the Pit River development together with the transmission lines which carry the energy southward to the distribution center at Vaca-Dixon substation. With the commencement of work on Pit River Power House No. 3 an increasing volume of messages is being received from the construction and auditing departments for transmission to the general offices of the company, and it is already apparent that additional carrier-current telephone sets will be required, one at the base of construction operations for Power House No. 3 and one at Claremont substation in Oakland to relieve the congestion on the wire line between Vaca-Dixon substation and the load dispatcher's office.

During the six months from October 1922 to the inauguration of the carrier-current telephone, the operation of the Pit-Vaca transmission system was directed by wire lines. In the absence of direct wire communication between the load dispatcher's office at Oakland and the power houses in the Pit River system, it was necessary to relay all messages one or more times which introduced a considerable delay and was subject to error, especially in view of the inductive interference usually encountered on telephone lines paralleling transmission lines. Since the carrier current telephone was placed in operation in April it has answered all dispatching requirements, and as the operators become more and more familiar with the peculiarities inherent in such a system its many advantages over the wire lines become more and more apparent.

The system is coupled to the transmission line through a single-wire antenna about 1800 feet long. This wire is attached to the twin vertical circuit transmission towers at a point on the center line of the towers and at the elevation of the middle arm. The main ground system for the station apparatus is also used for the carrier-current telephone ground and no counterpoise is used. The frequency adopted, after a series of tests ranging between 12,500 cycles and 85,000 cycles was 50,000 cycles. This is free from all

outside interference and gives the best combination of signal strength and voice modulation.

The transmission equipment is similar to that installed in several of the high-powered broadcasting stations in some respects, and employs two 250-watt oscillator tubes, two 250-watt modulator tubes and a 50-watt speech amplifier tube. It is appreciated that this is a relatively high-powered transmitter and for all normal conditions of operation such as an amount of power is not necessary. However, communication is more urgently needed during periods of abnormal condition than at any other time and it is then that this excess power is called upon to get the message through.

Calling is accomplished by mounting a standard telephone microphone in the horn of the loud speaker which, when the calling circuit is completed, will oscillate and howl in much the same manner that the ordinary telephone will howl when the receiver is placed against the transmitter. This gives a very loud note whose pitch will depend upon the natural period of oscillation of the diaphragms and which is clearly audible in all parts of the station. Ordinarily, it is not necessary to use the calling system, as the receivers are always in service and the operator near the set so that the loud speaker simply talks at him and he starts up his set and talks back.

The system is arranged for simplex operation and all that is necessary is to operate a small telephone switch which energizes a contactor to connect either the transmitting or receiving set to the antenna, thus permitting talking or listening. Some tests made with a view to establishing the possibility of operating as a duplex system are described further on in the paper.

Normal rating of the 250 watt tubes used is based upon a filament lighting supply of 11 volts and a plate pressure of 2000 volts. With the transmission line in operation and all conditions normal it is possible to obtain an antenna radiation of 6.2 amperes with the tubes operated at rated voltage. This gives a received signal at the other end of the 202 mile transmission line considerably louder than necessary. The receiver is a standard regenerative set using two stages of audio frequency amplification to operate a loud speaker, and speech can be heard all over the power house when maximum amplification is employed. For regular service, therefore, the filament lighting supply on the transmitter is reduced to about 10.4 volts and the plate pressure to 1600 volts, which gives an antenna radiation of approximately 5.0 amperes.

The tubes are extremely sensitive to variation in

filament voltage and it has been found by experience that 10.4 volts is about as low as it is desirable to operate. Below that point it is sometimes difficult to start oscillation and sluggish operation means delay in acknowledging receipt of a message. Communication has been carried on with a radiation as low as 2.5 amperes, but with poorer modulation. With a 5-ampere radiation at the sending station the receivers are set for minimum amplification and no difficulty is experienced in handling messages.

To one unaccustomed to listening to a loud speaker, the messages are often very hard to understand and some difficulty was at first experienced by the operators who had not had previous experience with loud speakers. However, this was easily overcome after a week or so of operation of the phones and it is now rarely necessary to repeat a message. Routine dispatching is carried on more easily with the carrier current telephone than with the wire phone due to absence of inductive interference. A considerable volume of accounting and construction department messages is handled over the carrier current telephone and this gave trouble in some instances when it was necessary to transmit unfamiliar proper names. It usually resulted in spelling and due to the difficulty in distinguishing between certain of the consonants which are similar in sound, this did not solve the problem. The method now generally used is to try the voice once and if any difficulty is experienced the name in question is transmitted by telegraph code. The operators have been supplied with a chart on which the Continental code is printed in large clear letters and those who have not memorized the code simply pick out a letter at a time and transmit it by means of the calling key. This may sound slow but in reality it is quicker and more positive than several voice repetitions of the letters composing the name in question. Naturally more speed is attained by the operators familiar with the code, and without exception all of the operators are taking a very great interest in the carrier current telephone and are practising with the code during the shift between midnight and five o'clock in the morning when other duties are at a minimum. It is desirable that the operators become used to the telegraph code and able to transmit five or ten words a minute because certain forms of line disturbance make voice transmission difficult and still permit of distinguishing the letters of the telegraph code which comes through as a high-pitched note of constant tone, readily distinguished from other noises. It is also possible to transmit the code when abnormal conditions make it difficult to secure sufficient radiation to give good voice modulation.

All operation of the carrier-current telephone to date has been carried on with one of the 220-kv. transmission lines still incomplete. The first work was done with two transmission lines complete from Vaca to Williams, a point about 50 miles north, and

a single line from Williams to Pit, about 150 miles. At Williams the two lines were tied solidly together. The copper for the second line was strung in place between Williams and Cottonwood, about 90 miles, but men were constantly at work upon the line and consequently it was solidly grounded at each tower on which a man was at work. Grounding this parallel line did not affect communication in any manner on the other line.

At present two three-phase circuits are in operation from Vaca to Cottonwood approximately 140 miles with a single circuit from Cottonwood to Pit River approximately 60 miles. The circuits are tied together solidly at Cottonwood and men are now at work on the second circuit between Cottonwood and Pit. A special test was recently made with one three-phase circuit solidly grounded at Vaca and the other circuit clear, both being tied together at Cottonwood, power, of course, being off the lines. No appreciable difference from usual operating conditions was noted in ability to communicate between Pit and Vaca.

Recently one wire on the completed three-phase circuit between Cottonwood and Pit River became grounded due to failure of a piece of insulator-hardware and resultant dropping of the wire on to the tower. This left only two wires completely insulated between Pit and Vaca with a ground on the third, but no difficulty was experienced in carrying on communication.

Communication cannot be carried on with three-phase grounds at either or both ends of the transmission line. Also, all three wires were recently grounded at Hat Creek, about three miles distant from Pit toward Vaca and communication could not be carried on. At least one wire, insulated from ground, between the two points is necessary for successful communication by carrier-current telephone.

When the transmission line is dead and isolated by opening the disconnecting switches at each end of the line considerably more power output from the transmitter is required than when the line is connected to the transformers and energized at 60 cycles. This difference is probably due to the change in transmission line constants by the removal of the reactance of the transformers which in turn cuts down on the current radiated from the antenna. When the transmission line is thus isolated the station operators immediately increase the power output of the carrier-current telephone transmitter to its maximum by raising plate and filament voltages to 2000 and 11 volts respectively. Communication is then carried on as usual and no difficulty is experienced in directing operations.

In order to carry on duplex communication, that is, to be able to send and receive at the same time, it is necessary to employ two antennas, one for the transmitter and one for the receiver. Some tests were recently made to establish the effectiveness of various types of receiving antennas. At Vaca it was possible

to receive messages from Pit River when using a bushing type current transformer on one of the 220-kv. line oil switches as an antenna. The leads from this current transformer are carried in lead covered cable about 300 feet to the substation wall, thence in rubber-covered wire in iron conduit to the switchboard, an additional 40 feet. The receiver was hooked on to one terminal of the line ammeter on the switchboard. Only the reactance of the ammeter coils was between the antenna and ground. The signals received were clear, but weak. It was necessary to use the head phones with all the amplification at hand to bring it in strong enough to understand. Stronger signals were received when using the secondaries of one of the 110-kv. potential transformers on the 110-kv. bus but they were not considered strong enough for use by the operators. As a matter of interest, one test was made using one side of the lighting circuit for an antenna. Very weak signals were heard which might have been brought in strong enough to be understood had a couple of stages of radio frequency amplification been available in addition to the two stages of audio frequency amplification which were employed. This reception was through three power transformers, *i. e.*, the main bank which steps down to 11,000 volts for the synchronous condensers, the station bank stepping from 11,000 to 440 volts and the lighting bank stepping from 440 to 110-220 with the mid point on the secondary grounded.

Finally a separate receiving antenna was strung at Vaca and also at Pit. These antennas were each about 250 feet long and placed in the most convenient temporary location. Excellent reception was obtained and the loud speaker could be operated at full volume from the short auxiliary antenna. The transmitter at Vaca was then lowered in frequency to about 30,000 cycles, with the Pit transmitter remaining at 50,000 cycles. With the Pit receiver tuned to 30,000 cycles it was not possible to transmit at 50,000 cycles while receiving because the transference of power between the sending and receiving antennas was so great as to blanket out the received signals. When duplex operation was tried at Vaca, the transference of power was sufficient to arc across the grid condenser which is a 23-plate variable condenser in the receiver used. It would seem that duplex transmission is not practical with two antennas when using transmitting sets of the power output necessary to successfully talk over a 202-mile transmission line, and accordingly no further tests were undertaken.

During the initial installation of the Pit-Vaca carrier-current telephone several tests were made

between the Vaca-Dixon substation and the Fourth Avenue substation of the Great Western Power Company in Oakland, where a similar carrier-current telephone set is installed. There is no direct transmission line between the two substations. The Great Western feeds the Pacific Gas and Electric Company through a 60-kv. transmission line which is carried for about three miles on the same steel tower line as the 110-kv. transmission line and on the same right of way as the 110-kv. twin circuit Oakland-Big Bend transmission line to which the carrier-current telephone is coupled. The 60-kv. feeder goes into the Ridge substation of the Pacific Gas and Electric Company, and thence on to the Claremont substation. There is a parallel of some three miles or so between the 60-kv. Ridge-Claremont line and the 110-kv. Claremont-Vaca line where the two circuits are on the same right of way. At Claremont the 60-kv. and 110-kv. are tied together through auto-transformers.

Conversation is readily carried on between Fourth Avenue and Vaca, a distance of about 60 miles, and during the initial tests between Pit and Vaca, the Great Western operators were able to listen in and understand what was being said at Pit. It is believed that this is a record for distance for carrier-current telephone transmission, somewhat over 260 miles with no direct transmission lines connecting the last 60 miles to the transmitter.

The Pacific Gas and Electric Company is entirely satisfied with the results of the carrier-current telephone secured to date. Many conditions of operation have been met and the carrier-current telephone has at all times been ready to perform the duties required of it. The principal difficulty to be overcome is that of understanding the loud speaker which is simply a matter of becoming accustomed to the voice as reproduced in a loud speaker horn rather than in a telephone receiver. The operators in general seem to prefer the loud speaker to the head phones, and rely upon it at all times to receive their messages.

As stated before, the volume of traffic over the carrier-current telephone is steadily increasing and plans are already being laid for the installation of additional sets at Pit River Power House No. 3 and Claremont substation. The last named set will be remote-controlled from the dispatcher's office in Oakland and a relatively small investment in apparatus will obviate the necessity of a 260-mile metallic telephone line to handle the operation of plants in the Pit River development, and results achieved to date indicate that it will be equally reliable and a much more quiet phone to talk over.

Carrier-Current Telephony on the High-Voltage Transmission Lines of the Great Western Power Company

BY JOHN A. KOONTZ, Jr.

Great Western Power Co., San Francisco, Calif.

Review of the Subject.—This paper includes a brief description of the power circuits and radio equipment used in the carrier-

current system; the method of calling employed, and use of this system as a trouble detector and recorder of switch operation.

THE reports of successful tests with high-frequency telephony early interested the Great Western Power Company, and experiments were undertaken to determine whether suitable equipment could be obtained for installing carrier-current communication on our 100-kv. circuits. This equipment was later installed at the Dispatcher's office in Oakland, at the Big Bend Power Station and the Caribou Power Station.

The distance from Oakland to Big Bend via the tower line is 153 miles and from Oakland to Caribou 193 miles. Three circuits run from Oakland to Big Bend, twin circuits being carried on one tower line and a third circuit designed for 165 kv., carried on a second tower line. These two tower lines with their three circuits are located on the same 100-foot right of way for 85 miles. The twin circuits stop at the Big Bend Power House and only the 165-kv. circuit extends for the remaining 40 miles to the Caribou Station.

Under present conditions these lines are operated in parallel at the same voltage, and are in general paralleled at Big Bend, Brighton and Oakland. There are a total of nine substations tapping these lines, one of these substations being located on a short branch line.

From this brief description I think it will be readily apparent to one familiar with power carrier-current work that this is an extremely difficult system on which to place carrier-current communication. Radio engineers who are familiar with this line of work estimate that each substation is equivalent to adding at least 10 miles to the length of line and a tap line may add even more. With this in mind it is easy to see that we have an equivalent transmission distance of about 300 miles. These radio engineers acknowledge this to be the most difficult system on which they have as yet worked.

Early experiments readily demonstrated the fact that 50-watt sets were far too small for this network of circuits. 250-watt sets were then installed and it was found that at certain times this was not sufficient power to give proper communication, so these sets were modified at Caribou and the Dispatcher's office, using two 250-watt tubes in the oscillating circuit with one 250-watt modulating tube. This equipment has been in operation for about one year and has given good

service. There have been a few cases of trouble but these have been few and not serious.

This system of communication apparently has many good points in connection with obtaining communication with water power plants which are situated in regions remote from the regular telephone communication. Any single telephone circuit as constructed either by the power or communication companies would be much more susceptible to mountain storms than the rugged tower circuits, and it is practically always the communication circuits that first show distress during severe storms. We were pleased to go through this last winter without a single total interruption in communication between the Dispatcher's Office and our water power stations.

At first an elaborate call bell equipment was planned and a relay was actually developed which worked very satisfactorily, but it was later found that by picking up the transmitter and placing same in the loud speakers, this particular combination would resonate to produce a howl in the loud speaker at the distant end, the frequency of which was much higher pitched than any noises around the power station and was easily detected above the power house noise.

This gave a mode of signaling without adding any additional equipment, and by simply operating the hook switch on the transmitter, code signals could be readily sent. This method of calling has proved quite satisfactory.

Because of our complex circuit arrangement we obtain at times an echoing effect in our receiving. This is possible due to the carrier current flowing along lines that have different characteristics, producing different attenuations, or due to reflection. There is, however, one very peculiar thing about this effect, and that is, often by shifting a substation from one of the twin circuits to the other the effect will be eliminated; and to date we seem to have no reasonable explanation of why this change should eliminate the trouble.

The general equipment consists of a 2000-volt, 3-wire, d-c. generator for producing suitable plate voltage for the tubes, 1000 volts being placed across the 50-watt amplifier tube and 2000 volts across the 250-watt tubes. Filaments are lighted from alternating current with rotary converters provided for supplying this current from the station storage battery

should there be a failure in the a-c. supply at the Dispatcher's office.

The Simplex System of communication is used, it being necessary to operate a double-pole, double-throw switch to change from talking to receiving. The antenna are strung upon the towers at two of the stations, while the Caribou antenna is stretched across the canyon about forty feet from the high-voltage wires. Here, a single $\frac{7}{8}$ -in. steel core aluminum cable 930 feet in length is used, tapped at the center, giving a "T" type aerial. The wire used is the same as used on the tower circuits.

The carrier-current system has several features which undoubtedly will be of interest to the operating power men. First, it is a good detector of poor switch contacts, as the minute a switch is closed a click can be heard on the loud speakers indicating that the switch is closed, and should the contacts continue to arc, a hissing or howling noise will immediately be set up in the loud speakers. In this way, faulty switch contacts have been located and taken out of service before any trouble occurred. In fact, the equipment is so sensitive that at the Dispatcher's office slight inconvenience was experienced for several days from a hissing sound in the loud speaker. This sound was not present at the other stations and it was finally located. A potential fuse on a 60-kv. potential transformer in the station adjoining the Dispatcher's office was partially blown and the current actually jumping a small gap, this arcing causing the disturbance on the receiving equipment.

Arcing grounds on the secondary systems can be instantly detected though they are often hard to locate. Grounds on the 4-kv. system fed through two banks of transformers and the bank of transformers connecting to the 100-kv. system located 80 miles from one of our receiving sets, have been noticed and finally

located. The high-frequency notes are readily detected, yet no normal frequency hum is noticeable in the receiving sets.

From present experience it would seem that this form of high-frequency communication as applied to the power line circuits, is a valuable addition to the communication system. I do not believe that it will in general replace wire lines on long high-voltage systems that necessarily cover considerable territory where public telephone communication would not be accessible for patrolmen or repair crews on maintenance work, but it is of great value in giving a reliable communication channel to the outlying stations for dispatching work, and in most cases can be utilized without very large expenditures for installation or maintenance.

This system is operating on a wave length of 5500 meters. This particular wave length was selected after careful test, as giving about the best transmission and was of suitable length so as to avoid most outside telegraph interference, this placing the station just between two of the high-powered government telegraph stations. The transmission lines make a good antenna for the longer wave lengths—3000 to 20,000 meters, but a very poor one for wave lengths as covered by the amateur or broad casting range.

The amateur operators seem to experience very little interference from our system as now operated. Only when they are situated close to the transmission lines have they reported receiving our signals, and then only at times when other radio stations were not operating. This interference has been greatly reduced by the elimination of accidental harmonics which were present during the experimental stage.

All experimental work and arrangement of equipment in connection with this system was designed and the installation directed by Dr. Leonard F. Fuller.

Mechanical Forces on Busbars Under Short-Circuit Conditions*

C. H. VAN ASPEREN

Associate, A. I. E. E.
Laboratories of the Hydro-Electric Power Commission of Ontario.

WITH the advent of the superpower station, with its concentration of enormous power and possibilities of very large short-circuit currents, the mechanical stresses to which different apparatus, including busbars may be subjected, demand serious consideration.

In the following pages the forces acting on busbars will be considered and an attempt has been made to furnish the designing engineer with a set of simple formulas by means of which he will be able to approximate with sufficient accuracy the magnitude of these forces and their distribution along the busbars. The basis of the permissible approximations has been determined by actual measurements. The combination of these forces when acting in a three-phase system will be analyzed and the characteristic action of the forces at the moment of short-circuit pointed out.

The Problem

In the problem under consideration the electric circuits are supposed to have no iron in the interlinked magnetic field. The busbar system in large stations will in general contain many different configurations and the general calculation will therefore consist of a large number of calculations for the individual configurations. Evidently then the formulas have to be of great simplicity if the labor involved is not to become prohibitive. Also mathematical precision is not required as a number of inaccurately known factors such as strength of materials, temperature, etc. entering into the construction, require the application of more or less arbitrary safety factors. As the mechanical forces acting on bus-bars may have a lever-action on their supports, it will be necessary to know their moments about any given point, requiring the knowledge of the distribution of the forces along the bars.

AVAILABLE METHODS OF CALCULATING MECHANICAL FORCES DUE TO ELECTRIC CURRENTS

Three methods for calculating these forces are known and have been referred to as:

1. The Action at a Distance Method.
2. The Energy Method.
3. A method using the magnetic field intensity at the conductor and the current strength in the conductor. The writer proposes for this the name *Current Field Method*.

The Action at a Distance Method is based upon the assumption that two elements of current can act on

*Awarded the "First Paper Prize" for the year 1922, by the A. I. E. E.

Presented at the Meeting of Toronto Section, A. I. E. E., November 3, 1922.

each other at a distance without an intervening medium¹ and thus significantly neglects the finite velocity of the electromagnetic field. It was used by Ampere in his famous researches on the action of an electric current on another electric current shortly after Oersted's discovery of the action of an electric current on a magnet, a hundred years ago.

The Energy Method, following Maxwell's theory of electromagnetism and taking account of the finite velocity of the electromagnetic field, applies the law of the conservation of energy from which the following general formula can be evolved:

$$\text{Force} = i_1 i_2 \cdot \frac{dL}{dl} \cdot C$$

Where i_1 and i_2 are the currents in one or two electric circuits, L the total inductance of the system and dl a virtual displacement of the part on which the force is to be calculated. C is a constant depending on the units employed.

The Current-Field method is based on a definition of the Unit of Current in the c. g. s. system, viz.

The unit current is that current of which an element of unit length (1 cm.) in the direction of the current, when placed in a magnetic field of unit intensity (1 maxwell = 1 line per sq. cm.) is acted upon by a mechanical force of 1 dyne at right angles to the direction of the current.

The external magnetic field due to a current in a cylindrical conductor is the same as if this current were concentrated at the axis of the cylinder or a so-called line current.

The formulas for the inductance used in the energy method and those of the magnetic force or field intensity used in the Current-Field Method are derived from the same fundamental formula, which is as follows:

The magnetic force or field strength at a point P , outside a line current i due to an element length of current dy and distant a length c from dy is equal to

$$i \cdot \frac{dy}{C^2} \sin \theta$$

Where θ is the angle between the direction of c and the line current. The magnetic force or the direction of the field is at right angles to the plane containing the line current and the point P .

The difference between the energy method and the current-field method lies in the fact that the former

1. It is interesting to observe that the newest theory, Einstein's Theory of Relativity, again seems to dispense with the necessity of an intervening ether of space.

uses the total magnetic field interlinked with the electric circuit or system of circuits, and only indirectly, through the geometrical relation of dl to the configuration of the system, takes in consideration the unequal distribution of the magnetic field intensity; while the latter method does so directly by using the algebraic sum of the field intensities due to the different component parts of the system.

As in general these parts do not contribute in equal amounts, the Current-Field method offers the greater facilities for approximation.

THE LITERATURE ON THE SUBJECT

The writer to whom the task was allotted to supply a set of simple formulas for the calculation of the mechanical forces on busbars, specially those acting on taps at right angles to them, found the existing literature on this subject very meagre from his point of view. Such as was available to him treated special cases while the generalizations in the standard text books seemed to be more of an academic than practical use. He therefore endeavored to develop such simple formulas by one of the three methods mentioned above, but did not succeed as he had nothing to go by to determine the amount of approximations which would be warranted, or assumptions that could be made in view of the desired result.

Moreover one of the writers² on the subject who used the energy method declared all other methods as fundamentally wrong and leading to erroneous results. At the time his arguments seemed to carry much weight as the writer had not then realized the common base of the energy and Field-Current methods as explained before. As for the Action at a Distance Method, Mr. H. B. Dwight has since shown this also to be mathematically correct.³

MEASUREMENTS OF MECHANICAL FORCES

It was therefore decided to make some actual measurements and through them either to determine the allowable approximations or assumptions or to evolve empirical formulas or curves which might facilitate the determination of these forces. These measurements were made at the Laboratories of the Hydro-Electric Power Commission of Ontario.

As the available current strength was limited, the forces to be measured would be very small. This introduced great difficulties as we were not equipped with the apparatus required for measurements which more properly belonged to the domain of a Physics laboratory. The equipment had therefore to be especially designed and constructed. After a large amount of preliminary work and trials, the following apparatus was set up.

2. See Mathematical Analysis of the Mechanical Forces on Switches and Busbars, by L. B. W. Jolley, *the Electrician*, (London), Dec. 3, 1920, p. 646, Dec. 10, 1920, p. 676.

3. See Magnetic Force in Disconnecting Switches by H. B. Dwight, *The Electrician* (London), Sept. 2, 1921, p. 291.

A short piece of flat copper bar 1 inch by $3/16$ inch and exactly 10 centimeters long was joined with insulating materials to a rigid brass rod provided with a steel cross-piece about $7\frac{1}{2}$ centimeters long with knife edges at the ends. The latter were supported in agate cups, the whole thus forming a pendulum. The little bar made an angle of 60 deg. with the brass rod and was provided at its upper end with a brass cup in the form of a scoop for holding mercury. A number of movable weights at different points in this system allowed the regulation of the position of the center of gravity. Two short copper bars of the same cross-section as the swinging bar were firmly fixed on a wooden support and in line at each end with the swinging bar but separated by a space of 3 millimeters from it.

The lower fixed bar had at its upper end a scoop similar to that on the swinging bar. The scoops were filled with mercury (Fig. A). Bars and scoops were insulated with paints and varnishes except the nickel plated ends (cross-sections) of the bars; thus forcing the

FIG. A

MEASUREMENTS OF MECHANICAL FORCES
SKETCH OF APPARATUS AND DIAGRAMS OF CIRCUITS

current through the mercury to follow practically the same path as if fixed and moving bars were one solid bar and the distortion of the magnetic field at the ends of the moving bar could be considered negligible. In front of and in a vertical plane passing through the center of the swinging bar a known weight was hung by a fine silk thread. This thread was suspended from a support attached to a $1\frac{1}{2}$ -inch aluminum tube fixed with an articulated joint to a heavy piece of wood permitting a movement parallel to the plane of swing of the pendulum. The $1\frac{1}{2}$ -inch aluminum tube was connected to a micrometer screw on a wooden support by means of a $\frac{1}{4}$ -inch aluminum tube about 6 feet long. On the front of the brass rod of the pendulum and above the knife edges was fixed a plane mirror. Underneath the micrometer was fixed, on the same support, a telescope with scale. The different dimensions and distances of the set-up gave a lateral movement of the swinging bar of 0.000346 inches for one

scale division. After experience was gained it was perfectly possible to distinguish a movement of one-half the thickness of a division line or about 1/10 of the above amount. The swinging bar was connected

FIG. 1

horizontally to the silk thread by a fine bronze wire of negligible weight.

By moving the support of the known weight by means of the micrometer a determinate force could be applied to the bronze wire to counteract the forces on the bar

FIG. 2

due to the current. The zero method was used throughout these experiments. Figs. 1, 2 and 3 show the described apparatus. The first measurements were made on the side of a rectangle (Fig. 1). In order to avoid as much as possible the influence of possible

current distribution in the conductors it was necessary to make the dimensions of the rectangle large, resulting in very small forces to be measured. The circuit was completed as shown in Fig. B. By moving the movable cross bars in steps along the inclined bars (keeping their distance apart constant), the forces on one side of the rectangle were measured on 10-cm. sections. The current employed was 1000 amperes, 60 cycles throughout.

Great difficulties of a mechanical and physical nature were encountered. They were mainly due to the unavoidable use of a liquid conductor (mercury) which necessitated the limiting of the possible lateral movement of the bar to a half scale division on either side of the zero line. This was done by means of adjustable stops.

The vertical circuit, also visible in Fig. 1 was used for a preliminary adjustment of the center of gravity of the pendulum. As it was not possible to adjust

FIG. 3

so accurately that a vertical force acting on the bar would have no effect in shifting the center of gravity, the final adjustment of the zero point had to be made by aligning the movable and fixed bars by means of a brass gage.

The forces so measured in a preliminary series of measurements, after correction for the constants of the apparatus were plotted, and it was found that the probable curve for the forces, near the corner of the rectangle came closely to $xy = \text{constant}$, where x is the distance from the corner and y the force. This led to the following reasoning. The percentage of the total force near the corner, due to the current in the parallel conductor should be comparatively small, and therefore the forces due to the current at right angle, and close to the corner should give a curve closely resembling a hyperbola.

The magnetic field intensity at a point P at a distance d from a line current of length l is

$$H = \frac{i}{d} \cdot \left(\frac{a}{\sqrt{a^2 + d^2}} \pm \frac{l-a}{\sqrt{(l-a)^2 + d^2}} \right)$$

lines per square cm.

We will refer to this formula as the Fundamental Formula.⁴

MEASUREMENTS OF MECHANICAL FORCES ON ELECTRICAL CONDUCTORS

⊙ Measurements on one half of side a of rectangle $a, b, c, d = 10 \text{ ft.} \times 6 \text{ ft.}$ (Fig. 1)

† Measurements along a of right angle d, a

A Calculated curve of Forces on a , due to current in d (Fig. 1-2)

A' Calculated curve of Forces on a , due to current in b . (Fig. 1)

B Calculated curve of Forces on a , due to current in c (Fig. 1)

C Calculated curve of total Forces on a (Fig. 1). Current employed 1000 amperes 60 cycles.

If P is situated at right angles to one of the ends of l , we get:

$$H = \frac{i}{d} \cdot \frac{l}{\sqrt{l^2 + d^2}}$$

If d is very small compared with l , we have approximately $H = i/d$, or if i is constant: $H \cdot d = \text{constant}$.

As the mechanical force with constant current is proportional to H , we have $F \cdot d = \text{constant}$ and plotted for different values of d would give a hyperbola.

From this we derived the assumption that the formulas for line-currents would express the values of the mechanical forces with sufficient approximation for our purpose subject to confirmation by actual measure-

⁴ See Bulletin of the Bureau of Standards, Vol. 4, p. 303 and p. 309.

ment. Consequently, with the aid of the fundamental formula, curves were plotted for the mechanical forces on one side of the rectangle. These curves are given on Curve Sheet (C). After making a few additional refinements in the apparatus a new set of measurements was made.

The curve of the total force C was divided into parts

by erecting the ordinates at every 10 cm. of abscissa corresponding to the successive positions of the swinging bar and each such 10 cm. divided into a sufficiently large number of equal parts to allow for the assumption that the curve between the ordinates on these divisions could be considered a straight line. By an approximate integration the point was then found for each 10 cm. where the total force on that 10 cm. could be applied to give the same total moment about a given point, or in other words, where the force per unit length would be equal to the total force on 10 cm. divided by 10.

The corrected values of the measured forces divided by 10 were then plotted at these points of application and are marked ⊙.

It will be seen that with the exception of points

between 40 and 70 cm. the measured and calculated forces agree very well considering the difficulty of the measurements of such small forces. (From 18 to 1.60 grams.).

An investigation into the disturbing factors causing the larger deviations between 40 and 70 cm. pointed to the following two probable sources: 1st, shifting of zero point through expansion of the cross bars and

FIG. 4

bending of $\frac{1}{4}$ inch aluminum tube. 2nd, the difficulty of alining the swinging bar by means of a gage.

The first cause was remedied by the insertion in the circuit of two additional mercury cups, (Fig. 4), Fig. (C). The $\frac{1}{4}$ -inch aluminum tube was replaced by a fine steel piano wire and counterweight. The second one by arranging the circuit as in Fig. (D). Fig. 4 also gives a partial view of this circuit.

It was now possible by alternately switching the

FIG. C

FIG. D

current through the two possible circuits to find this zero point by electrical means as the upward force on the swinging bar was the same in both cases.

It will be seen that in this circuit the influence of the parallel conductor has been eliminated and that only the force due to the currents in the movable and fixed cross conductors came into play. The force due to the fixed cross conductor, which was of course, the same for each measurement, was calculated by the

formula and added to the measured force and the point of application taken the same as for curve C. The slight error so introduced was deemed to be negligible as Curve A (the force due to a current at right angles) has very closely the same form as C. The points so obtained are marked + and it will be seen that the agreement between the calculated and measured forces is very close indeed. The additional mercury cups did not permit the measurement of points closer to the corner than on the section 20 to 30 centimeters.

The outstanding result is the close agreement of the measured and calculated forces close to the corner where unequal current distribution might be supposed to have the largest influence and especially is this true for the first point which is shown on the enlarged curve in the right hand upper corner of curve sheet C, which was verified by two separate series of measurements, one of 6 giving an average of 18.06 grams (uncorrected) and another of 5 giving 18.00 grams. The latter was made with a slightly different weight on the silk thread as the weight was immersed in oil to dampen the oscillations.

As regards forces on busbars we are mainly concerned with their moment and we find that for the moment of

FIG. G

the force on a length of 4 times the width of the bar, counting from a point less than the width of the bar from the corner of the center lines, we may with sufficient approximation assume line currents. As to possible shearing forces due to large forces close to the corner, it is very probable that stresses due to uneven temperature distribution during short circuit in the corner where the bars are bolted together, will exceed in magnitude any forces due to the short-circuit currents themselves.

Calculation of Mechanical Forces

From the fundamental formula for the field strength at a point in the space surrounding an electric current I_1 , the formula for the mechanical force in dynes on an element of electric current I_2 at that point is found by multiplying H by I_2 , where I_1 and I_2 are expressed in abamperes and all dimensions are in centimeters. This force is acting at right angle to the current. With the application of proper conversion factors, this force can be expressed in any required units. By considering this force on an element of the current, the force on a determinate length of current can be found

of the right angle and cross piece are equal, and the currents in them in phase with each other. The results have been given in the curves on Curve Sheet (D). The current assumed is 100,000 amperes. The forces at half the width of the bar from the corner of the right angle and at the joints of the cross piece have been calculated by the approximate method by dividing the current sheets into 8 parallel and equal currents. As this force is practically independent of the length of the conductors this maximum force may be taken constant for such a conductor, it depending only on the

CURVE SHEET A—SINGLE-PHASE SHORT CIRCUIT FORCE ON PARALLEL CONDUCTORS DUE TO CURRENT IN RETURN CIRCUIT

cross-section of the conductor. Further examples of numerical calculations will be found in Appendix A.

With a direct current in the conductors the force on them will be constant. With an alternating-current measured in r. m. s. value the force will be the average or equivalent steady force but the maximum force will have twice this value if the current is sinusoidal, *i. e.*, having a peak value = r. m. s. value $\sqrt{2}$. This maximum force acts twice during one cycle.

COMBINATION OF FORCES IN THREE-PHASE CIRCUITS UNDER SHORT-CIRCUIT CONDITIONS

Single-Phase Short Circuit. In this case the current

FIG. H

in the third conductor is negligible and the only forces to be considered are those of the remaining circuit and its return circuit, the two currents having a phase difference of 180 deg. This acts with double frequency. (See Curve Sheet A.)

Three-Phase Short Circuit. The phase angle of the short-circuit currents will remain at 120 deg. Consider three parallel conductors Nos. 1, 2 and 3, situated in the same plane, No. 2 being midway between 1 and 3 and let the force due to unit current in "1" on unit current in "2" be represented by f_{1-2} etc.

Let the phase rotation of the current be 1, 2, 3, and

the impedance of the three short-circuited branches be equal, then,

If I_m is the maximum current, the currents in 1, 2, 3, at any instant are:

$$I_m \sin \varphi, \quad I_m \sin (\varphi - 120^\circ), \quad I_m \sin (\varphi - 240^\circ)$$

On account of symmetry we have only to consider the force exerted on "1" by currents in "2" and "3" and on "2" by currents in "1" and "3."

Then the force exerted at any one instant on conductor "1" is:

$$F_1 = f_{2-1} \{ I_m \sin \varphi \cdot I_m \sin (\varphi - 120^\circ) \} + f_{3-1} \{ I_m \sin \varphi \cdot I_m \sin (\varphi - 240^\circ) \}$$

or

$$F_1 = I_m^2 \cdot f_{2-1} \cdot \sin \varphi \{ \sin (\varphi - 120^\circ) + p \sin (\varphi - 240^\circ) \} \quad (16)$$

$$\text{where } p = f_{3-1}/f_{2-1} = < 1.$$

$$\text{Putting } \frac{dF_1}{d\varphi} = 0 \text{ we get}$$

$$\tan 2\varphi = - \frac{\sqrt{3}(1-p)}{1+p} \quad (17)$$

The maximum and minimum value of F_1 may now be found by substituting the value of φ from (17) in (16). They are distinguished by the relation

$$\frac{d^2 F_1}{d\varphi^2} = I_m^2 \cdot f_{2-1} \{ -(1+p) \cos 2\varphi + \sqrt{3} \cdot (1-p) \sin 2\varphi \} \quad (18)$$

which indicates that

A maximum occurs with φ in 2nd and 4th quadrants

A minimum occurs with φ in 1st and 3rd quadrants

For the purpose of graphic representation formula (16) may be transformed to

$$F_1 = \frac{I_m^2}{4} \cdot f_{2-1} \left\{ -(1+p) - 2\sqrt{1-p+p^2} \cdot \sin \left[2\varphi - \tan^{-1} \frac{1+p}{(1-p)\sqrt{3}} \right] \right\} \quad (19)$$

showing that the force consists of a constant force superimposed on a sinusoidal force of double the frequency of the currents.

If the phase rotation of the currents is changed to "1, 3, 2" we find in the same way

$$F_1' = \frac{I_m^2}{4} \cdot f_{2-1} \left\{ -(1+p) + 2\sqrt{1-p+p^2} \cdot \sin \left[2\varphi + \tan^{-1} \frac{1+p}{(1-p)\sqrt{3}} \right] \right\} \quad (20)$$

also we get

$$F_2 = \frac{I_m^2}{4} \cdot f_{2-1} \{ \pm 2\sqrt{3} \cdot \sin 2\varphi \} \quad (21)$$

Because for the middle conductor $p = -1$.

The variations of these forces are graphically represented for $p = 1/2$ and the duration of one cycle on Curve Sheet (B)

PHASE DIFFERENCES OF THE FORCES ALONG PARALLEL CONDUCTORS

From formula (19) and (20) it will be seen that the phase difference between the force and the current for the outside conductors of the three-phase depends upon the ratio p of the two forces. The curves for A_1 on Curve Sheet I show that for parallel conductors at different distances from a third conductor this ratio changes from the center towards the ends of the conductors. The forces acting on such conductors at different points will therefore not reach their maximums and minimums at the same instant.

CURVE SHEET B

Three-Phase short circuit. Forces on 3 parallel conductors in same plane. No. 2 midway between 1 and 2.

F : phase rotation 1, 2, 3
 F' : " " 1, 3, 2
 p assumed = $1/2$

COMBINATION OF FORCES

In combining several forces acting in different directions it will thus be necessary to take into account the above phase differences. It follows that the resultant forces will change in direction as well as magnitude during a cycle, while the maximum will not occur at the same time on different points along the conductors. Therefore the moment of the Resultant Force will change in magnitude and direction during the cycle.

VIBRATION IN BUSBARS

Under the influence of these double-frequency forces the conductors will have a tendency to vibrate. That this vibration may reach considerable magnitude was shown by an experiment made at these laboratories. Two busbars $3/8$ -inch by $1/4$ -inch were placed side by side with 1 inch spacers at the supports and firmly clamped. The bars formed a loop. A current of 300 amperes, 25 cycles was sent through the loop and the amplitude of the vibrations measured.

By changing the distance between supports a series of amplitude was measured and are shown in the curve on Curve Sheet E.

It will be seen that at the resonance spacing of 26

inches the amplitude experienced a very sudden increase being 70 times the deflection at 18-inch spacing.

The striking analogy between mechanical and electrical vibration can be seen by a comparison of this curve with the well known "tuning" curves of wave meters. In both cases the ordinates are functions of the square of the currents and the abscissa functions of frequency. As the external resistance to vibration of the bar is but the air resistance and therefore low, the mechanical tuning will be sharp.

For such cases where vibration can not practically be avoided the calculation of the stresses in the busbars and supports becomes much more complicated as we have to use the maximum forces and their change in time, i. e., energy impulses.

Fortunately it will nearly always be possible to space the supports at such a distance as to reduce vibration to practical negligible values. It may however have a bearing on the fatigue of the materials used.

IMPULSES DUE TO SHORT-CIRCUIT CURRENTS

In our measurements a decided "Kick" of the movable bar was observed every time at the moment of closing the circuit. This could only be ascribed to the small impedance of our circuit allowing the current to suddenly build up to its maximum value, i. e., the current had a steep wave front. As however, this repeated closing of the switch might have occurred at any time during a cycle it is not quite clear why the bar was invariably kicked out far beyond its steady position due to the average current.

It is well known that if a weight is suddenly applied to a bar which is prevented from bending the com-

CURVE SHEET E

Vibration of Busbar on 25-cycle symmetrical current 300 amperes. Busbars $3/8$ in. by $1/4$ in. side by side. One-in. spacers at points of support.

pression of the bar and therefore the stresses in the bar can be expressed by

$$y = e(1 + \sqrt{1 + 2h/e})$$

where y = maximum compression produced

h = height from which weight drops or the distance through which the force of gravitation acts on the weight before striking the bar.

e = Compression due to the static weight

If $h = 0$, then $y = 2e$.

From which it follows that an instantaneously applied force without kinetic energy will cause a stress double the stress produced by the same steady force.

It is difficult to conceive of a magnetic field or an electric current to have mass, although the latter is now generally regarded as an actual flow of electrons which each have an exceedingly small mass due to their electric charge. We are used to talking about electric impulses but it is difficult to conceive the mechanism which transforms them into mechanical impulses. That they must do so follows however from the law of the conservation of energy.

We know that the electric energy consumed by the induced e. m. f. equals the mechanical energy produced plus the increase in stored magnetic energy.

If then the e. m. f. is induced wholly impulsively, *i. e.*, starting from zero, the increase of stored magnetic energy (when no iron is present) is also wholly impulsive and from the foregoing equation the mechanical energy produced must be impulsive.

An impulse can not be measured in pounds but must be expressed in foot-pounds and the time element has to be brought in. The magnitude of the stresses produced in the bars will thus depend upon the steepness of the wave front of the short-circuit current.

From the above formula for the stresses due to impulses it will be seen that they may reach very high values depending upon the value h/e .

With $h = 4e$, the stresses will be 4 times the stresses due to the static force with $h = 24e$, 8 times as much, etc. Unfortunately our measuring apparatus could not be used to measure these stresses and until more is known of the real constitution of electric currents and magnetic fields we have to assume no mass for them and to accept for these stresses a value twice the stress created by the force due to the maximum value of the short-circuit current. This seems safe enough as in large stations enough impedance is put into the circuit to reduce considerably the steepness of the short current wave front.

CONCLUSIONS

To sum up the results we may say that these measurements have proved that for practical engineering purposes we may assume line currents in the busbars even very close to the corners of right angle taps, a fact which the writer thinks could not be previously assumed, and that consequently we were able to derive some very simple formulas and methods for the calculation of the mechanical forces on busbars, which formulas may also be of use in checking the mechanical strength and construction of electrical apparatus and specially of the leading-in conductors.

In addition to a bibliography in Appendix A will be found an example of calculations and in Appendix B are given the mathematical derivations of the formulas.

The writer wishes to acknowledge his indebtedness

to the engineers of the laboratories of the Hydro-Electric Power Commission, who one and all were always ready with valuable advice and suggestions for overcoming the considerable difficulties encountered in these measurements; to Mr. R. Gemmell who built and erected the apparatus and to Mr. A. E. Frampton who assisted in taking the measurements.

Appendix A

PARALLEL CONDUCTORS

FIG. I

FOR POINTS BETWEEN PERPENDICULAR PLANES AT THE ENDS OF CONDUCTOR l

FIG. II

FOR POINTS OUTSIDE PERPENDICULAR PLANES AT THE ENDS OF CONDUCTOR l

I_1, I_2 currents in amperes

$$a/l = K \quad d/l = n$$

Force at a point P .

$$F_P = \frac{I_1 I_2}{d} \left[\frac{K_1}{\sqrt{K^2 + n^2}} + \frac{1 - K}{\sqrt{(1 - K)^2 + n^2}} \right] \left\{ \begin{array}{l} 1.02 \times 10^{-5} \text{ grams per cm.} \\ d \text{ in cm.} \\ 2.248 \times 10^{-8} \text{ lbs. per inch} \\ d \text{ in inches} \end{array} \right\} \quad (1)$$

For case of Fig. 1

$$F_P = \frac{I_1 I_2}{d \text{ (cm./inches)}} \times A_1 \times \left\{ \begin{array}{l} 1.02 \times 10^{-5} \text{ grams per cm.} \\ 2.248 \times 10^{-8} \text{ lbs. per inch} \end{array} \right\} \quad (1a)$$

For case of Fig. 2

$$F_P = \frac{I_1 I_2}{d \text{ (cm./inches)}} \times A_2 \times \left\{ \begin{array}{l} 1.02 \times 10^{-5} \text{ grams per cm.} \\ 2.248 \times 10^{-8} \text{ lbs. per inch} \end{array} \right\} \quad (1b)$$

The values of A_1 and A_2 may be scaled from the curves of Curve Sheets I and II.

If the currents are in the same direction F_P is positive and is an attraction, if in opposite direction F_P is negative and is a repulsion.

The force is at right-angle to the current at the point and in the plane containing l and P .

The force on a section $P_1 - P_2$ is:

$$F_{P_1-P_2} = \frac{I_1 I_2}{n} \left[\sqrt{K^2 + n^2} - \sqrt{(1 - K)^2 + n^2} \right] \left\{ \begin{array}{l} 1.02 \times 10^{-5} \text{ grams} \\ 2.248 \times 10^{-8} \text{ lbs.} \end{array} \right\} \quad (2)$$

$$F_{P_1-P_2} = I_1 I_2 \times A_3 \left[\begin{matrix} 1.02 \times 10^{-5} \text{ grams} \\ 2.248 \times 10^{-8} \text{ lbs.} \end{matrix} \right] \quad (2a)$$

CURVE SHEET I—VALUES OF A_1 OF FORMULA (1.a)CURVE SHEET II—VALUES OF A_2 OF FORMULA (1.b)CURVE SHEET III—VALUES OF A_3 OF FORMULA (2A)

The values of A_3 may be scaled from the curves of Curve Sheet III.

The moment of the force $F_{P_1-P_2}$ about the point O is given by

$$M_{O/P_1-P_2} = I_1 I_2 \times \frac{l}{2} \left[\begin{aligned} & K/n \cdot \sqrt{K^2 + n^2} \\ & - \frac{1+K}{n} \cdot \sqrt{(1-K)^2 + n^2} \\ & - 2.303 n \{ \log_{10} (K + \sqrt{K^2 + n^2}) \\ & + \log_{10} ((1-K) + \sqrt{(1-K)^2 + n^2}) \} \end{aligned} \right] \left[\begin{matrix} 1.02 \times 10^{-5} \text{ grams-cm.} \\ l \text{ in cm.} \\ 2.248 \times 10^{-8} \text{ inch-pounds} \\ l \text{ in inches} \end{matrix} \right] \quad (3)$$

The moment of $F_{P_1-P_2}$ about any point of the conductor or its extension may also be found by dividing the proper curve (I or II) (or interpolated curve) in such number of parts that each part can be treated as a straight line. The moments of the forces of each part of the conductor can then be found by the method of approximate integration.

Note. Formula (1) can be written

$$F_P = \frac{I_1 I_2}{d} \left[\begin{aligned} & \frac{1}{\sqrt{1 + (n/K)^2}} \\ & \pm \frac{1}{\sqrt{1 + \left[\frac{n}{K-1} \right]^2}} \end{aligned} \right] \left[\begin{matrix} 1.02 \times 10^{-5} \text{ grams per cm.} \\ d \text{ in cm.} \\ 2.248 \times 10^{-8} \text{ lbs. per inch} \\ d \text{ in inches} \end{matrix} \right] \quad (1c)$$

The value of each term under the brackets may then be found from curve B_1 substituting n/K and

$$\frac{n}{K-1} \text{ for } n. \quad \pm = K \lesssim 1.$$

If two conductors of rectangular cross-section ($h \times w$) and of length l are spaced very close together such as the bars of a built-up busbar, the mechanical force acting between them, may be computed by dividing each conductor into an equal number of strips of equal width, for instance, a_1, b_1, c_1 and a_2, b_2, c_2 . If n is the number of strips the current in each strip is, if I_1 and I_2 are the currents in the bars I_1/n and I_2/n respectively, the total force or its distribution can be calculated by taking the algebraic sum of the forces acting between the different strips of one bar and the strips of the other bar with the aid of formulas (1) to

FIG. J

(3), replacing $I_1 I_2$ by $\frac{I_1 I_2}{n^2}$ and taking for d the distance of the centre lines of the strips under consideration.

CONDUCTORS AT RIGHT-ANGLES

FIG. K

The Force at a point P is:

$$F_P = \frac{I_1 I_2}{d} \left[\frac{1}{\sqrt{n^2 + 1}} \right] \times \begin{cases} 1.02 \times 10^{-5} \text{ grams per cm. } (d \text{ in cm.}) \\ 2.248 \times 10^{-8} \text{ lbs. per inch } (d \text{ in inches}) \end{cases} \quad (4)$$

or

$$F_P = \frac{I_1 I_2}{d \text{ cm./inches}} \times B_1 \times \begin{cases} 1.02 \times 10^{-5} \text{ grams. per cm.} \\ 2.248 \times 10^{-8} \text{ lbs. per inch} \end{cases} \quad (4a)$$

The force on a section $P_1 - P_2$ is:

$$F_{P_1-P_2} = I_1 I_2 [\log_{10} (\sqrt{n^2 + 1} - 1) - \log_{10} \frac{n_2}{n_1}] \times \begin{cases} 2.35 \times 10^{-5} \text{ grams} \\ 5.177 \times 10^{-8} \text{ lbs.} \end{cases} \quad (5)$$

or

$$F_{P_1-P_2} = I_1 \times I_2 \times B_2 \times \begin{cases} 2.35 \times 10^{-5} \text{ grams} \\ 5.177 \times 10^{-8} \text{ lbs.} \end{cases} \quad (5a)$$

The moment of $F_{P_1-P_2}$ about point O is:

$$M_{O/P_1-P_2} = I_1 \times I_2 \times l [\log_{10} (n + \sqrt{n^2 + 1})] \times \begin{cases} 2.35 \times 10^{-5} \text{ grams-cm. } (l \text{ in cm.}) \\ 5.177 \times 10^{-8} \text{ foot-pounds } (l \text{ in feet}) \end{cases} \quad (6)$$

OR

$$M_{O/P_1-P_2} = I_1 \times I_2 \times l_{\text{cm./feet}} \times B_3 \times \begin{cases} 2.35 \times 10^{-5} \text{ gram-cm.} \\ 5.177 \times 10^{-8} \text{ foot-pounds} \end{cases} \quad (6a)$$

CURVE SHEET IV

Values of B_1 formula (4. a)

B_2 " (5. a)

B_3 " (6. a)

Note: The values of B_2 represent the logarithm of a quotient and the curve has been drawn in 3 parts having respectively the characteristic 1, 2 and 3. The ordinates of the curves represent the mantissas.

The values of B_1, B_2 and B_3 may be scaled from the curves on curve-sheet IV.

If it is necessary, for greater accuracy, to take in account the current distribution in flat bars, the computation can be performed in a similar way as outlined for parallel bars by dividing the bars into strips. Or

FIG. 5

they may be calculated by formula (7a) or (7b) developed by Mr. H. B. Dwight.

Note. In these formulas the assumption has been made that the conductor l is round and the current I_1 thus may be considered concentrated at the centre of the bar.

The force on m is:

when $m < l$

$$F_m = I_1 \times I_2 \left[2.303 \log_{10} \left(\frac{2m}{h_1} \right) - 1/4 m^2/l^2 + 1/16 h_1^2/l^2 + 3/32 m^4/l^4 - 1/16 \frac{m^2 h_2^2}{l^4} + \dots \right] \left\{ \begin{array}{l} 1.02 \times 10^{-5} \text{ grams} \\ 2.248 \times 10^{-8} \text{ lbs.} \end{array} \right\} \quad (7a)$$

when $m > l$

$$F_m = I_1 \times I_2 \left[2.303 \log_{10} \left(\frac{4l}{h_1} \right) - l/m - 1/24 h_2^2/l^2 + 1/16 h_1^2/l^2 + 1/6 l^3/m^3 + 1/24 \frac{l h_2^2}{m^3} - 3/40 l^5/m^5 - 1/16 \frac{l^3 h_2^2}{m^5} + \dots \right] \left\{ \begin{array}{l} 1.02 \times 10^{-5} \text{ grams} \\ 2.248 \times 10^{-8} \text{ lbs.} \end{array} \right\} \quad (7b)$$

The force on a section $P_1 - P_2$ can be found by

$$F_{P_1-P_2} = F_{m2} - F_{m1}$$

The moment of the force on any part of the bar about any point in the plane of the couple may then be found from the curve as explained under parallel bars.

between flat conductors close together the same procedure can be followed as indicated under "Parallel Conductors."

The force at a point P is: (Fig. 10).

$$F_P = \frac{I^2}{m \text{ cm./inches}} \left[\frac{1.414 + v}{\sqrt{v^2 + 1.414v + 1}} - 1 \right] \left\{ \begin{array}{l} 1.02 \times 10^{-5} \text{ grams per cm.} \\ 2.248 \times 10^{-8} \text{ lbs. per inch} \end{array} \right\} \quad (8)$$

or

$$F_P = \frac{I^2}{m \text{ cm./inches}} \times C_1 \left\{ \begin{array}{l} 1.02 \times 10^{-5} \text{ grams per cm.} \\ 2.248 \times 10^{-8} \text{ lbs. per inch} \end{array} \right\} \quad (8a)$$

The force on a section $P_1 - P_2$ is:

$$F_{P_1-P_2} = I^2 \left[2.303 \log_{10} (2v + \sqrt{2}) + 2 \sqrt{v^2 + v\sqrt{2} + 1} + 1.795 \log_{10} v + 0.98 - 3.26 \log_{10} (2 \sqrt{v^2 + v\sqrt{2} + 1} + v\sqrt{2}) + 2 \right]_{v_1}^{v_2} \left\{ \begin{array}{l} 1.02 \times 10^{-5} \text{ grams} \\ 2.248 \times 10^{-8} \text{ lbs.} \end{array} \right\} \quad (9)$$

or

$$F_{P_1-P_2} = I^2 \times C_2 \left\{ \begin{array}{l} 1.02 \times 10^{-5} \text{ grams} \\ 2.248 \times 10^{-8} \text{ lbs.} \end{array} \right\} \quad (9a)$$

The Moment about O is:

$$M_{O/P_1-P_2} = I^2 l_{cm./feet} \times \left[\sqrt{v^2 + v\sqrt{2} + 1} - v + 1.63 \log_{10} (2v + \sqrt{2}) + 2 \sqrt{v^2 + v\sqrt{2} + 1} \right]_{v_1}^{v_2} \times \left\{ \begin{array}{l} 1.02 \times 10^{-5} \text{ gram-centimeter} \\ 2.248 \times 10^{-8} \text{ foot-pounds} \end{array} \right\} \quad (10)$$

OR

$$M_{O/P_1-P_2} = I^2 \times l_{cm./feet} \times C_3 \left\{ \begin{array}{l} 1.02 \times 10^{-5} \text{ gram-centimeter} \\ 2.248 \times 10^{-8} \text{ foot-pounds} \end{array} \right\} \quad (10a)$$

The values of C_1 , C_2 , C_3 may be scaled from curves on Curve-Sheet No. V.

CURVE SHEET V
Values of C_1 formula (8.a)
 C_2 " (9.a)
 C_3 " (10.a)

90 DEG. CIRCULAR BEND

FIG. L

I = current in amperes
 $l/r = p$
 $m/r = q$
 r supposed large compared with width of conductor

The force at P due to the circular current is:

$$F_c = \frac{I^2}{4r} \left[\frac{\sin \theta \times \sqrt{2}}{(1 - \cos \theta) \sqrt{1 - \cos \theta}} + \frac{\cos \theta \times \sqrt{2}}{(1 - \sin \theta) \sqrt{1 - \sin \theta}} - 2.303 \log_{10} \tan. \theta/4 + 2.303 \log_{10} \left[\frac{\cos \theta + \sqrt{2} \times \sqrt{1 - \sin \theta}}{1 - \sin \theta} \right] \right] \times \left\{ \begin{array}{l} 1.02 \times 10^{-5} \text{ grams per cm.} \\ r \text{ in cm.} \\ 2.248 \times 10^{-8} \text{ lbs. per inch} \\ r \text{ in inches} \end{array} \right\} \quad (11)$$

This force acts in the direction of the radius at P and away from the centre of the circle.

The force due to currents in l and m are respectively

when $\frac{l}{r} = p$, $\frac{m}{r} = q$

$$F_{lcm, \text{inches}} = \frac{I^2}{r(1 - \sin \theta)} \times \left[\frac{p + \cos \theta}{\sqrt{(1 - \sin \theta)^2 + (p + \cos \theta)^2}} - \frac{\cos \theta}{\sqrt{(1 - \sin \theta)^2 + \cos^2 \theta}} \right] \times \left\{ \begin{array}{l} 1.02 \times 10^{-5} \text{ grams per cm.} \\ 2.248 \times 10^{-8} \text{ lbs. per inch} \end{array} \right\} \quad (12)$$

$$F_{m \text{ cm./inches}} = \frac{I^2}{r(1 - \cos \theta)} \times \left[\frac{q + \sin \theta}{\sqrt{(1 - \cos \theta)^2 + (q + \sin \theta)^2}} - \frac{\sin \theta}{\sqrt{(1 - \cos \theta)^2 + \sin^2 \theta}} \right] \times \left\{ \begin{array}{l} 1.02 \times 10^{-5} \text{ grams per cm.} \\ 2.248 \times 10^{-8} \text{ lbs. per inch} \end{array} \right\} \quad (13)$$

The total force at P is:

$$F_P = F_c + F_l + F_m \quad (14)$$

The forces on sections and their moments are to be computed from curves by approximate integration.

90 DEG. CIRCULAR BEND

FIG. M

$i = 0.262r$
 $m/r = q$
 $a/l = K$
 $d/l = n$

To find the force at the point P due to a current in the 90° circular part, we have

$$l = 0.262r$$

when

$$k = a/l$$

$$n = d/l$$

$$q = m/r$$

$$a = r(E + q \cos \alpha) \quad d = r(H + q \sin \alpha)$$

α	$\sin \alpha$	$\cos \alpha$	E	H
7.5°	0.1305	0.9914	0.262	0.009
22.5°	0.3827	0.9239	0.513	0.076
37.5°	0.6088	0.7934	0.731	0.207
52.5°	0.7934	0.6088	0.924	0.391
67.5°	0.9239	0.3827	1.055	0.617
82.5°	0.9914	0.1305	1.122	0.869

The force at P due to any of the six parts of the current can be calculated by formula (1c) and the total force will be

$$F_P = \sum_1^6 F \quad (15)$$

The force on a section $P_1 - P_2$ can be found through approximate integration. For forces close to the junction of curve and straight line it will be necessary to divide the current sheet into a number of parallel currents as described before.

Note. In case the radius of the circular conductor is not large compared with the width of the conductor it will be necessary to consider the current sheet as composed of a number of parallel conductors and to replace each of these circular currents as a polygon and so compute the total forces at each point.

APPROXIMATE INTEGRATION

FIG. N

A = Area of curve $y = f(x)$ bounded by the curve, the x -axis and the ordinates $x = x_0$ and $x = x_n$

Rectangular Rule.

$$A_R = h (y_0 + y_1 + y_2 + \dots + y_{n-1})$$

$$A_R' = h (y_1 + y_2 + y_3 + \dots + y_n)$$

$$A_R'' = \frac{A_R + A_R'}{2}$$

Simpson's Rule.

Divide the interval into an even number of parts.

$$A_s = 1/3 h [(y_0 + y_n) + 4 (y_1 + y_3 + y_5 + \dots + y_{n-1}) + 2 (y_2 + y_4 + y_6 + \dots + y_{n-2})]$$

Note. The approximation is closer the larger the number of intervals h .

A_R'' may be used for very close approximations

A_s requires less intervals for the same approximation

FIG. O

Straight Line.

A = the area of the line $y = f(x)$ bounded by the line, the x -axis and the ordinates $x = x_1$ and $x = x_2$

$$A = 1/2 (x_2 - x_1) (y_1 + y_2)$$

If A represents a force then the moment of that force about O is given by:

$$M = 1/6 \{ (y_1 + 2y_2) x_2^2 - (y_2 + 2y_1) x_1^2 + (y_1 - y_2) x_1 x_2 \}$$

Example

FIG. P

$$a_1 = 24 \text{ inches} \quad K_1 = 24/80 = 0.3$$

$$a_2 = 72 \text{ inches} \quad K_2 = 72/80 = 0.9$$

$$l = 80 \text{ inches} \quad n = 16/80 = 0.2$$

current = 20,000 amps.

Given. A conductor CD with parallel return conductor AB connected by AC at right-angle to them as in the above figure.

Required.

a The force at P_1 due to the current in AB and AC

b The force on the section $P_1 - P_2$ due to the same currents

c The moment of the force on $P_1 - P_2$ about the point C .

a. For the force due to AB we apply formula (1a).

The value of A_1 scaled from the curve $n = 0.2$ (Curve Sheet I) for $K = 0.3$ is 1.79. Remembering that the currents in AB and CD are in opposite directions we have:

$$F_{P_1}' = - \frac{4 \times 10^8}{16} \times 1.79 \times 2.248 \times 10^{-8} \text{ lbs. per inch}$$

$$F_{P_1}' = - 1.005 \text{ lbs. per inch}$$

If n had such a value that interpolation would be difficult formula (1c) can be used and we have:

$$n/K = 0.2/0.3 = 0.667 = n'$$

$$\frac{n}{K-1} = - 0.2/0.7 = - 0.286 = n''$$

(The sign is immaterial as the formula contains n'^2) From Curve B_1 (curve sheet IV) we scale $B_1' = 0.832$ and $B_1'' = 0.960$ as $K < 1$ the $+$ sign has to be used in formula (1c) and the term under the brackets is thus $0.832 + 0.960 = 1.792$ the same value as has been scaled before for A_1 . The force due to AC is found by formula (4a) where $n = 24/16 = 1.5$. From curve B_1 (Curve Sheet IV) we scale $B_1 = 0.555$.

Here the currents have different directions with regard to their junction point C and thus opposite signs

$$\text{and we have } F_{P_1}'' = - \frac{4 \times 10^{+8}}{16} \times 0.555 \times 2.248$$

$\times 10^{-8}$ lbs. per inch or $F_{P_1}'' = - 0.312$ lbs. per inch and the total force $F_{P_1} = - 1.005 - 0.312 = - 1.317$ lbs. per inch.

The negative sign indicates a repulsive force.

b For the force due to AB we use formula (2a) and from the curve $n = 0.2$ for A_2 (Curve Sheet III) we scale for:

$$K_1 = 0.3 \dots A_3' = -1.80$$

$$\text{and thus } A_3]_{k_1}^{k_2} = 5.27$$

$K_2 = 0.9 \dots A_3'' = +3.47$
and $F'_{P_1-P_2} = -4 \times 10^8 \times 5.27 \times 2.248 \times 10^{-8} = -47.5$ pounds. For the force due to AC we use formula (5a) and have for

$$P_1 \dots n_1 = 24/16 = 1.5$$

$$P_2 \dots n_2 = 72/16 = 4.5$$

from the curve for B_2 (Curve Sheet IV) we scale for $n = 1.5$ $B_2' = 1.728$. The curve does not extend to $n = 4.5$ and B_2'' has therefore to be calculated by formula (5) which gives $B_2'' = 1.904$ and we get

$$B_2]_{n_1}^{n_2} = 1.904 - 1.728 = 0.176$$

and

$$F''_{P_1-P_2} = -4 \times 10^8 \times 0.176 \times 5.177 \times 10^{-8} = 3.01 \text{ pounds}$$

The total force is thus:

$$F_{P_1-P_2} = -47.5 - 3.01 = -50.51 \text{ pounds}$$

This force is repulsive and directed away from AB .

If in calculating $F'_{P_1-P_2}$, interpolation should prove difficult, its value can be found by formula (2). This formula can be written thus:

$$F_{P_1-P_2} = I_1 I_2 \left[\sqrt{1 + (K/n)^2} - \sqrt{1 + \left(\frac{1-K}{n} \right)^2} \right]_{k_1}^{k_2}$$

or

$$F_{P_1-P_2} = I_1 I_2 \left[\sqrt{1 + n_1^2} - \sqrt{1 + n_2^2} \right]_{k_1}^{k_2}$$

and the values under the roots found by taking the reciprocals of the values given by curve B_1 (curve sheet IV).

c. The Moment of the force is found by formula (3) for the force due to AB and we have

$$K_1/n = 1.5$$

$$K_2/n = 4.5$$

$$K_1/n \sqrt{K_1^2 + n^2} = 0.54$$

$$K_2/n \sqrt{K_2^2 + n^2} = 4.15$$

$$\frac{1+K_1}{n} \sqrt{(1-K_1)^2 + n^2}$$

$$\frac{1+K_2}{n} \sqrt{(1-K_2)^2 + n^2}$$

$$= 4.74$$

$$= 2.12$$

$$\log_{10} (K_1 + \sqrt{K_1^2 + n^2}) = 1.81994$$

$$\log_{10} (K_2 + \sqrt{K_2^2 + n^2}) = 0.26055$$

$$\log_{10} \left\{ \frac{(1-K_1)}{1 + \sqrt{(1-K_1)^2 + n^2}} \right\} = 0.15473$$

$$\log_{10} \left\{ \frac{(1-K_2)}{1 + \sqrt{(1-K_2)^2 + n^2}} \right\} = 1.51001$$

$$\text{Sum of log.} = 1.97467$$

$$\text{Sum of log.} = 1.77056$$

$$2.303 \times 0.2 \times -0.0253 = -0.0117$$

$$2.303 \times 0.2 \times -0.2294 = -0.1058$$

The term between brackets k_1

$$[] = 0.54 - 4.74 + 0.01 = -4.19$$

The term between brackets k_2

$$[] = 4.15 - 2.12 + 0.11 = +2.14$$

and we have

$$M'_{C/P_1-P_2} = -4 \times 10^8 \times 80/2 [2.14 + 4.19] \times 2.248 \times 10^{-8} \text{ inch-pounds}$$

$$M'_{C/P_1-P_2} = -2275 \text{ inch-pounds} = -189.5 \text{ foot-pounds.}$$

The negative sign indicates a couple around C and turning away from AB . For the moment of $F''_{P_1-P_2}$ we apply formula (6a) and we have

$$l = 16/12 = 1.33 \text{ feet } n_1 = 24/16 = 1.5$$

$$n_2 = 72/16 = 4.5$$

from the curve for B_3 (Curve Sheet IV) we scale for $n = 1.5$.

$$B_3' = 0.518$$

The curve not extending beyond $n = 2$, we calculate B_3'' for $n = 4.5$ by formula (6) and find

$$B_3'' = 0.960 \text{ and thus}$$

$$B_3]_{n_1}^{n_2} = 0.960 - 0.518 = 0.442$$

$$M''_{C/P_1-P_2} = -4 \times 10^8 \times 1.33 \times 0.442 \times 5.177 \times 10^{-8} \text{ foot-pounds}$$

$$M''_{C/P_1-P_2} = -12.22 \text{ foot-pounds}$$

and the total moment

$$M_{C/P_1-P_2} = -189.5 - 12.2 = -201.7 \text{ foot-pounds.}$$

As an example of the approximate method we will apply it to the calculation of $F'_{P_1-P_2}$ and M'_{C/P_1-P_2} . Suppose then that the forces had been calculated for a number of points between P_1 and P_2 and a curve plotted with the forces as ordinates and CP_2 as the axis of the abscissa. This curve will be similar to the curves on curve sheet I and in this case we can take the curve $n = 0.2$ remembering that the ordinates will

$$\text{finally have to be multiplied by } \frac{-4 \times 10^8}{16} \times 2.248$$

$\times 10^{-8}$ to represent the forces in lbs. per inch. We divide the curve between the abscissa $x = 24$ in. and $x = 72$ in. into an even number of parts (in this case we will take 12) through ordinates spaced 4 in. apart or in terms of K at 0.3, 0.35, 0.4, ..., 0.85, 0.9. As the curve is symmetric on both sides of the ordinate $x = (K = 0.5)$ the value of the ordinate at $K = 0.7$, 0.75 etc., can be found at $K = 0.3$, 0.25 etc.

To find the force $F'_{P_1-P_2}$ we apply Simpson's Rule where $h = 4$ in. and we have the following values for the ordinates as scaled from curve $n = 0.2$ (curve sheet I).

y_0	= 1.79	y_1	= 1.82	y_2	= 1.84
y_{12}	= 1.43	y_3	= 1.85	y_4	= 1.86
		y_5	= 1.85	y_6	= 1.84
Sum	= 3.22	y_7	= 1.82	y_8	= 1.79
		y_9	= 1.74	y_{10}	= 1.68
		y_{11}	= 1.57		
				Sum	= 9.01
				Sum	= 10.65

and

$$F'_{P_1-P_2} = - \frac{4 \times 10^8}{16} \times 2.248 \times 10^{-8} \times 1/3$$

$$\times 4 [3.22 + 4 \times 10.65 + 2 \times 9.01]$$

$$F'_{P_1-P_2} = 47.8 \text{ pounds}$$

$$F''_{P_1-P_2} \text{ as calculated before} = 3.01 \text{ pounds}$$

thus

$$F_{P_1-P_2} = 50.81 \text{ pounds.}$$

To find the moment of this force we may consider the parts of the curve between ordinates as straight lines and find the moments of the forces between successive ordinates by the formula given for Appr. Intg. Finally we will have to multiply with the same factor as before in order to give the scaled values of the ordinates their proper value as forces.

The total moment is equal to the sum of the partial moments.

X_1	X_2	M
24	28	1,120
28	32	1,322
32	36	1,488
36	40	1,706
40	44	1,858
44	48	2,021
48	52	2,180
52	56	2,278
56	60	2,468
60	64	2,530
64	68	2,579
68	72	2,485
Sum =		24,035

$$M_{cl P_1-P_2} = - \frac{4 \times 10^8}{16} \times 2.248 \times 10^{-8} \times 1/6$$

$$\times 24035 = - 2250 \text{ inch pounds}$$

$$= - 187.5 \text{ foot-pounds.}$$

$$M_{c P_1-P_2} = - 187.5 - 12.2 = - 199.7 \text{ foot-pounds.}$$

Summary

$$F_{P_1} = - 1.317 \text{ pounds per inch by formula (1a), (4a)}$$

$$F_{P_1-P_2} = - 50.51 \text{ pound by formula (2a), (5a), (5)}$$

$$F_{P_1-P_2} = - 50.81 \text{ pounds by formula (5a), (5), Approx. Met.}$$

$$M_{cl P_1-P_2} = - 201.7 \text{ foot-pounds by formula (3), (6a), (6)}$$

$$M_{cl P_1-P_2} = - 199.7 \text{ foot-pounds by formula (6a), (6), Approx. Met.}$$

The distance from C of the point of the section $P_1 - P_2$ where the moments of the forces, on both sides of it to P_1 and P_2 respectively, are equal and where the total force can replace the distributed force is $M/F = 201.7/50.51 = 3.99 \text{ feet} = 48 \text{ inches.}$

Appendix B

DERIVATION OF FORMULAS

Fig. Q

From the fundamental formula for the field intensity we have for the field intensity at P_1 due to i_1

$$H_{P_1} = \frac{i_1}{d} \left[\frac{a}{\sqrt{a^2 + d^2}} + \frac{l-a}{\sqrt{(l-a)^2 + d^2}} \right] \text{ maxwells}$$

and for the force at P_1

$$F_{P_1} = H_{P_1} \cdot i_2 = \frac{i_1 i_2}{d} \left[\frac{a}{\sqrt{a^2 + d^2}} + \frac{l-a}{\sqrt{(l-a)^2 + d^2}} \right] \text{ dynes}$$

Putting $a/l = K$ and $d/l = n$, we can write at once

$$F_P = \frac{i_1 i_2}{d} \left[\frac{K}{\sqrt{K^2 + n^2}} + \frac{1-K}{\sqrt{(1-K)^2 + n^2}} \right] \text{ dynes per cm. (1)}$$

$$F_P = \frac{i_1 i_2}{d} \left[\frac{a}{\sqrt{a^2 + d^2}} - \frac{a-l}{\sqrt{d^2 + (a-l)^2}} \right] \text{ dynes}$$

or

$$F_P = \frac{i_1 i_2}{d} \left[\frac{K}{\sqrt{K^2 + n^2}} - \frac{K-1}{\sqrt{(K-1)^2 + n^2}} \right]$$

dynes per cm.

which is the same as formula (1). (See Fig. II App. A).

To find the force on a part of current i_2 from P_1 to P_2 consider a small extension of a , da and integrate over the distance $P_1 - P_2$ or between limits a_1, a_2 we have

$$F_{P_1-P_2} = \frac{i_1 i_2}{d} \left[\int \frac{a da}{\sqrt{a^2 + d^2}} + \int \frac{(l-a) da}{\sqrt{d^2 + (l-a)^2}} \right]_{a_1}^{a_2}$$

$$\int \frac{a da}{\sqrt{a^2 + d^2}} = \sqrt{a^2 + d^2} = l \sqrt{K^2 + n^2}$$

$$\int \frac{(l-a) da}{\sqrt{d^2 + (l-a)^2}} = - \sqrt{d^2 + (l-a)^2} = - l \sqrt{n^2 + (1-K)^2}$$

from which if $a_1/l = K_1, a_2/l = K_2$.

$$F_{P_1-P_2} = \frac{i_1 i_2}{n} \left[\sqrt{K^2 + n^2} - \sqrt{(1-K)^2 + n^2} \right]_{K_1}^{K_2} \text{ dynes (2)}$$

The moment of $F_{P_1-P_2}$ about O is then

$$M_{O/P_1-P_2} = \frac{i_1 i_2}{d} \left[\int \frac{a^2 da}{\sqrt{a^2 + d^2}} + \int \frac{a(l-a) da}{\sqrt{d^2 + (l-a)^2}} \right]_{a_1}^{a_2}$$

$$\frac{1}{d} \int \frac{a^2 da}{\sqrt{a^2 + d^2}} = \frac{1}{d} \cdot \left[\frac{a}{2} \cdot \sqrt{a^2 + d^2} - \frac{d^2}{2} \log_e \left(a + \sqrt{a^2 + d^2} \right) \right]$$

$$= \left(\frac{l}{2} \right) \cdot \left[\frac{K}{n} \cdot \sqrt{K^2 + n^2} - n \log_e (K + \sqrt{K^2 + n^2}) - n \log_e l \right]$$

$$\frac{1}{d} \int \frac{a(l-a) da}{\sqrt{d^2 + (l-a)^2}} = \frac{1}{d} \cdot \left[\frac{l-a}{2} \sqrt{d^2 + (l-a)^2} - \frac{d^2}{2} \log_e \left\{ (l-a) + \sqrt{d^2 + (l-a)^2} \right\} \right]$$

and

$$M_{O/P_1-P_2} = i_1 i_2 \cdot \frac{l}{2} \cdot \left[\frac{K}{n} \sqrt{K^2 + n^2} - \frac{1+K}{n} \sqrt{(1-K)^2 + n^2} - 2.303 \{ \log_{10} (K + \sqrt{K^2 + n^2}) + \log_{10} ((1-K) + \sqrt{(1-K)^2 + n^2}) \} \right]_{k_1}^{k_2}$$

dynes cm. (3)

FIG. R

Here $a = 0$ and from the fundamental formula we get

$$F_{P_1} = \frac{i_1 i_2}{d} \cdot \frac{l}{\sqrt{d^2 + l^2}}$$

or if $d/l = n$.

$$F_{P_1} = \frac{i_1 i_2}{d} \left[\frac{1}{\sqrt{n^2 + 1}} \right] \text{ dynes per cm. (4)}$$

For the force on $P_1 - P_2$ we have

$$F_{P_1-P_2} = \int_{d_1}^{d_2} \frac{i_1 i_2}{d} \cdot \frac{l dd}{\sqrt{d^2 + l^2}}$$

$$= i_1 i_2 \cdot l \int_{d_1}^{d_2} \frac{dd}{d \sqrt{d^2 + l^2}}$$

$$= i_1 i_2 \left[\log_e \frac{\sqrt{d^2 + l^2} - l}{d} \right]_{d_1}^{d_2}$$

$$= i_1 i_2 \left[\log_e \left\{ \frac{1}{n} \cdot (\sqrt{n^2 + 1} - 1) \right\} \right]_{n_1}^{n_2}$$

or

$$F_{P_1-P_2} = i_1 i_2 \cdot 2.303 [\log_{10} (\sqrt{n^2 + 1} - 1) - \log_{10} n] \text{ dynes (5) or}$$

For the moment of $F_{P_1-P_2}$ about O we have

$$M_{O/P_1-P_2} = \int_{d_1}^{d_2} i_1 i_2 \frac{l dd}{\sqrt{d^2 + l^2}}$$

$$= i_1 i_2 [l \cdot \log_e (d + \sqrt{d^2 + l^2})]_{d_1}^{d_2}$$

$$= i_1 i_2 \cdot l [\log_e l + \log_e (n + \sqrt{n^2 + 1})]_{n_1}^{n_2}$$

l is the unit used for measuring n , thus $\log_e l = 0$ and thus

$$M_{O/P_1-P_2} = i_1 i_2 \cdot l [2.303 \log_{10} (n + \sqrt{n^2 + 1})]_{n_1}^{n_2}$$

dynes cm. (6)

FIG. S

Here we have

$$a = l + d$$

$$d = m/\sqrt{2}$$

$$m/l = v$$

if

then

$$K = \frac{\sqrt{2} + v}{\sqrt{2}}$$

and

$$n = v/\sqrt{2}$$

from formula (1)

$$F_P = \frac{i_1 i_2 \sqrt{2}}{m} \left\{ \frac{\frac{\sqrt{2} + v}{\sqrt{2}}}{\sqrt{\left[\frac{\sqrt{2} + v}{\sqrt{2}} \right]^2 + (v/\sqrt{2})^2}} + \frac{1 - \frac{\sqrt{2} + v}{\sqrt{2}}}{\sqrt{\left[1 - \frac{\sqrt{2} + v}{\sqrt{2}} \right]^2 + (v/\sqrt{2})^2}} \right\}$$

$$= \frac{i_1 i_2}{m} \left\{ \frac{\sqrt{2} + v}{\sqrt{v^2 + v\sqrt{2} + 1}} - 1 \right\}$$

$$F_P = \frac{i_1 i_2}{m} \left\{ \frac{1.414 + v}{\sqrt{v^2 + 1.414v + 1}} - 1 \right\}$$

dynes per cm. (8)

For the force on a length $P_1 P_2$ we have

$$\begin{aligned}
 F_{P_1-P_2} &= \int_{v_1}^{v_2} \frac{i_1 i_2}{l \cdot v} \left\{ \frac{\sqrt{2} + v}{\sqrt{v^2 + v \sqrt{2} + 1}} - 1 \right\} l dv \\
 &= i_1 i_2 \left\{ \sqrt{2} \int_{v_1}^{v_2} \frac{dv}{v \sqrt{v^2 + v \sqrt{2} + 1}} \right. \\
 &\quad \left. + \int_{v_1}^{v_2} \frac{dv}{\sqrt{v^2 + v \sqrt{2} + 1}} - \int_{v_1}^{v_2} \frac{dv}{v} \right\} \\
 F_{P_1-P_2} &= i_1 i_2 \left[\sqrt{2} \left\{ -\log_e \left(\frac{\sqrt{v^2 + v \sqrt{2} + 1} + 1}{v} \right) \right. \right. \\
 &\quad \left. \left. + \sqrt{2}/2 \right\} + \log_e (2v + \sqrt{2} \right. \\
 &\quad \left. + 2 \sqrt{v^2 + v \sqrt{2} + 1}) - \log_e v \right]_{v_1}^{v_2} \\
 \text{or} \\
 F_{P_1-P_2} &= i_1 i_2 [-\sqrt{2} \log_e (2 \sqrt{v^2 + v \sqrt{2} + 1} \\
 &\quad + v \sqrt{2} + 2) + (\sqrt{2} - 1) \log_e v + \sqrt{2} \log_e 2 \\
 &\quad + \log_e (2v + \sqrt{2} + 2 \sqrt{v^2 + v \sqrt{2} + 1})]_{v_1}^{v_2} \\
 &\quad \text{dynes} \quad (9)
 \end{aligned}$$

For the moment we have

$$\begin{aligned}
 M_{O/P_1-P_2} &= i_1 i_2 \int_{v_1}^{v_2} \left\{ \frac{\sqrt{2} + v}{\sqrt{v^2 + v \sqrt{2} + 1}} - 1 \right\} l dv \\
 &= i_1 i_2 \left[l \int_{v_1}^{v_2} \frac{\sqrt{2} dv}{\sqrt{v^2 + v \sqrt{2} + 1}} \right. \\
 &\quad \left. + l \int_{v_1}^{v_2} \frac{v dv}{\sqrt{v^2 + v \sqrt{2} + 1}} - l \int_{v_1}^{v_2} dv \right] \\
 M_{O/P_1-P_2} &= i_1 i_2 \cdot l \left[\sqrt{v^2 + v \sqrt{2} + 1} - v \right. \\
 &\quad \left. + \frac{\sqrt{2}}{2} \cdot \log_e (2v + \sqrt{2} \right. \\
 &\quad \left. + 2 \sqrt{v^2 + v \sqrt{2} + 1}) \right]_{v_1}^{v_2} \text{ dynes cm.} \quad (10)
 \end{aligned}$$

FIG. T

Consider a small l of a circular current of radius r

and of unit strength. The field strength at P due to l is then

$$H = 1/d \left[\frac{a}{\sqrt{a^2 + d^2}} - \frac{a-l}{\sqrt{d^2 + (l-a)^2}} \right]$$

if l is an element of the current

$$l = r d\alpha$$

and

$$a = r \sin \alpha$$

$$d = r(1 - \cos \alpha)$$

Substituting

$$\begin{aligned}
 H &= \frac{1}{r(1 - \cos \alpha)} \left[\frac{r \sin \alpha}{\sqrt{r^2(1 - \cos \alpha)^2 + r^2 \sin^2 \alpha}} \right. \\
 &\quad - \frac{r \sin \alpha}{\sqrt{r^2(1 - \cos \alpha)^2 + (r d\alpha - r \sin \alpha)^2}} \\
 &\quad \left. + \frac{r d\alpha}{\sqrt{r^2(1 - \cos \alpha)^2 + (r d\alpha - r \sin \alpha)^2}} \right]
 \end{aligned}$$

$r d\alpha = 0$ compared with $r \sin \alpha$ and the first two terms under the brackets become equal thus:

$$dH = \frac{d\alpha}{r(1 - \cos \alpha) \sqrt{(1 - \cos \alpha)^2 + \sin^2 \alpha}}$$

To find the field strength at P due to the 90° bend we have to integrate this expression between the limits $\alpha = \theta$ and $\alpha = -(\pi/2 - \theta)$.

It is:

$$\begin{aligned}
 &\frac{d\alpha}{r(1 - \cos \alpha) \sqrt{(1 - \cos \alpha)^2 + \sin^2 \alpha}} \\
 &= \frac{d\alpha}{r \sqrt{2} (1 - \cos \alpha) \sqrt{1 - \cos \alpha}} \\
 &= \frac{1}{r \sqrt{2}} \cdot \frac{d\alpha}{2 \sin^2 1/2 \alpha \cdot \sin 1/2 \alpha \cdot \sqrt{2}} \\
 &= \frac{1}{4r} \cdot \frac{d\alpha}{\sin^3 1/2 \alpha} = \frac{1}{2r} \cdot \frac{d(1/2 \alpha)}{\sin^3 1/2 \alpha}
 \end{aligned}$$

Thus

$$H_{Pe} = \frac{1}{2r} \int_{\alpha = -(\pi/2 - \theta)}^{\alpha = \theta} \frac{d(1/2 \alpha)}{\sin^3 1/2 \alpha}$$

or

$$\begin{aligned}
 H_{Pe} &= \frac{1}{4r} \left\{ -\frac{\cot 1/2 \alpha}{\sin 1/2 \alpha} + \log_e (\operatorname{cosec} 1/2 \alpha \right. \\
 &\quad \left. - \cot 1/2 \alpha) \right\} \Bigg|_{\alpha = -(\pi/2 - \theta)}^{\alpha = \theta}
 \end{aligned}$$

This can be written

$$\begin{aligned}
 H_{Pe} &= \frac{1}{4r} \left\{ -\frac{\sin \alpha \sqrt{2}}{(1 - \cos \alpha) \sqrt{1 - \cos \alpha}} \right. \\
 &\quad \left. + \log_e \left(\frac{\sqrt{2} \cdot \sqrt{1 - \cos \alpha} - \sin \alpha}{(1 - \cos \alpha)} \right) \right\} \Bigg|_{\alpha = -(\pi/2 - \theta)}^{\alpha = \theta}
 \end{aligned}$$

Inserting the limits and remembering that $\operatorname{cosec} 1/2 \alpha$

— $\cot 1/2 \alpha = \tan \alpha/4$, we find for the force on a point P of a circular current of strength i , making an angle θ from one end of a 90° circular bend and due to the current in the Bend.

$$F_c = \frac{i^2}{4r} \left[\frac{\sin \theta \sqrt{2}}{(1 - \cos \theta) \sqrt{1 - \cos \theta}} + \frac{\cos \theta \sqrt{2}}{(1 - \sin \theta) \sqrt{1 - \sin \theta}} - 2.303 \log_{10} \tan^2 \theta/4 + 2.303 \log_{10} \left(\frac{\sqrt{2} \cdot \sqrt{1 - \sin \theta} + \cos \theta}{1 - \sin \theta} \right) \right] \text{ dynes per cm.} \quad (11)$$

FIG. U

To find the force due to a tangent current l on a point P of the 90° circular bend.

$$F_{Pl} = \frac{i^2}{d} \cdot \left(\frac{a}{\sqrt{a^2 + d^2}} - \frac{a - l}{\sqrt{d^2 + (l - a)^2}} \right)$$

and we have

$$a = l + r \cos \theta$$

$$d = r (1 - \sin \theta)$$

Substituting

$$F_l = \frac{i^2}{r (1 - \sin \theta)} \left[\frac{l + r \cos \theta}{\sqrt{r^2 (1 - \sin \theta)^2 + (l + r \cos \theta)^2}} - \frac{r \cos \theta}{\sqrt{r^2 (1 - \sin \theta)^2 + r^2 \cos^2 \theta}} \right]$$

Writing $l/r = p$ we get

$$F_l = \frac{i^2}{r (1 - \sin \theta)}$$

$$\left[\frac{p + \cos \theta}{\sqrt{(1 - \sin \theta)^2 + (p + \cos \theta)^2}} - \frac{\cos \theta}{\sqrt{(1 - \sin \theta)^2 + \cos^2 \theta}} \right] \text{ dynes per cm.} \quad (12)$$

Writing $m/r = q$, we get

$$F_m = \frac{i^2}{r (1 - \cos \theta)} \left[\frac{q + \sin \theta}{\sqrt{(1 - \cos \theta)^2 + (q + \sin \theta)^2}} - \frac{\sin \theta}{\sqrt{(1 - \cos \theta)^2 + \sin^2 \theta}} \right] \text{ dynes per cm.} \quad (13)$$

All these forces acting in the same direction, we get for the total force

$$F_P = F_c + F_l + F_m \quad (14)$$

To find the force due to a current in a 90° circular bend on a point P situated in the current tangent to the end of the bend: Divide bend in 6 equal parts containing 15° arc and consider the length l of each part as being a straight line of length $0.262 r$. We have then for the constants

FIG. V

$$a = bc + ce + ef$$

or

$$a = 0.131 r + r \tan 1/2 \alpha + (m + r \tan 1/2 \alpha) \cos \alpha$$

writing $m/r = q$

$$a = r \{ \tan 1/2 \alpha (1 + \cos \alpha) + 0.131 + q \cos \alpha \}$$

$$a = r [E + q \cos \alpha]$$

$$d = fP = (m + r \tan 1/2 \alpha) \sin \alpha$$

$$= r \{ \tan 1/2 \alpha \sin \alpha + q \sin \alpha \}$$

$$= r \{ (1 - \cos \alpha) + q \sin \alpha \}$$

or

$$d = r [H + q \sin \alpha]$$

The forces can now be calculated as shown and their sum will be the total force

$$F_p = \sum_1^6 F \quad (15)$$

A Diaphragmless Microphone for Radio Broadcasting

BY PHILLIPS THOMAS

Associate, A. I. E. E.

Research Engineer, Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa.

THE broadcasting of regular programs of entertainment and instruction was begun in the Fall of 1920. It was not long before the service became quite generally used, although at first this was due to its novelty. Judged by present standards, the character of the programs rendered, and the quality of modulation attained, was susceptible to great improvement; and the development of better apparatus and methods of modulation has gone hand in hand with the broadening of the scope of entertainment offered.

At the time when the writer's attention was directed to this matter, the gradual improvement being made in the speech amplifier and modulator system, was making it increasingly evident that the carbon granule microphone could not be relied upon for accurate reproduction of music.

In order to transform sound vibrations, without distortion, into electrical vibrations in the ether, given a distortionless amplifying system, certain conditions must be met by the reproducing device. These, briefly, are as follows:

1. An incident sound wave, of a given pitch and intensity, must always have the same effect upon the microphone.

2. There must be a linear relation between sound intensity and effect produced.

3. The device must be critically damped, in order to correctly copy complex sound waves.

4. There must be no resonance points in the curve of variation of response with frequency, which should preferably be a straight line parallel to the frequency axis.

5. It is very desirable that this curve of response against frequency, be to some extent adjustable at the microphone. This is desirable in order to be able to correct for attenuation in overhead or cable lines from the signal source to the broadcasting station.

The carbon granule microphone depends for its action upon the variation of contact resistance between numbers of carbon particles. This variation is caused by movement of a diaphragm, actuated in turn by the incoming sound waves. When used for voice transmission in the usual way, an average intensity of reproduction will be maintained over indefinite periods because the speaker talks directly into the mouthpiece, causing a considerable agitation of the granules. In reproducing music comprising more than one tone, or one instrument, it is not feasible to direct the sound waves into the mouthpiece, and a much diminished sound intensity must be employed. This results in a gradual loss of sensitivity of the microphone,—the

familiar "packing",—so that the first of the above conditions cannot be met. Conditions (2) and (3) are complied with, approximately, over fairly wide limits. The use of a loaded diaphragm, however, means that there will be a fundamental or natural period and its overtones, due to the instrument itself. At these frequencies the response will, by mechanical resonance, be much exaggerated. Usually this fundamental frequency is purposely placed at or near eight hundred cycles, the figure adopted as the average speech frequency. This means that below the natural frequency, the response increases with frequency, rising to a peak as resonance is reached, and falling off rapidly at higher frequencies. The timbre of the various musical instruments is due to the frequency and intensity of the various harmonics present. These occur mainly in the range above eight hundred or one thousand cycles,—the range through which the sensitivity of the carbon microphone is low and decreasing. All such microphones, to a greater or lesser extent, have undesirable characteristics such as described; hence it is apparent that one cannot expect faithful reproduction of music by this means.

The carbon microphone is ordinarily used to vary the current in a circuit, supplied at constant potential, by varying the resistance of the microphone. Since in the Ohm's law equation for current, directly applicable, the circuit resistance appears in the denominator, the current variation cannot be an exact copy of the resistance variation. The distortion will be the greater, the larger is the proportion of microphone resistance to total resistance in circuit. In other words, the greater the sound intensity at the diaphragm,—which tends to prevent packing,—the more will the reproduction be distorted.

It was found possible to remove this cause of distortion by using the microphone in a constant current circuit, instead of one worked at constant potential. By connecting the instrument in series with either a high resistance or high inductance, and securing proper current by adjustment of the supply voltage, the current will remain constant, and the potential at the microphone terminals will be directly proportional to the resistance, instead of inversely. By suitable amplification of this voltage variation, much better quality can be obtained; however, the resonance characteristics and the unsteady performance cannot be improved in this way.

Although it was found possible to correct, in some measure, the tendency to resonance, it was felt that such devices are by their very nature unsuited to the purpose in hand.

The first alternative taken up was an electrodynamic

or moving coil transmitter, whose coil was connected to the center of a diaphragm clamped at its edge, which moved the coil in a strong magnetic field. If connected in a circuit of large inductance and low resistance, the movement of the diaphragm will cause alternating currents to flow in the coil circuit. These currents will be, for sound waves of constant amplitude, independent of the sound frequency. Proper corrugation of the diaphragm will annul any harmonic resonance, leaving the fundamental period alone to be corrected for. Hence the response curve will be of the same shape as an electrical resonance curve, and may be corrected in the amplifying network, by the use of suitable filters.

It was shown experimentally that such a transmitter could be produced. The compensation was satisfactory in the lower and intermediate audio ranges, but at the higher frequencies mechanical hysteretic effects in the diaphragm became prominent, and the resonance characteristics of the moving coil and connection system came into play, so that the results could not be considered satisfactory.

At about this time, advantage was taken of the condenser transmitter, developed primarily for use in measurements of sound intensity.¹ This instrument left, theoretically, little to be desired, since it had been shown² to be possible to construct it with critical damping and with a response characteristic practically independent of frequency. However, it developed after several months' use in broadcasting, that the problem of maintaining its insulation resistance high and constant, to avoid loss of sensitivity and introduction of ground tone, is difficult of solution. There is also a marked tendency for the diaphragm, originally tightly stretched, to sag and lower its natural frequency until it comes well within the audio range, which defeats the primary object of the construction. The high order of impedances involved, as well as the considerable amount of amplification required, make the instrument difficult to maintain in satisfactory operating condition. Even with these defects, however, the condenser transmitter represents practically the best solution of the problem of sound reproduction by use of a diaphragm. It thus became apparent that the production of a diaphragmless microphone would be a distinct step forward.

There are several ways in which sound waves may be electrically reproduced without the use of a diaphragm. In many cases, however, while fundamental frequencies and resonant harmonics are avoided, the mechanism employed is not free from inertia. This is true, for example, in the case of the inverted Goldschmidt thermophone, in which the sound waves vary the temperature and hence the resistance of a heated wire or strip. The sensitivity may be made independent of frequency, in such cases, by damping the lower ranges,

but its value will then be no greater than the undamped value at the highest frequency used. The required amplification thus becomes so large that the ratio of tube noise to signal is difficult to keep small enough for quiet operation.

The variation of the impedance of an ionic stream, as the pressure is varied by the incident sound waves, offers great promise, especially if so-called cold ionization can be used. In this case there will be practically no energy loss, no heat developed, and hence no inertia at the instrument. Calculations, however, of the space current to be expected in air at atmospheric pressure, with radium or emanation as source, showed that the impedances to be expected would be of even higher order than those in the condenser transmitter circuits. Experimental tests showed the same to be true of ionization currents due to ultraviolet light.

An operative microphone was made by using the ionization from a Nernst glower. The response curve fell off very badly as the frequency was raised. It was found to be impossible to eliminate the hum caused by the commutator of the dynamo furnishing the current to heat the Nernst glower. Following this lead, it was found that the response was due in the main to change of temperature of the glower, and not to direct change of impedance due to the sound wave. This explained the mass or inertia effect found to be present.

At this time the writer's attention was brought to the relatively great change in potential across a so-called "glow-discharge," at reduced pressures, which is known to occur upon altering the length of discharge path. It was suggested that something of the same effect might be present in air at atmospheric pressure. A calculation showed that this effect would afford ample sensitivity at reasonable impedance, were it to be even one hundredth as great in open air as at the pressures employed in the published work. Tentative tests were made along this line, which seemed to show that the sensitivity in open air would not be sufficient for the purpose; also it was necessary to use a diaphragm. The writer, however, was able to show that the discharge impedance could be varied directly, without the intermediary diaphragm, by pressure variation from sound waves reaching the discharge path.

The direct-current glow discharge, at low pressure, is a fairly well known form of ionization conduction, little has been published, however, on its characteristics in open air. Since the new microphone makes use of such a discharge as its variable impedance, a brief description of the phenomena is thought to be desirable.

The application of moderately high direct potential between two electrodes separated a short distance in air, with enough series resistance to prevent formation of the usual type of heavy current arc, will cause the establishment of a peculiar low current, high voltage discharge having a characteristic glowing appearance, from which is derived the name, "glow-discharge."

1. E. C. Wentz, *Phys. Rev.*, II, Vol. 10, p. 39, 1917.

2. I. B. Crandall, *Phys. Rev.*, II, Vol. 11, p. 449, 1918

The order of current is from one to twenty milliamperes or more, at voltages ranging from two or three hundred to one thousand volts.

Such a discharge, when produced between electrodes of certain metals, of which copper is one of the best, is remarkably quiet and steady to the unaided ear and eye. The discharge path is similar to that produced at low pressure, except that certain portions are of much less length. There are eight portions, of which but four are of importance in the open air. Fig. 1, schematic, shows these portions, which comprise, as we go from the anode towards the cathode; the anode glow, the anode column, the Faraday dark space, and the cathode glow. Between the cathode glow and the negative electrode there is a second dark space, called

FIG. 1—ENLARGED (SCHEMATIC) APPEARANCE OF GLOW DISCHARGE

the Crookes' or cathode dark space. The potential drop across this space is quite large, but its length in open air is very short.

If such a discharge be connected as shown in Fig. 2, it is found that the incidence of sound waves at the gap will produce alternating potentials of equivalent frequencies across the coupling condenser *C*, whose function is to block off the direct potential drop from the grid of the amplifier tube *A*. The rectifier tube shown in the discharge circuit serves to maintain the current at a constant value as the discharge impedance changes with varying pressure. The sensitivity is surprisingly large; an amplification of ten to one will give loud signals in a head set. The discharge imped-

FIG. 2—DIAGRAM OF CONNECTIONS, CONSTANT CURRENT GLOW DISCHARGE, SHOWING FIRST STEP OF AMPLIFICATION

ance is of the order of five hundred thousand ohms, which is low enough to cause no trouble in maintaining insulation resistance, or in adapting the device for use with standard vacuum tubes.

Equipment of this nature was tried out in formal broadcasting from station *K D K A*, in the spring of 1922. The discharge gap or holder used is shown diagrammatically in Fig. 3. The following defects were found to be present:

1. The curve of sensitivity as function of frequency was not flat, but fell off considerably at the higher frequencies.

2. There was considerable "ground tone,"—rumbling, hissing and popping noises not connected with the

sounds being copied. These noises were not prominent enough to interfere with the modulation, but were quite disagreeable during quiet intervals. At times they were strong enough to cause overmodulation of the system.

3. As was to be expected, there was extreme sensitiveness to drafts or air currents, because no draft shields had been attached to the discharge holder. The sudden opening of a door into the studio would cause enormous variations in gap voltage. The blocking condenser *C* of Fig. 2 thus became overcharged, the potential on the first amplifier grid was made positive, and the sensitivity to sound was entirely lost until the condenser could discharge through the grid leak.

4. There was a certain amount of radio frequency regeneration.

These defects were sufficiently pronounced to make the device unsuitable for use in broadcasting. The advantages afforded, namely simplicity, durability, low impedance, and high sensitivity, in addition to elimination of the diaphragm, were so great that it was decided to see what could be done in the way of improvement. The matter of unequal response with

FIG. 3—FIRST GLOW DISCHARGE MICROPHONE

varying frequency was taken up first, being the most serious defect. To avoid loss of sensitivity, it was desirable if possible to reinforce the weak portions of the curve, rather than to cut down the stronger portions. Unsuccessful attempts were made to do this by the use of various designs of single and double amplifying horns. It finally became necessary to make a study of the sound response of the different portions of the discharge, to find out what if any portions would give proper response. This was accomplished by the use of a perforated exploring electrode, through which the discharge was allowed to pass. As shown in Fig. 4, connection to the amplifier grid could be made from the exploring electrode and either terminal of the discharge. The most sensitive portion was found to be the positive column. Its sensitivity was so great that when using the whole gap, as in Fig. 2, but little was contributed by the other parts of the discharge. The sensitivity of the portion from the end of the positive column to the cathode terminal was found to be much less than that of the positive column, and to be independent, through wide limits, of frequency. While more amplification

is required when the positive column effect is eliminated, the effect of frequency can be made negligible.

It will now be apparent that by suitably proportioning the discharge gap, and properly placing the exploring electrode, we can control, to a great extent, the shape of the frequency response curve. It should be noticed here that as the separation of the main electrodes is increased, nothing in the character of the discharge is altered, except the length of the positive column and the voltage drop across this column. The positive column gradient is roughly fifteen hundred volts per centimeter of length. If a short gap is used, with the exploring electrode close to the cathode terminal, the response will be obtained mainly from the cathode and will be practically flat. If the gap is lengthened, without altering the distance from cathode to exploring electrode, the differential action of the cathode portions and the positive column, on the voltage change at the exploring electrode, will result in partial suppression of the response on the lower audio register. An upward sloping curve will result. As the exploring electrode is moved nearer to the anode end, the positive column characteristic will become gradually

FIG. 4—GLOW DISCHARGE MICROPHONE WITH EXPLORING ELECTRODE

more dominant, until at the limit, when the whole gap is used as pick-up, the characteristic will have a pronounced downward slope. The use of this microphone, therefore, should enable one to use a distortionless amplifier network and to control or modify the character of the modulation at will, by simple adjustments at the microphone itself.

It has been found that the bad effects of drafts can be avoided without essentially altering the response to sound waves. This was accomplished by the use of properly designed draft shields placed across either end of the short tube containing the glow discharge terminals. The air current resistance of the two shields was made quite different, so that as now used, the instrument is sensitive mainly at one end only. It was found to be undesirable to completely close one end, as this resulted in diminished sensitivity as well as resonance at the natural frequency of the enclosure.

While the ratio of ground tone to signal was greatly reduced by the use of the exploring electrode described above, it was found necessary to determine the source of the noises. There resulted the development of an alloy of low heat conductivity and melting point, to be used for the electrodes. By the proper proportioning

of diameter and length of electrodes, and the use of discharge currents of proper value, it proved possible to operate the device continuously over long periods of time, without objectionable ground tone. Furthermore, while the electrodes eventually fail, this occurs after about the same length of service in all cases. It is then a simple matter to design the microphone holders and units so as to be readily replaceable, and to renew them long before they become inoperative.

The development was completed by the working out of a low-current, high-voltage rectifier, with resistance-capacity filters, which permits the discharge to be struck or started by flashover, and maintains its current practically independent of discharge impedance. Units of substantially this construction have been used in the regular broadcasting programs of station *K D K A* for several months.

In conclusion, it may be said that although it is desirable and will doubtless become possible to use a microphone giving a response independent of frequency, this is not done at present. The imperfections of the existing designs of head telephones and loud speakers make it advisable to adjust the modulation, to some extent, so that the received audio signals will be more nearly faithful copies of the originals. This is readily accomplished with the new microphone, so that advantage may be taken of improvements in receiving apparatus as they appear.

Discussion

R. L. Jones: I believe we would all find ourselves in substantial agreement with Dr. Thomas in respect to the first four conditions which he sets down as those which must be met by a high quality telephonic reproducing apparatus. It is to be regretted, however, that he does not give data to show how well the glow discharge transmitter fulfills them: data as to its physical efficiency; frequency response characteristics; and its load capacity, or the degree of linearity with which it responds over a wide range of intensities. The general idea of a telephone transmitter depending upon ionic discharge is old,¹ but this is the first time, to my knowledge, that a telephone transmitter depending upon the phenomenon has been utilized practically. The world is eager for better tools of communication, and the impetus lately given by radio and public address systems stimulates interest. If the glow discharge transmitter fulfills even a part of the fundamental conditions better than other available types, it is probable, in spite of the high-voltage supply and other operating disadvantages, that it will have a certain field of use. In view of the present lack of data showing its performance under the variety of actual conditions, however, it remains for the future to reveal what place it has.

Referring to Condition 5 of the paper, the most flexible and upon the whole the most desirable system is not one where distortion in one element is compensated in another, but rather one with elements as nearly perfect in quality as possible. One of the other papers on the Convention program² explained the manner in which distortion in line and cable circuits can be compensated by means of network structures or attenuation equalizers associated with the lines. The possibility of design-

2. Use of Public Address System with Telephone Lines, by W. H. Martin and A. B. Clark.

ing modulators, detectors, and amplifiers having practically horizontal frequency characteristics has been demonstrated; and coming down to the terminal instruments, the trend of the development of improved transmitters and receivers is in the direction of instruments which are in themselves reproducers of high quality. In such an instrument frequency distortion is usually symptomatic of conditions which give rise to load distortion at intensities lower than it would otherwise be possible for the instrument to reproduce. This matter of load distortion is an important consideration with public address and radio systems, and one which has not received consideration generally as pointed out in the paper referred to above.

The author of the paper has concluded that neither the condenser type nor the carbon type of telephone transmitter is suitable for such high quality pick-up work as that in connection with radio broadcasting. After relating his experience he says of the carbon transmitter, "It was felt that such devices are by their very nature unsuited to the purpose in hand." And again, after relating defects experienced with a model of the condenser type, he says, "It thus became apparent that the production of a diaphragmless microphone would be a distinct step forward." From these remarks one not intimately familiar with the communication art might fairly conclude that the type of telephone transmitter which employs a diaphragm is in a state of decline and that, with the growing requirements for high quality, the diaphragm type of instrument is moribund. In view of this it seems advisable to supplement the paper by giving some information regarding the characteristics, and the extent of use of two high quality transmitters employing diaphragms, which have been developed recently. These transmitters have had considerable use mainly in connection with high quality public address systems and with radio broadcasting work in the Bell System.

Transmitters of these two types are described in another of the Convention papers presented yesterday.³ The condenser transmitter consists essentially of a thin steel diaphragm which is stretched and spaced at a distance of $1/1000$ of an inch from a rigid plate which constitutes the second electrode. The carbon transmitter similarly employs a stretched steel diaphragm, and has a push-pull construction with two granular carbon resistance elements. It would be desirable to tune both instruments in such a way that their resonance frequencies were above the voice range. In the condenser transmitter this is actually accomplished. In the carbon transmitter, the region of resonance is designed to be in the upper part of the voice range and is so flattened out by high damping that in conjunction with the high frequency of tuning satisfactory quality of reproduction is obtained.

Neither instrument is as high in sensitivity as the ordinary telephone transmitter, and with the condenser instrument a vacuum tube amplifier is always associated as a part of the transmitting set. The quality of the latter instrument is indicated by the fact that the range of variation of its response over a region from 200 to 6000 cycles is less than three miles.⁴ In the case of the carbon transmitter, the range of variation is about twelve miles. From other investigations it is known that the range of variation of ear sensitivity of normal persons frequently varies over ten miles in this frequency range, so that a reproducing system, the variations of which do not exceed this limit may be considered entirely satisfactory for high quality work.

The author mentions difficulty with maintaining insulation resistance of the condenser transmitter and a tendency for the diaphragm to sag. Due to construction of the instrument a sag even as small as one mil would cause complete short circuit and the instrument would become inoperative. In view of this fact it seems probable that the author refers to the diaphragm

giving somewhat, and thereby lowering its natural period. We have had no such experience in the Bell System laboratory. Instruments have been found with their normal tuning and otherwise in good condition after approximately four years of rather hard laboratory service. In addition to a substantial number of instruments in use for various laboratory purposes, there are three of the leading radio broadcasting stations employing condenser transmitters regularly, and some of these instruments have been in service for nearly a year. While it is true that the insulation of the instrument will vary somewhat, if proper precautions are taken no more difficulty should be experienced from this source than in the case of other elements common in circuits characterized by weak currents and high amplification. It is our experience that there is less difficulty due to the insulation of the transmitter than to that of the wiring of the amplifiers used in systems such as are under discussion. Under careful handling the life of such an instrument should be as great as that of ordinary telephone apparatus. Because of the very satisfactory quality of the instrument and its great constancy, a transmitter of this type is now being favorably considered for use as a reference instrument in laboratory measurements of telephone transmission.

From the author's reference to a fundamental frequency near 800 cycles for the carbon transmitter, it is thought that he has the common form of subscribers' telephone transmitter in mind. This transmitter, which is satisfactory for commercial telephone service where speech alone is transmitted, and where hand receivers are employed, is not suitable for high quality pick-up work, where music must be transmitted, and where transmission must be suitable for loud speaker reproduction. The carbon transmitter developed in the Bell System laboratories for such purposes is free from packing or any other changes of efficiency with time. Its natural frequency is several times the "average speech frequency" mentioned by the author.

Such carbon transmitters are in daily use at about thirty of the most important radio broadcasting stations in the United States, in addition to other frequent use with a considerable number of public address equipments. Altogether there are over two hundred of them out in the field, and after practical experience extending over more than a year, it can be stated that they have made a very good record for themselves, both as to the quality of their reproduction and as to their general serviceability.

G. D. Robinson: Mr. Thomas has undoubtedly developed a valuable tool. Although his prime object has undoubtedly been the reproduction of sound frequencies lying within the ordinary range, it appears that this tool might well find use in physics or elsewhere, where the frequency is outside of the ordinary sound range. I would be obliged if Mr. Thomas would tell us anything that he knows about the extreme limiting values of frequency at which this device may be applied.

Phillips Thomas: I have to thank Mr. Jones for his very valuable contribution to the discussion. He has brought up many points, on most of which little was said in the paper.

In regard to condition 5, we are I think all in substantial agreement with Mr. Jones, that ultimately we should strive for constructive improvement all down the line, rather than correct, in the final result, inaccuracies occurring at one point by the introduction of inaccuracies at other points. It is, however, a regrettable fact that the present loud speakers, without notable exception, are far from sufficiently perfect to give satisfactory reproduction of undistorted electrical currents. The day of great novelty in radio broadcasting has passed; a large and increasing proportion of radio listeners are musically educated to a surprising degree; and these people will recognize and condemn imperfect results very quickly. The fact that a great proportion of the well-known makes of loud speakers are defective in much the same way, makes it possible to correct at the source, as stated in the paper, and give music-lovers a much

3. Public Address Systems, by I. W. Green and J. P. Maxfield.

4. The term "mile" as used in this discussion refers to the attenuation of one mile of standard cable at 800 cycles, corresponding to a relative power ratio of $e^{-0.218}$.

nearer approach to desired results than they would receive were all the apparatus to function in a distortionless manner, with the exception of loud speakers.

I am sorry to say that we have at present but little to present in the way of quantitative data on the performance of the glow discharge transmitter as regards variation of sensitivity with frequency or with load. Such data is being gathered as rapidly as possible, and will be presented at the earliest possible moment. We do know, however, that the load characteristic is very good; also that the sensitivity to extremely weak signals is quite as good, as determined by an audibility meter, at 20 cycles as at 4000 cycles, when proper allowance is made for the characteristics of the telephone receivers used.

I am sure that Mr. Jones will agree with me that, other things being equal, the pick-up having the least actual mass of material to be moved by the sound energy will give the best results. The results secured by the use of the condenser type transmitter, for instance, are admittedly superior, when the instrument is at its best, to anything obtainable with even the most perfect double button transmitter, although this superiority may not be evident from the response curves themselves, taken one note at a time. The ability to copy involved sound signals, such as those from a large orchestra, is much greater with the condenser type than with the double button. In fact, in the absence of any better type, the condenser has been taken as the accepted reference standard. A careful comparison between a glow discharge transmitter and a standard condenser transmitter, however, is indeed a revelation. It is surprising, to say the least, how much more natural the result sounds; how every individual instrument of a large orchestra may be as readily

picked out as can be done by the ear when listening at the source. We are convinced that this is due, in part at least, to the fact that the glow transmitter is, to all intents and purposes, a point receiver, without appreciable inertia, and at all times critically damped—having no natural period, high or low.

In reply to Mr. Robinson, I am obliged to repeat the statement that we have at present no quantitative data on frequency response curves from the glow discharge transmitter. We have some evidence of a qualitative nature, however, which seems to indicate a very high upper limit to the sensitivity. Although at least so far as we know extremely high frequencies are not transmitted by any existing loud speaker, we are developing an experimental device of this kind, which has a very high upper limit; and we have not been able to find, as yet, the limiting high frequency for the glow discharge microphone, with instruments of this type. As you probably know, the rattling of a bunch of keys fails entirely to be heard through the media of a transmitter and loud speaker of the usual type. Such signals come through in a satisfactory manner, when the condenser type transmitter or the glow discharge transmitter is used in connection with a loud speaker of the experimental type referred to above.

In conclusion, I would say that while there is no intention of detracting from the known good record of the better known types of transmitters, in their field, it is felt that the glow discharge transmitter is a decided step in advance. It is possible, however, that this in turn will be outdistanced by some other form of diaphragmless pick-up which will not have the disadvantage of high operating voltage with its attendant complications.

Report of the Board of Directors

FOR THE FISCAL YEAR ENDING APRIL 30, 1923

The Board of Directors of the American Institute of Electrical Engineers presents herewith to the membership its Thirty-ninth Annual Report, for the fiscal year ending April 30, 1923. A general balance sheet showing the condition of the Institute's finances on April 30, 1923, together with other detailed financial statements, is included herein. The following is a brief summary of the principal activities of the Institute during the year; more detailed information has been published from month to month in the Institute JOURNAL.

Directors' Meetings.—The bi-monthly meeting policy of the Board of Directors instituted in 1921 was continued through the past year with the Executive Committee functioning in the interim.

The Board held seven meetings during the year; six of these were held in New York and one at Niagara Falls, Ontario.

Information regarding the more important activities of the Institute which have been under consideration of the Board of Directors, the committees and the various officers, is published each month in the section of the JOURNAL devoted to "Institute Activities."

Meetings.—The policy of holding in addition to the Annual business meeting four general meetings of the Institute each year was continued. The meetings held were as follows: Annual, Pacific Coast, Midwinter and Spring Conventions.

Annual Meeting.—The Annual Business Meeting was held at Institute headquarters, New York, on May 19, 1922. The Annual Report of the Board of Directors for the fiscal year ending April 30, 1922 was presented. The Tellers Committee made its report upon the election of officers for the administrative year beginning August 1, 1922.

In the evening the members of the Board of Directors, past-presidents of the Institute and the president-elect met at dinner and informally discussed the affairs of the Institute.

Annual Convention.—The Thirty-eighth Annual Convention was held at Niagara Falls, Ontario on June 26 to June 30, 1922. Seven technical sessions were held, including two parallel sessions and one afternoon and one evening session. A total of thirty-four papers were presented. Among a total registration of 953 were representatives from 31 states, 7 foreign countries including 4 foreign engineering societies. The annual conferences of the Sections Committee were held on the Monday preceding the official opening of the convention, thirty-nine Sections were represented. Results of the conferences were published in pamphlet form.

Pacific Coast Convention.—The Eleventh Pacific Coast Convention was held at Vancouver, B. C. on August 8th to 11th, 1922. Seven technical sessions were held at which 18 papers and 4 addresses were presented. Attendance 235.

Midwinter Convention.—The Eleventh Midwinter Convention was held in New York on February 14-17, 1923. Seven technical sessions were held and

32 technical papers presented. One evening session was devoted to a joint New York-Chicago session with direct phone connection between the two cities with loud speakers so that papers and discussions were heard in each city simultaneously. The session concluded with a lecture on European Railway practise. Thursday evening a very successful smoker was held under the auspices of the New York Section. Friday night was assigned to the Annual Dinner-Dance. Total attendance was 1200.

Spring Convention.—The second Spring Convention of the Institute was held in Pittsburgh, Pa., April 24-26, 1923. Five technical sessions were held at which nineteen papers were presented. On one afternoon and evening all those attending were the guests of the Westinghouse Electric and Manufacturing Company at an inspection trip, banquet and entertainment. Another evening was devoted to a banquet and the last day to inspection trips.

Abstracts of the reports of the chairman of many of the Institute committees and delegations are included herein under various headings.

Meetings and Papers Committee.—This Committee has solicited and reviewed the papers submitted to the Institute for presentation and publication and has arranged, in cooperation with local convention committees, the programs for the Institute conventions held during the past year.

In 1921 there was inaugurated in the JOURNAL the use of a story of the specialist's paper designed to tell briefly of the conditions of the art, the reasons for writing the paper, the new material added by experimental and analytical work, and the general conclusions reached—all in language that is found acceptable to executives and readable by the membership at large. Only a few of these stories have been written.

Progress has been slow on account of the necessity of building up a staff of engineer-editors. There are available plenty of men of academic training who can criticise the expressions used, but they are not familiar with the technical subjects. On the other hand, there are plenty of engineers who understand thoroughly the technical work, but it is difficult to find engineers in all activities represented by fifteen technical committees who are trained and willing to devote the time and energy necessary to make the specialists' articles readable to a wider range of our membership. The conditions are not hopeless. Persistence in this effort

will finally result in making all the articles by specialists comprehensible to the general reader. To make improvements, a first requisite has been to induce authors to submit their papers early enough to allow time for editorial work. For the next Midwinter Convention it now seems practicable to enforce the ruling for receipt of papers three months in advance of the Convention.

One of the most important problems before the Committee is the best method of treating mathematical papers and increasing the number of readers of such papers. The Committee, recognizing the fact that only a small proportion of the Institute membership reads mathematical papers in detail, is developing a plan which it is hoped will result in emphasizing the importance of these papers by providing for their expansion into more readable form; this plan includes the publication of abstracts, including explanations that will interpret such papers for the benefit of the non-specialist, the publication of these papers in full in pamphlet form for circulation to those especially interested and the final publication in full in the *TRANSACTIONS*.

These mathematical papers which are often the real basis of advances in the art of electrical engineering, but which necessarily appeal to but a few specialists, will thus always be available for purposes of record and reference. By thus omitting a portion of the mathematical papers from the *JOURNAL* it will be possible to devote a larger proportion of space to high-class contributions upon engineering topics of more general interest.

Publication Committee.—The two main problems before the Publication Committee this year, as in recent years, were handling the material presented for publication so that the best interests of the membership and of the Institute shall be served at the minimum outlay in publishing costs, and through conferences with chairmen of other committees, Section chairmen, and thinking members widely distributed, gathering representative views and opinions of what classes of printed matter the *JOURNAL* should contain.

During the year various mechanical improvements have been made in the *JOURNAL* which have bettered the typographical makeup to an extent that has called forth favorable comment.

There is continuous pressure from various directions urging that in the monthly issues of the *JOURNAL* there should be a larger amount of "semi-technical" engineering material published. Various engineering groups, "theoretical" and "practical," look to the *JOURNAL* as an avenue of expression. Only a limited number of pages per year can be published, and the committee is using its best endeavors in cooperation with the Meetings and Papers Committee, to meet the wishes of the membership regarding the scope of the contents of the publications, keeping in mind the maintenance of the traditional high standard both in form and substance.

Sections and Branches.—The various Sections of the Institute throughout the country continued their activities during the past year upon about the same scope as heretofore as indicated by the brief reports published each month in the *JOURNAL*. Numerous requests were received for information relative to the formation of new Sections, indicating a strong desire on the part of the membership, so located geographically that they can not ordinarily take part in Institute meetings, to arrange for more active participation. Two new Sections were authorized and established, as follows: Southern Virginia and Springfield, Mass.

The activity among the Student Branches has been particularly marked during the past year. Many of the colleges have held a much larger number of meetings than heretofore as shown in the following table. New Branches were authorized at the University of Denver and at Northeastern University. Requests for Student enrollment were received in such volume and from such widely varying classes and types of schools that it was found desirable to revise the By-laws governing student enrollment so as to make them more definite. This was done under date of December 8, 1922.

Standards Committee.—By action of the Board of Directors on June 29, 1922, the Standards Committee was reorganized, the object being to create a body which would be better constituted to handle and correlate the manifold standardizing activities of the Institute. Under the new plan of organization, the executive work of the Committee has been placed in the hands of an Executive Committee now consisting of 12 members, which meets monthly. The development of standards is carried out by working committees of the Standards Committee and by representatives of the Committee on Sectional Committees and other cooperative standardizing bodies.

The Committee has undertaken a complete revision of the A. I. E. E. standards. The scope and character of this revision is described in the April *JOURNAL*. It is proposed that the revised standards will be in the form of a considerable number of sections, each section containing complete standards for one type of apparatus, or for one branch of the art. Between 20 and 30 of

such sections are now contemplated and the number will of course, be increased from time to time.

In connection with this revision, the Standards Committee has organized a cooperative effort with other interested organizations, with a view to arriving at a single set of standards for each type of apparatus, which set of standards can be presented to the American Engineering Standards Committee for adoption as American standards. To this end a Cooperative Committee has been formed, which now consists of one representative each of the A. I. E. E., the Electric Power Club, the N. E. L. A. and the A. M. E. S. The representatives of this Committee will present such subject matter as their societies think should properly be included in the suggested American standards, and pass judgment on the resulting compilation. The Committee already have before them a section of standards for control apparatus which has been made up in connection with the revision of the Institute standards.

In addition to the general revision, the Standards Committee has 15 working committees, who have in hand a large number of specific problems. These problems include the translation of the 1922 standards into Spanish, the development of proper standards and testing specifications for high-voltage insulators, the determination of temperature rise limits for Class "B" insulation, the preparation of standards for electric welding apparatus, metallic resistance materials and lightning arresters, the standardization of graphical symbols, and numerous other problems involving modifications in and additions to the present Standards.

About 25 members of the Standards Committee are engaged in the field of cooperative standardizing work as Institute representatives and as chairmen of Institute delegations on sectional committees and other cooperative standardizing bodies. The amount of this work in which the Institute is represented is rapidly increasing, and it is the purpose of the Standards Committee to correlate the work of the Institute's representatives, and to properly relate it to the standardizing work within the Institute itself.

American Engineering Standards Committee.—The following statistical summary of the work of the American Engineering Standards Committee, upon which the Institute is represented, is taken from the Year Book of the committee for 1922:

Member-bodies—organizations or groups of organizations whose representatives form the A. E. S. C.....	23
National organizations included in the Member-bodies.....	33
Representatives forming the Main Committee.....	55
Standards approved to January 1st, 1923.....	29
Standards up for approval by the A. E. S. C. on January 1st, 1923.....	45
Projects having official status (already approved, or on which work is under way)....	121

Projects for which sponsorship has been accepted.....	76
Organizations acting as sponsors for projects...	48
Trade, technical or governmental bodies co-operating through representatives on special or sectional committees.....	275
Individuals on sectional committees.....	917

A plan for increasing the income of the committee has been adopted, which provides for a new class of membership known as sustaining-members. A sustaining-member is an organization, firm or individual interested in the work of the Committee and contributing directly to its support. Sustaining-members are given a special information service on the progress of industrial standardization work in this country and abroad. A schedule of recommended subscriptions has been arranged.

The Federal Specifications Board which has been organized to unify the specifications of the various departments and independent establishments of the Government has appealed to the Committee to aid it in its work, and cooperative arrangements between the Board and the A. E. S. C. have been made by which the Government specifications are being submitted, at first informally, for criticism by industry and to determine their acceptability to industry. It is expected that in future editions many, if not most, of the specifications adopted by the Federal Specifications Board will go through the regular procedure of the A. E. S. C. in order that the industrial and Government specifications may be unified, resulting in truly national specifications recognized by industry and Government alike.

Among specifications which have already been submitted to the A. E. S. C. under the cooperative arrangement are those for dry cells, snap switches, rigid conduits, and rubber insulated wires and cables. Other electrical projects which have an official status before the Committee are: electrical fire and safety code; safety code for electrical power control; safety code for lightning protection; terminal markings for electrical apparatus; rating of electrical machinery; insulated wires and cables (other than telephone and telegraph); symbols for electrical equipment of buildings and ships; electrical properties of aluminum; electrical installations on shipboard; specification for 600-volt d-c. overhead trolley construction; electrical safety rules for bituminous coal mines.

The cordial arrangement between the Committee and the Division of Simplified Practice of the Department of Commerce has been continued during the year. The work of the Committee generally has increased very rapidly but it is expected that the new financial arrangements will make it possible to care adequately for the new projects.

U. S. National Committee of the I. E. C.—This Committee has held two general meetings and the Executive Council of the Committee has held several meetings during the year. It has not been possible

for the Committee to work on proposals to the I. E. C. on the Rating of Electrical Machinery pending further progress by the A. E. S. C. Sectional Committee on that subject. To the meeting of the I. E. C. Advisory Committee on Rating held in Geneva, Switzerland, in November, recognizing the great desirability of general international discussion on the subject for the adjustment of differences of attitude and policy in regard to the basis and specification of rating which had arisen shortly after the Brussels meeting of 1920, a delegation was sent representing all the different views held in this country. The Advisory Committee was therefore able to obtain a very clear conception of the different views outstanding here, although our Committee made no proposals and assumed a neutral open minded participation in the discussions of the subject.

No restrictions were necessary in regard to the participation of the delegation in the work of the three other Advisory Committees, namely the Committees on Edison Screw Lamp Bases and Sockets, on Standard Pressures and on Graphical Symbols, and it took an active part in the work of all these committees. The outcome of deliberations on a uniform Edison socket was very satisfactory, the prospect being opened of an internationally standardized socket. Complete report of the Committee has been filed with A. I. E. E.

U. S. National Committee, International Commission on Illumination—This Committee has held during the past year two formal meetings and a number of less formal conferences.

The principal question before the Committee during the past year has been the matter of holding a plenary session of the I. C. I. in this country in 1924. It was voted at the Paris meeting of 1922 that such a meeting should be held, but the troubled conditions in Europe have somewhat clouded the prospects of success of such a meeting. However, it is still hoped that the original plan can be successfully carried out. Preliminary arrangements to that end have been quite fully discussed and some of the necessary committees have been appointed, so that when the general question is once decided, there need be no loss of time in getting to work.

In the meantime the international committees of the Commission have been put into operation, and work is in progress which will come up for discussion at the next plenary session.

Three of the delegates of the A. I. E. E. have been abroad during the year and have had useful discussions with officers of other National Committees regarding the work, with the result that in several respects decided gains have been made.

Committee on Safety Codes.—The work of the Committee on Safety Codes, which formerly related chiefly to the Electrical Codes, is gradually broadening to include various kinds of codes as they are being developed under the organization of the American Engineering Standards Committee.

The Chairman of this Committee represents the Institute on the following committees:

(a) The National Electrical Committee of the National Electrical Protective Association, which has to do chiefly with interior wiring. (b) The Sectional Committee of the A. E. S. C., for the revision of part 2 of the National Electrical Safety Code. (c) The Sectional Committee of the A. E. S. C. on Safety Code for Electrical Power Control.

The National Electrical Code is revised biennially, the latest revision becoming effective during the year 1923.

The Sectional Committee, for the revision of part 2 of the National Electrical Safety Code, has been organized into four subcommittees during the past year and the work is proceeding in an orderly way.

The Sectional Committee on Safety Code for Electric Power Control has also been organized and is gathering data for the formulation of rules relating to this subject.

The Institute has been asked to designate representatives to act for it in the formulation of safety codes for electrical work in mines and for electrically operated elevators. In these cases the Safety Codes Committee has recommended the appointment of members of the Institute who are specialists in these subjects who are not members of the Safety Codes Committee.

Research Committee.—The principal efforts of the Committee have been directed to the preparation of a comprehensive statement of the experimental problem in the field of research on electrical insulation. The results of this work are embodied in a report which will be published in the JOURNAL for June 1923.

In addition, the Research Committee has, through correspondence, endeavored to stimulate experimental work, has urged the completion of several investigations already under way.

Technical Committees.—Reports of Technical Committees embracing an outline of the year's work and a summary of progress in the industry will be presented at the Annual Convention and printed in the JOURNAL.

Membership.—The results of the Membership Committee's efforts this year are shown in the following table:

	Honor-ary Member	Fellow	Member	Assoc-iate	Total
Membership, April 30, 1922 . . .	6	558	2,097	11,602	14,263
Additions:

Membership, April 30, 1923 . . .	6	578	2,264	12,450	15,298
Net increase in Membership during the year					1035

Deaths.—The following deaths have occurred during the year.

Fellows: Clare F. Beams, John F. Kelly, Arthur B. Stitzer, Schuyler Skaats Wheeler, M. Yokura.

Members: Frank J. Baker, Alexander Graham Bell, Harry H. Blades, Robert E. Chetwood, William Hamilton Garfield, William A. La Due, Alexander Lodyguine, William B. Vansize, George G. Ward, Valentine C. Wynne.

Associates: George J. Blum, William J. Clark, William W. Comstock, Charles W. Davis, F. G. Dieterich, B. H. Elkins, Henry W. Elsasser, J. T. Fahy, David D. Faris, Walter G. Franz, Frank W. Frueauff, George H. Guy, Thomas S. Haddaway, T. T. Haldeman, Roscoe S. Helvie, Robert W. Hemphill, Jr., James H. Jeans, J. J. Hunter Johnston, Thomas F. Judge, Sadaharu Katsuno, P. O. Keilholtz, Thomas W. Kennedy, J. E. Kershner, Frank P. Lewis, F. N. Maddux, F. L. Marsh, John Martin, Herbert S. Miller, Merritt B. Miller, O. B. Moorhead, L. B. Newell, H. J. Norregaard, Clyde Pattee, John C. Pennie, James M. Petrie, Byrl C. Rathburn, Luke Robinson, Dwight C. Rockwood, William Russin, Walter Schmidt, H. E. Shaw, Frank Warren Smith, Ralph W. Stearns, Edward R. Tracy, Frank S. Washburn, William P. White, F. G. Wiswell, Walker Gill Wylie.

Total deaths, 63.

Board of Examiners.—The Board of Examiners during the year held ten meetings, averaging about two hours and 45 minutes each. It considered and referred to the Board of Directors a total of 4137 applications for admission or transfer to the higher grades. This is an increase of about 20% over the figures of last year and is very close to the figures of the year ending April 30, 1921, the record year in Institute growth.

Total.....	4144	

Committee on Code of Principles of Professional Conduct.—During the year a new edition of the code as adopted by the Board of Directors in 1912 has been published, distributed, and commented upon in a number of the leading technical publications of the country.

Since the adoption of the code by the Institute in 1912, several other engineering societies have also adopted codes of conduct, including the national societies of civil and mechanical engineers; and these other societies have also established committees, or other agencies, for the administration and enforcement of such codes.

American Committee on Electrolysis.—The American Committee on Electrolysis as a whole has been inactive during the past year, but the work of the Committee is going forward gradually through the compilation by its Research Committee of data that it is believed will be valuable in the work of the main Committee.

Scholarships.—The governing bodies of Columbia University placed at the disposal of the Institute a scholarship in Electrical Engineering beginning with the academic year 1922-23 and continuing until further notice. The scholarship pays \$350 toward the annual tuition, and reappointment for completion of course is conditioned upon maintenance of good standing.

Two applications have been received for this scholarship for the year 1923-24 but no award has yet been made as neither applicant has submitted the information which will enable the committee to arrive at a decision.

The announcement of the availability of the scholarship was made in the monthly Institute JOURNAL and also by means of a circular letter addressed to the professors of electrical engineering in the principal educational institutions of the country in which electrical engineering courses are given.

Institute Prizes.—At the meeting of the Board of Directors of the Institute of April 16, 1921, recommendations were approved establishing two Institute prizes to be awarded yearly to authors of worthy papers. The 1921 Transmission Prize was awarded to F. C. Baum for his paper presented at the Salt Lake City Annual Convention, June 1921. Although all Sections were notified early in the year and announcements were printed in the JOURNAL, no "First Paper Prize" was awarded for the year 1921 as no paper was offered in competition. The awards for papers presented in 1922 will probably be announced in June 1923.

North Eastern District Prize.—In December 1922 the Executive Committee of the North Eastern District established a cash prize of \$25.00, and certificate, to be awarded each year to the author of the most worthy paper presented before any Section in District No. 1 during the Institute year and who has never had a paper published in the JOURNAL or TRANSACTIONS.

For complete details and conditions of award see the JOURNAL for April 1923.

International Engineering Congress in Brazil.—On the invitation of the Brazilian Embassy to the engineering societies of this country the Institute appointed eight delegates to the International Engineering Congress, held in Rio de Janeiro, Brazil, September 7 to 30, 1922. A program calling for the presentation of a number of papers was arranged and carried out. For details see August, September and November JOURNALS, 1922.

Edison Medal.—The Edison Medal for 1922 has been awarded to Dr. Robert A. Millikan of Pasadena, Cal., for his experimental work in electrical science. The presentation will be made during the Pacific Coast Convention of the Institute at Del Monte, California, October 2-5, 1923.

John Fritz Medal.—The John Fritz Medal Board of Award, which is composed of representatives of the national societies of Civil, Mining, Mechanical and Electrical Engineers, awarded the medal to Senator Guglielmo Marconi "for the invention of wireless telegraphy." The medal was presented at a large gathering of engineers at the Engineering Societies Building, New York on the evening of July 6, 1922.

Employment Service.—The employment service maintained for many years at Institute headquarters and during the latter part of 1918 coordinated with the similar service of the other Founder Societies, and which on January 1, 1921 was transferred to the auspices of American Engineering Council, was returned to the control of the Founder Societies under date of July 1, 1922 and is now being conducted under the supervision of a Board consisting of the secretaries of these Societies for the benefit of members only. A committee was appointed by the Societies to study the whole question of conducting and developing the service and the report has recently been prepared for consideration by the governing boards of the Societies.

In addition to a direct service, the Bureau prepares an engineering service bulletin which is published each month in the Institute JOURNAL and it has served to place many members in positions of responsibility, both in this country and abroad. The bulletin is subdivided into two parts: one containing announcements of vacancies; and the other containing lists of men available, with condensed records of their experience. All announcements are published without charge either to the employers or to the members of the Institute seeking positions.

Federated American Engineering Societies.—The 1923 roster is made up of six national societies having a total membership of 42,627 and 22 local societies having a membership of 6920, an aggregate of 49,587. In 1921 the total number of members of the participating societies was 41,932. American Engineering Council has functioned with 64 delegates and held its annual meeting in Washington on January

11-12. The Executive Board composed of 30 members has held 4 meetings, namely: Pittsburgh, May 26-27, 1922; Boston, Sept. 8-9, 1922; Washington, at the time of the Annual Council meeting, Jan. 11-12, 1923; and Cincinnati, March 23-24, 1923. In the interim between these meetings the Procedure Committee has held a number of meetings at irregular periods and whenever necessity required it.

The meeting of the Council and meetings of the Executive Board and of the Procedure Committee have been very well attended and while developing the liveliest discussions regarding the various subjects under consideration, have been marked with an earnestness and sincerity of purpose that is very gratifying and by an ultimate harmony of conclusions. The views of the Institute representatives have been treated with the utmost consideration, and it is safe to say that no policies to which they have objected have ever been adopted.

American Engineering Council has been active through its officers and Committees over a wide range during the year but as these activities have been chronicled from month to month in the JOURNAL, they will not be recapitulated here. It is believed that this organization is performing a very useful function. It is both serving the nation and increasing the prestige of engineers. The Institute's representatives believe that the Institute took a wise step in supporting American Engineering Council and that it should retain its membership therein and continue to participate vigorously in its activities.

United Engineering Society.—This Society performs for the national societies of Civil, Mining, Mechanical and Electrical Engineers, certain specific acts which are governed by contracts; the primary function of the United Society being to hold in trust and to administer for these societies the Engineering Societies Building, in which the headquarters of the national societies are located.

Extracts from the annual financial report of the United Engineering Society were published in the March 1923 JOURNAL.

Engineering Societies Library.—The library of the Institute is combined with the libraries of the national societies of Civil, Mining and Mechanical Engineers, administered as the "Engineering Societies Library" under the direction of the Library Board of the United Engineering Society; this board is composed of representatives of each of the four societies referred to above.

In order to place the facilities of the library at the disposal of persons residing at a distance from New York, a Library Service Bureau has been established, and a staff of expert searchers and translators is employed to cover almost any engineering topic, in the following manner: abstracting, translating, bibliographing, statistical searches and reports, searches

for patent purposes, copying, preparing reference cards, etc.

An abstract of the annual report of the Engineering Societies Library covering the calendar year 1922 was published in the March 1923 JOURNAL.

Engineering Foundation.—Engineering Foundation is a trust fund established in 1914 by Ambrose Swasey, of Cleveland, Ohio, by gifts to United Engineering Society as a nucleus of a large endowment "for the furtherance of research in science and in engineering, or for the advancement in any other manner of the profession of engineering and the good of mankind." It is administered by the Engineering Foundation Board upon which the Institute and other national engineering societies are represented. The Board is a Department of United Engineering Society.

During latter part of 1922 in order to meet expanding activities the office of Director of the Engineering

Foundation was established and Alfred D. Flinn, who retired as Chairman of Engineering Division, National Research Council, was selected to fill the post.

Representatives.—The Institute has continued its representation upon various national committees and other local and national bodies with which it has been affiliated in past years, and has appointed representatives upon a number of new Sectional Committees of American Engineering Standards Committee and upon the Charles A. Coffin Fellowship and Research Fund Committee. A complete list of representatives is published frequently in the JOURNAL.

Finance Committee.—During the year the committee has held monthly meetings, has passed upon the expenditures of the Institute for various purposes, and otherwise performed the duties prescribed for it in the Constitution and By-laws.

Haskins and Sells, certified public accountants, have audited the books, and their report follows:

American Institute of Electrical Engineers,
33 West 39th Street,
New York.

Dear Sirs:

Pursuant to engagement, we have audited your books and accounts for the year ended April 30, 1923, and submit herewith our certificate and the following described exhibits and schedule:

Exhibit "A"—General Balance Sheet, April 30, 1923.

Schedule No. 1—Reserve Capital Fund—Securities.

Exhibit "B" Summary of Income and Profit & Loss for the Year ended April 30, 1923.

Yours truly,

HASKINS & SELLS

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

CERTIFICATE OF AUDIT

We have audited the books and accounts of the American Institute of Electrical Engineers for the year ended April 30, 1923, and

WE HEREBY CERTIFY that the accompanying General Balance Sheet properly exhibits the financial condition of the Institute at April 30, 1923, that the Summary of Income and Profit & Loss for the year ended that date is correct, and that the books of the Institute are in agreement therewith.

HASKINS & SELLS

 F. S. Clark, L. A. Hawkins, G. W. Pierce,
 E. H. Colpitts, D. C. Jackson, H. J. Ryan,
 E. E. F. Creighton, A. E. Kennelly, C. H. Sharp,
 W. A. Del Mar, J. R. Klumpp, C. E. Skinner.

SPECIAL COMMITTEES

COLUMBIA UNIVERSITY SCHOLARSHIP

Francis Blossom, Chairman, 52 William St., New York.
 Frank B. Jewett, W. I. Slichter.

AWARD OF INSTITUTE PRIZES

E. E. F. Creighton, Chairman, General Electric Co., Schenectady, N. Y.
 Chairmen of Technical Committees.

TECHNICAL COMMITTEES

EDUCATIONAL

W. E. Wickenden, Chairman, 195 Broadway, New York.
 W. C. Bauer, C. E. Magnusson, Harold B. Smith,
 Edward Bennett, G. H. Pfeif, W. L. Upson,
 C. R. Dooley, H. W. Price, J. B. Whitehead,
 Charles S. Howe, Charles F. Scott, Wm. R. Work.

ELECTRICAL MACHINERY

B. A. Behrend, Chairman, 85 Devenshire St., Boston, Mass.
 A. S. McAllister, Secretary, 455 W. 153rd St., New York.
 B. L. Barns, V. A. Fynn, P. M. Lincoln,
 R. E. Brown, David Hall, H. P. Liversidge,
 James Burke, H. U. Hart, F. D. Newbury,
 N. A. Carle, H. M. Hobart, R. F. Schuchardt,
 G. Faccioli, V. Karapetoff, Philip Torchio,
 W. J. Foster, R. B. Williamson.

ELECTROCHEMISTRY AND ELECTROMETALLURGY

J. L. Yardley, Chairman, W. E. & M. Co., East Pittsburgh, Pa.
 F. G. Clark, Carl Hering, J. A. Seede,
 Saul Dushman, L. E. Imlay, G. W. Vinal.

ELECTROPHYSICS

F. W. Peek, Jr., Chairman, General Electric Co., Pittsfield, Mass.
 E. F. Burton, Wm. Fondiller, Chester W. Rice,
 L. W. Chubb, Charles Fortescue, F. B. Silsbee,
 J. C. Clark, Roy S. Glasgow, H. B. Smith,
 C. P. Eldred, E. P. Hyde, J. B. Whitehead,
 J. H. Morecroft.

INDUSTRIAL AND DOMESTIC POWER

H. D. James, Chairman, W. E. & M. Co., East Pittsburgh, Pa.
 P. H. Adams, C. W. Drake, H. W. Rogers,
 S. F. Davies, T. D. Montgomery, W. I. Slichter.

INSTRUMENTS AND MEASUREMENTS

G. A. Sawin, Chairman, W. E. & M. Co., East Pittsburgh, Pa.
 P. A. Borden, A. L. Ellis, Irving B. Smith,
 H. B. Brooks, Paul MacGahan, H. C. Snook,
 F. P. Cox, F. V. Magalhaes, F. W. Springer,
 E. D. Doyle, H. S. Vassar.

IRON AND STEEL INDUSTRY

E. S. Jefferies, Chairman, Steel Co. of Canada, Hamilton, Ont.
 P. B. Crosby, W. S. Hall, G. E. Stoltz,
 Gordon Fox, E. T. Moore, N. W. Storer,
 Eugene Friedlaender, D. M. Petty, Wilfred Sykes,
 R. B. Gerhardt, J. D. Wright.

LIGHTING AND ILLUMINATION

G. H. Stickney, Chairman, Edison Lamp Works, G. E. Co., Harrison, N. J.
 A. B. Cooper, G. C. Hall, R. C. Powell,
 E. C. Crittenden, Henry Logan, Charles F. Scott,
 W. T. Dempsey, A. S. McAllister, B. E. Shackelford,
 F. F. Fowle, J. F. Meyer, W. M. Skiff.

MARINE

G. A. Pierce, Jr., Chairman, W. Cramp & Sons S. & E. B. Co., Philadelphia, Pa.
 L. C. Brooks, Secretary, Bethlehem Shipbuilding Corp. Ltd., Quincy, Mass.
 J. B. Bassett, Wm. Hetherington, Jr. I. H. Osborne,
 R. A. Beekman, H. L. Hibbard, Arthur Parker,
 Maxwell W. Day, J. S. Isdale, H. A. Pratt,
 E. G. Gallagher, Wm. F. James, H. M. Southgate,
 Com. C. S. Gillette, Com. M. A. Libbey, W. E. Thau,
 H. Franklin Harvey, Jr., Com. C. S. McDowell, A. E. Waller,
 W. F. Meschenmoser.

MINES

Graham Bright, Chairman, W. E. & M. Co., East Pittsburgh, Pa.
 Willard C. Adams, L. C. Ilsley, D. C. McKeegan,
 R. T. Andrae, G. M. Kennedy, W. F. Schwedes,
 C. N. Beebe, R. L. Kingsland, F. L. Stone,
 M. C. Benedict, A. B. Kiser, W. A. Thomas,
 H. W. Eales, C. D. Woodward.

POWER STATIONS

Nicholas Stahl, Chairman, Turks Head Building, Providence, R. I.
 H. A. Barre, F. C. Hanker, D. C. McClure,
 J. T. Barron, C. F. Hirshfeld, I. E. Moulthrop,
 A. E. Bauhan, H. A. Kidder, A. L. Penniman,
 E. T. Brandon, W. H. Lawrence, F. A. Scheffler,
 D. H. Braymer, H. P. Liversidge, R. F. Schuchardt,
 H. W. Eales, R. B. Williamson.

PROTECTIVE DEVICES

H. R. Woodrow, Chairman, 360 Pearl Street, Brooklyn, N. Y.
 G. H. Bragg, B. G. Jamieson, F. E. Ricketts,
 P. H. Chase, M. G. Lloyd, D. W. Roper,
 L. B. Chubbuck, A. A. Meyer, C. H. Sanderson,
 F. C. Hanker, W. H. Millan, E. R. Stauffacher,
 S. E. M. Henderson, A. G. Pierce, E. C. Stone,
 E. A. Hester, N. L. Pollard, A. H. Sweetnam,
 F. L. Hunt, John B. Taylor.

TELEGRAPHY AND TELEPHONY

O. B. Blackwell, Chairman, 195 Broadway, New York.
 C. W. Burkett, H. W. Drake, Chester W. Rice,
 G. A. Cellar, D. H. Gage, J. K. Roosevelt,
 H. P. Charlesworth, H. Hulatt, Gen. Edgar Russell,
 L. W. Chubb, F. H. Kroger, Arthur B. Smith,
 E. H. Colpitts, F. J. Mayer, I. J. Thorp,
 R. N. Conwell, L. F. Morehouse, F. A. Wolff,
 C. E. Davies, W. O. Pennell, C. A. Wright,
 F. A. Raymond.

TRACTION AND TRANSPORTATION

N. W. Storer, Chairman, W. E. & M. Co., East Pittsburgh, Pa.
 George Gibbs, W. S. Murray, Hugh Pattison,
 Dugald C. Jackson, W. B. Potter.

TRANSMISSION AND DISTRIBUTION

E. B. Meyer, Chairman, 80 Park Place, Newark, N. J.
 R. W. Atkinson, F. M. Farmer, C. N. Rakestraw,
 A. E. Bauhan, L. M. Klauber, C. C. Robinson,
 F. G. Baum, J. A. Koontz, Jr. D. W. Roper,
 Wallace S. Clark, C. H. Kraft, C. E. Schwenger,
 W. H. Cole, W. S. Lee, C. H. Shaw,
 R. N. Conwell, G. J. Newton, Robert Sibley,
 W. A. Del Mar, A. M. Perry, W. K. Vanderpoel,
 L. L. Eiden, G. G. Post, C. T. Wilkinson.

ON AMERICAN ASSOCIATION FOR THE ADVANCEMENT
OF SCIENCE, COUNCIL

A. E. Kennelly, John B. Taylor.

ON AMERICAN BUREAU OF WELDING

W. L. Merrill.

A. I. E. E. Representatives

ON AMERICAN COMMITTEE ON ELECTROLYSIS

Bion J. Arnold, N. A. Carle, F. N. Waterman.

ON AMERICAN ENGINEERING COUNCIL OF THE
FEDERATED AMERICAN ENGINEERING SOCIETIES

Comfort A. Adams, W. A. Layman, Charles S. Ruffner,
 *C. G. Adsit, *William McClellan, *Charles F. Scott,
 John H. Finney, *L. F. Morehouse, C. E. Skinner,
 F. L. Hutchinson, L. T. Robinson, L. B. Stillwell,
 *Frank B. Jewett, Calvert Townley,
 *Members of Executive Board.

ON AMERICAN ENGINEERING STANDARDS COMMITTEE

H. M. Hobart, Harold Pender, C. E. Skinner,
 L. T. Robinson (Alternate)

ON BOARD OF TRUSTEES, UNITED ENGINEERING SOCIETY

H. H. Barnes, Jr., Bancroft Gherardi, H. A. Lardner.

ON CHARLES A. COFFIN FELLOWSHIP AND RESEARCH FUND
COMMITTEE

Frank B. Jewett.

ON ENGINEERING FOUNDATION BOARD

Frank B. Jewett, E. W. Rice, Jr.

ON FRANCO-AMERICAN ENGINEERING COMMITTEE

A. M. Hunt, L. B. Stillwell.

ON JOHN FRITZ MEDAL BOARD OF AWARD

A. W. Berresford, John J. Carty, Frank B. Jewett,
Wm. McClellan.

ON JOSEPH A. HOLMES SAFETY ASSOCIATION

John H. Finney.

ON LIBRARY BOARD OF UNITED ENGINEERING SOCIETY

Edward D. Adams, F. L. Hutchinson, W. I. Slichter,
E. B. Craft, Alfred W. Kiddle.

ON NATIONAL FIRE PROTECTION ASSOCIATION, ELECTRICAL COMMITTEE

The chairman of the Institute's Committee on Safety Codes.

ON NATIONAL RESEARCH COUNCIL, ENGINEERING DIVISION

C. A. Adams, Bancroft Gherardi, W. R. Whitney.

ON U. S. NATIONAL COMMITTEE OF THE INTERNATIONAL ILLUMINATION COMMISSION

A. E. Kennelly, C. O. Mailloux, Clayton H. Sharp.

ON WASHINGTON AWARD, COMMISSION OF

John Price Jackson, Charles F. Scott.

LIST OF SECTIONS

Name	Chairman	Secretary
Akron.....	S. C. Henton	A. P. Regal
Atlanta.....	G. K. Selden	H. N. Pye
Baltimore.....	W. B. Kouwenhoven	F. T. Leilich
Boston.....	E. L. Moreland	F. S. Dellenbaugh
Chicago.....	F. E. Goodnow	J. E. Kearns
Cincinnati.....	A. M. Wilson	C. G. Eichelberger
Cleveland.....	L. D. Bale	Chester L. Dows
Columbus.....	F. C. Caldwell	F. C. Nesbitt
Connecticut.....	E. H. Everit	A. E. Knowlton
Denver.....	H. B. Barnes	R. B. Bonney
Detroit-Ann Arbor.....	J. H. Cannon	E. L. Bailey
Erie.....	W. J. Seibert	M. W. Metzner
Fort Wayne.....	S. W. Greenland	A. B. Campbell
Indianapolis-Lafayette.....	D. C. Pyke	J. W. Hannon
Ithaca.....	J. G. Pertsch, Jr.	Geo. F. Bason
Kansas City.....	Geo. C. Shaad	W. E. A. Nottorf
Lehigh Valley.....	D. M. Petty	H. G. Harvey
Los Angeles.....	J. N. Kelman	E. R. Stauffacher
Lynn.....	J. W. West	W. M. Howe
Madison.....	H. M. Crothers	R. G. Walter
Milwaukee.....	G. G. Post	F. A. Kartak
Minnesota.....	Fred A. Otto	H. W. Meyer
New York.....	Calvert Townley	A. E. Waller
Oklahoma.....	F. W. Insull	A. D. Stoddard
Panama.....	F. B. Coyle	M. P. Benninger
Philadelphia.....	E. B. Tuttle	Ross B. Mateer
Pittsburgh.....	E. C. Stone	O. Needham
Pittsfield.....	W. P. White	A. C. Stevens
Portland, Ore.....	D. W. Proebstel	E. F. Pearson
Providence.....	R. W. Adams	F. N. Tompkins
Rochester.....	G. A. Scoville	E. A. Roeser
St. Louis.....	J. M. Chandlee	Lee S. Washington
San Francisco.....	H. H. Henline	A. G. Jones
Schenectady.....	C. M. Davis	C. W. Fick
Seattle.....	C. F. Terrell	E. S. Code
Southern Virginia.....	Wm. C. Bell	H. C. Leonard
Spokane.....	H. L. Melvin	E. R. Hannibal
Springfield, Mass.....	W. A. Dick	J. Frank Murray
Syracuse.....	R. D. Whitney	Elmer E. Strong
Toledo.....	Gilbert Southern	Max Neuber
Toronto.....	S. E. M. Henderson	D. B. Fleming
Urbana.....	H. A. Brown	E. B. Paine
Utah.....	C. C. Pratt	C. R. Higson
Vancouver.....	T. H. Crosby	F. W. MacNeill
Washington, D. C.....	L. T. Blaisdell	Roland Whitehurst
Worcester.....	F. J. Adams	Stuart M. Anson
Total 46.		

LIST OF BRANCHES

Name and Location	Chairman	Secretary
Alabama Poly. Inst., Auburn, Ala.	K. H. Stough	J. F. Nettles
Alabama, Univ. of, University, Ala	J. M. Lakeman	R. L. Harris
Arizona, Univ. of, Tucson, Ariz.	R. A. Macdonald	H. A. Hillman
Arkansas, Univ. of, Fayetteville, Ark.	R. C. Mason	E. J. Anderson

Total 70.		

INDEX

INDEX OF PAPERS, DISCUSSIONS AND REPORTS

A

Alabama Power Co. Installation, The (W. W. Lewis) . . .	419
Analysis of Experiments (Chester W. Rice)	664
Analyzer, Another Harmonic (F. S. Dellenbaugh, Jr.) . . .	1138
See index page	
Anchors and Tower Supports, Insulation Design of, for 110,000-Volt 4427-Foot Span Over Carquinez Straits (L. J. Corbett)	977
Annual Reports 1922-1923, Technical Committee	753
Antenna, A New Type of Highly Directive, The Wave Antenna (H. H. Beverage, C. W. Rice and E. W. Kellogg)	215
Apparatus, Methods of Tests and (J. L. R. Hayden and W. N. Eddy)	594
Apparent Dielectric Strength of Cables, The (Robert J. Wiseman)	1
Applications and Limitations of Thermocouples for Measuring Temperatures (Irving B. Smith)	349
— of Electric Motors for Driving Tube Mills (Fraser Jeffery). See index page	1138
— — Long Distance Telephony on the Pacific Coast (H. W. Hitchcock)	1071
Arcing Ground, Voltage Induced by (J. F. Peters and J. Slepian)	478
Art of Sealing Base Metals Through Glass (William G. Houskeeper)	870
Artificial Electric Lines, A General Consideration of T- and Pi-Type, In Connection with a Proposed Compensated Pi-Line (H. Nukeyama and K. Okabe)	824
— Transmission Lines with Distributed Constants (F. S. Dellenbaugh, Jr.)	803
Auto Transformers, Performance of, with Tertiaries Under Short-Circuit Conditions (J. Mini, Jr., L. J. Moore and R. Wilkins)	1060
Automatic Railways Substations, Discussion of Application and Economics of (L. D. Bale)	127
— Train Control Problem, The (E. J. Blake)	117
Axially Controlled Magnetron, The (Albert W. Hull)	915

B

Balance Methods in Alternating Current Measurement (Perry A. Borden)	395
Base Metals, The Art of Sealing, Through Glass (William G. Houskeeper)	870
"Blondelion," The, A Kinematic Device which Indicates the Performance of a Polyphase Synchronous Generator or Motor (Vladimir Karapetoff)	144
Bus Supports, Magneto-Mechanical Loads on (Lloyd N. Robinson)	1020
Busbars, Mechanical Forces on, under Short-Circuit Conditions (C. H. Van Asperen)	1091
Bushings, Lightning Arresters, High-Voltage Switches (Harold Michener)	1015

C

Cable, A New Method for the Routine Testing of Alternating-Current High-Voltage Paper-Insulated (H. S. Phelps and E. D. Tanzer)	54
— Charge and Discharge (Charles P. Steinmetz)	577
— Geometry and the Calculation of Current-Carrying Capacity (Donald M. Simons)	600
Cables, Apparent Dielectric Strength of (Robert J. Wiseman)	1
Calculation, Cable Geometry and the, of Current-Carrying Capacity (Donald M. Simons)	600
— Mathematical (Charles P. Steinmetz)	474
Calculations, Numerical (Charles P. Steinmetz)	590
Capacity, Cable Geometry and the Calculation of Current-Carrying (Donald M. Simons)	600
Carrier-Current Communication, Recent Developments in (Leonard F. Fuller)	1082
— — Telephone, Some Experiences with a 202-Mile (E. A. Crellin)	1086

— — Telephony on the High-Voltage Transmission Lines of the Great Western Power Company (John A. Koontz, Jr.)	1089
Cement, Power Absorbed in Making a Barrel of Portland (S. H. Harrison). See index page	1138
Charge and Discharge, Cable (Charles P. Steinmetz)	577
Circuit-Breakers, High-Voltage (A. W. Copley)	1019
— — Switches and Fuses, Subcommittee on (B. G. Jamieson, Chairman)	753
Circuits, Telephone Equipment for Long Cable (Charles S. Demarest)	742
— Transmission over Long Cable (Alva B. Clark)	86
Classification of Temperature Measurement (Irving B. Smith)	353
Committee, Electrical Machinery	787
Complex Angles, Physical Interpretation of, and their Functions (Aram Boyajian)	279
Computing Kinematic Device, A, The "Heavisidion," for Long Transmission Lines (Vladimir Karapetoff) . . .	42
Conclusions and Summary (E. C. Stone)	452
— Summary and (Chester W. Rice)	674, 699
Conductors of Telegraph and Telephone Lines, Wind Shielding Between (P. J. Howe)	205
Consideration, Physical (Charles P. Steinmetz)	577
Continuous-Current Generator for High Voltage (I. R. Bergman)	910
Control, The Automatic Train, Problem (E. J. Blake) . . .	117
Convection, Experiments on Forced Heat, in Gases and Liquids (Chester W. Rice)	687
— Langmuir's Film Theory of (Chester W. Rice)	677
— of Heat in Gases and Liquids, Free and Forced (Chester W. Rice)	653
Conversion, Frequency by Third Class Conductor and Mechanism of the Arcing Ground and other Cumulative Surges (Charles P. Steinmetz)	470
Cooling of Electric Machines, The (George E. Luke)	636
Current-Limiting Reactors, (Operating Experience with (N. L. Pollard)	546
Currents, Experimental Determination of Short-Circuit, in Electric Power Networks (O. R. Schurig)	10
Cylinders, Forced Heat Convection from (Chester W. Rice)	679
— Summary of Available Data on Free Convection from (Chester W. Rice)	665

D

Design Constants and Measuring Units (Lawrence E. Widmark). See index page	1138
Developments in Autovalue Lightning Arresters 1922 (A. L. Atherton)	179
— of the Large Electric Melting Furnace (Frank Hodson). See index page	1138
Discussion, see page	1138
Diaphragmless Microphone for Radio Broadcasting, A (Phillips Thomas)	1111
Dielectric Strength Ratio Between Alternating and Direct Voltages (J. L. R. Hayden and W. M. Eddy) . . .	593
Dielectrics-III, The Effect of Transient Voltages (F. W. Peek, Jr.)	940
Dimensions, Film Thickness, by the Method of (Chester W. Rice)	660, 678
Discharge, Cable Charge and (Charles P. Steinmetz)	577
Discussion of Application and Economics of Automatic Railway Substations (L. D. Bale)	127
Dissymmetrical Electrical Conducting Networks (A. E. Kennelly)	267
Distance Relay for Automatically Sectionalizing Electrical Networks, The (Leslie N. Crichton)	527
Distribution Circuits, Lightning Disturbances on (Malcolm MacLean)	538
Disturbances, Lightning on Distribution Circuits (Malcolm MacLean)	538
Duplication and Safeguarding in the Electrical Equipment of a Generating Station, Desirable (William F. Sims). See index page	1138
Discussion, see index page	1138

Duquesne Light Company, Selective Relay System of the 66,000-Volt Ring of the, (H. P. Sleeper).....

E

Eastman Theatre and School of Music, Electrical and Illuminating Equipment of the (Frederic A. Mott and Lloyd A. Jones). See index page..... 1138
 Economic Considerations of the Power Factor Control of Long High-Voltage Lines (A. V. Joslin)..... 1057
 Edison Electric Illuminating Co. of Boston, The, Some Engineering Features of the Weymouth Station of (I. E. Moulthrop and Joseph Pope)..... 621
 Education for the Functional Divisions of Engineering (Edward Bennett). See index page..... 1138
 Educational Committee, Report of the,..... 790
 Effect of Transient Voltages on Dielectrics-III, The (F. W. Peek, Jr.)..... 940
 Electric Furnace, Operation, Some Problems in (F. V. Andreae)..... 494
 — Furnaces, Improvements in Ferro-Alloy, of High Power Input (B. D. Saklatwalla and A. N. Anderson)..... 506
 — Machinery, Transient Conditions in (W. V. Lyon)..... 157
 — Machines, The Cooling of (George E. Luke)..... 636
 — Wave Filters, Theory of Built up of Coupled Circuit Elements (Leo J. Peters)..... 98
 Electrical Communication, Frequency Measurement in (J. W. Horton, N. H. Ricker and W. A. Marrison)..... 730
 — and Illuminating Equipment of the Eastman Theatre and School of Music (Frederic A. Mott and Lloyd A. Jones). See index page..... 1138
 — Loud Speakers (A. Nyman)..... 793
 — Machinery Committee,..... 787
 — Measuring Instruments, The Standardization (H. B. Brooks)..... 894
 — Net works, The Distance Relay for Automatically Sectionalizing (Leslie N. Crichton)..... 527
 — Plant of Transocean Radio Telegraphy, The (E. F. W. Alexanderson, A. E. Reoch and C. H. Taylor)..... 707
 Electro-Chemistry and Electro-Metallurgy, Report of Committee on,..... 792
 Electromagnetic Forces; A Search for More Rational Fundamentals; a Proposed Revision of the Laws (Carl Hering)..... 311
 Electrophysics Committee, Report of,..... 757
 Equipment for Long Cable Circuits, Telephone (Charles S. Demarest)..... 742
 Expansion of Oscillography by the Portable Instrument (J. W. Legg)..... 381
 Experience with Bearings and Vibration Conditions of Large Hydro-Electric Units (John Harisberger)..... 996
 Experimental (Chester W. Rice)..... 662
 — Determination of Short-Circuit Currents in Electric Power Networks (O. R. Schurig)..... 10
 Experiments, Analysis of (Chester W. Rice)..... 664
 — on Forced Heat Convection in Gases and Liquids (Chester W. Rice)..... 687
 Explanation A. Physical (Charles P. Steinmetz)..... 470

F

Film Theory of Convection, Langmuir's (Chester W. Rice)..... 654
 — Thickness by the Method of Dimensions (Chester W. Rice)..... 660
 Filters, Theory of Electric Wave, Built up of Coupled Circuit Elements (Leo J. Peters)..... 98
 Fixed Charges, Multiple Plant Method for the Equitable Apportionment of, (George H. Moore). See index page..... 1138
 Floating Neutral N-Phase Systems (Leonard A. Doggett)..... 860
 Forced Convection from Larger Surfaces (Chester W. Rice)..... 692
 — — — in Hydrogen (Chester W. Rice)..... 697
 — — — of Heat (Chester W. Rice)..... 676
 — Heat Convection from Cylinders (Chester W. Rice)..... 679
 — — — in Gases and Liquids, Experiments on (Chester W. Rice)..... 687
 — — — — Mixtures (Chester W. Rice)..... 695
 — — — — Pipes (Chester W. Rice)..... 685
 Forces Short-Circuit on Reactor Supports-1 (R. E. Doherty and F. H. Kierstead)..... 552
 Free and Forced Convection of Heat in Gases and Liquids (Chester W. Rice)..... 653
 — Convection from Cylinders, Summary of Available Data on (Chester W. Rice)..... 665

Free Convection from Large Surfaces (Chester W. Rice)..... 672
 — — — Spheres (Chester W. Rice)..... 671
 — — — of Heat (Chester W. Rice)..... 653
 Frequency Conversion by Third Class Conductor and Mechanism of the Arcing Ground and other Cumulative Surges (Charles P. Steinmetz)..... 470
 — Measurement in Electrical Communication (J. W. Horton, N. H. Ricker and W. A. Marrison)..... 730
 Francis Turbines A Study of Irregularity of Reaction in (Roy Wilkins)..... 1001
 Fuel Determinations Made on Locomotives Operated by the Southern Pacific System, Some (A. H. Babcock). See index page..... 1138
 — Discussion, see index page..... 1138
 Furnace, Development of the Large Electric Melting (Frank Hodson). See index page..... 1138
 — Discussion, see index page..... 1138
 — Improvements in Ferro-Alloy Electric, of High Power Input (B. D. Saklatwalla and A. N. Anderson)..... 506

G

Gaseous Ionization in Built up Insulation (J. B. Whitehead)..... 921
 General Considerations in Grounding the Neutral of Power Systems (H. H. Dewey)..... 405
 — Consideration of T-and Pi-Type Artificial Electric Lines in Connection with a Proposed Compensated Pi-Line, A (H. Nukiyama and K. Okabe)..... 824
 — Discussion of Problems (O. R. Schurig)..... 832
 Glass, The Art of Sealing, Base Metals Through, (William G. Houskeeper)..... 870
 Ground Selector for Undergrounded Three-Phase Distribution Systems (P. Ackerman)..... 518
 Grounding, Present Day Practises in, of Transmission Systems (Subcommittee on Grounding of Protective Devices Committee A. I. E. E.)..... 446
 Group Operation of Systems Having Different Frequencies (E. R. Stauffacher and H. J. Briggs)..... 1078

H

Harmonic Analyzer, Another (F. S. Dellenbaugh, Jr.). See index page..... 1138
 Heat, Forced Convection of (Chester W. Rice)..... 676
 — Free and Forced Convection of, in Gases and Liquids (Chester W. Rice)..... 653
 — — Convection of (Chester W. Rice)..... 653
 Heating a Cotton Weave Shed by Electricity (C. T. Guildford). See index page..... 1138
 "Heavision," The, A. Computing Kinematic Device for Long Transmission Lines (Vladimir Karapetoff)..... 42
 High Voltage, A Continuous-Current Generator for (S. R. Bergman)..... 910
 High-Voltages Circuit Breakers (A. W. Copley)..... 1019
 — Voltage Insulation (J. L. R. Hayden and Charles P. Steinmetz)..... 1029
 — — Lines, Economic Considerations of the Power Factor Control of Long (A. V. Joslin)..... 1057
 — — — Methods or Voltage Control of Long, by Use of Synchronous Condenser (John A. Koontz, Jr.)..... 1054
 — — Switches, Bushings, Lightning Arresters (Harold Michener)..... 1015
 — — Systems, Transformers for (A. W. Copley)..... 1068
 Hydrogen, Forced Convection in (Chester W. Rice)..... 697
 Hydroelectrics Units, Experience with Bearings and Vibration Conditions of Large (John Harisberger)..... 996

I

Illuminating Equipment of the Eastman Theatre and School of Music, Electrical and, (Frederic A. Mott and Lloyd A. Jones). See index page..... 1138
 Improvements in Ferro-Alloy Electric Furnaces of High Power Input (B. D. Saklatwalla and A. N. Anderson)..... 506
 Incandescent Lamps, the Quality of (John W. Howell and Henry Schroeder)..... 865
 Industrial and Domestic Power Committee, Report of the Influence of Gaseous Ionization and Spark Discharge on Fibrous Insulating Materials and on Mica (J. B. Whitehead). See index page..... 1138
 Installation, The Alabama Power Co. (W. W. Lewis)..... 419
 Instrument Development in Europe During the Past Year, Subcommittee on (Irving B. Smith)..... 763

Instruments, The Standardization of Electrical Measuring (H. B. Brooks).....	894
— and Measurements Committee, Report of the,.....	762
Insulation, Gaseous Ionization of Builtup (J. B. Whitehead).....	921
— High-Voltage (J. L. R. Hayden and Charles P. Steinmetz).....	1029
— Design of Anchors and Tower Supports for 110,000-Volt 4427-Foot Span Over Carquinez Straits (L. J. Corbett).....	977
Insulating Materials and on Mica, Influence of Gaseous Ionization and Spark Discharge on Fibrous (J. B. Whitehead). See index page.....	1138
Insulation, the Problem of. (Report of the Committee on Electrical Insulation, Division of Engineering, National Research Council). See index page.....	1138
Insulator, Pin, Design Test Specifications as Tentatively Proposed (Insulator Subcommittee of the A. I. E. E. Standards Committee).....	562
— Subcommittee of the Standard Committee, A. I. E. E. for 1922-1923,.....	564
— Suspension, Proposed Test Specification (Insulator Subcommittee of the A. I. E. E. Standards Committee).....	564
Insulators, Suspension, Test Results on the Performance of, in Service (C. F. Benham).....	981
— for High-Voltage Lines, Mechanical Electrical Construction of Modern Power Transmission Lines (C. B. Carlson and W. R. Battey).....	959
Interpretations, Physical, of Complex Angles and Their Functions (Aram Boyajian).....	279
Investigation, Mathematical (Charles P. Steinmetz)....	382
Ionization and Spark Discharge on Fibrous Insulating Materials and on Mica, Influence of Gaseous, (J. B. Whitehead). See index page.....	1138

K

Kinematic Device A, The "Blondelion," which Indicates the Performance of a Polyphase Synchronous Generator or Motor (Vladimir Karapetoff).....	144
--	-----

L

Lamps, Incandescent, the Quality of (John W. Howell and Henry Schroeder).....	865
Langmuir's Film Theory of Convection (Chester W. Rice).....	677
Lighting and Illumination Committee, Report of the,....	777
Lightning Arrester, Pellet Type of Oxide Film (N. A. Lougee).....	905
— Arresters, 1922 Developments in Autovalve (A. L. Atherton).....	179
— — High-Voltage Switches, Bushings (Harold Michener).....	1015
— — Subcommittee on (F. L. Hunt, Chairman).....	754
— Disturbances on Distribution Circuits (Malcolm Mac Laren).....	538
Line Transients, Transmission (V. Bush).....	878
Locus Diagrams of Electrical Machinery, Use of the Scalar Product of Vectors in, (Vladimir Karapetoff). See index page.....	1138
Long Distance Telephony, Applications of, on the Pacific Coast (H. W. Hitchcock).....	1071
Loud Speakers, Electrical (A. Nyman).....	793

M

Machine Switching Telephone System for Large Metropolitan Areas (E. B. Craft, L. F. Morehouse and H. P. Charlesworth).....	187
Machines, The Cooling of Electric (George E. Luke)....	636
Marine Committee.....	757
Mathematical Calculation (Charles P. Steinmetz).....	474
— Investigation (Charles P. Steinmetz).....	582
Magneto-Mechanical Loads on Bus Supports (Lloyd N. Robinson).....	1020
Magnetron, The Axially Controlled (Albert W. Hull)....	915
Measurement, Balance Methods in Alternating Current (Perry A. Borden).....	395
— in Electrical Communication, Frequency (J. W. Horton, N. H. Ricker and W. A. Morrison).....	730
— of Power in Polyphase Circuits, The, (Charles Fortescue).....	358
— — Transients (Frederick E. Gorman).....	389
Measuring Units, Design Constants and, (Lawrence E. Widmark). See index page.....	1138

Mechanical Computation of Root Mean Square Values (L. A. Umansky). See index page.....	1138
Mechanical Electrical Construction of Modern Power Transmission Lines—Insulators for High-Voltage Lines (C. B. Carlson and W. R. Battey).....	959
— Forces on Busbars under Short-Circuit Conditions (C. H. Van Speren).....	1091
Meters, Volt-Ampere (R. C. Fryer).....	376
Methods, Null (Perry A. Borden).....	395
— of Studying High-Voltage Discharges, Two Photographic (Karl B. McEachron).....	947
— — Tests and Apparatus (J. L. R. Hayden and W. W. N. Eddy).....	594
— — Voltage Control of Long High-Voltage Lines by the Use of Synchronous Condenser (John A. Koontz, Jr.).....	1054
— Semi Null (Perry A. Borden).....	399
Microphone, A. Diaphragmless for Radio Broadcasting (Phillips Thomas).....	1111
Miniature A-C. Transmission System, A, For the Practical Solution of Network and Transmission—System Problems (O. R. Schurig).....	831
Mixtures, Forced Heat Convection in (Chester W. Rice)...	695
Modification of Polyphase Induction Motor Performance by Introduction of e. m. i. in Secondary (K. L. Hansen). See index page.....	1138
Motors, for Driving Tube Mills, Application of Electric (Fraser Jeffery). See index page.....	1138
— Performance by Introduction of e. m. f. in Secondary, Modification of Polyphase Induction (K. L. Hansen). See index page.....	1138
— Polyphase Reaction Synchronous (J. K. Kostko). See index page.....	1138
— Starting of Polyphase Squirrel-Cage, (Benjamin F. Bailey). See index page.....	1138
Mountain Ranges, Transmission Line Construction in Crossings (M. T. Crawford).....	970
Multiple Plant Method for the Equitable Apportionment of Fixed Charges (George H. Moore). See index page.....	1138

N

National Engineering Societies, The, Their Problems of the Past, Present and Future (F. B. Jewett).....	571
Networks, Dissymmetrical Electrical Conducting A (E. Kennelly).....	267
Neutral, General Considerations in Grounding the, of Power Systems (H. H. Dewey).....	405
— Grounding Reactor, The (W. W. Lewis).....	417
— N-Phase Systems, Floating (Leonard A. Doggett)....	860
New Equation for the Static Characteristic of the Normal Electric Arc, A (W. B. Nottingham).....	302
— Method for the Routine Testing of Alternating-Current High-Voltage Power—Insulated Cable, (A. H. S. Phelps and E. D. Tanzer).....	54
Normal Electric Arc, A New Equation for the Static Characteristic of the (W. B. Nottingham).....	302
Null Methods (Perry A. Borden).....	395
Numerical Calculations (Charles P. Steinmetz).....	590

O

Observations on Electric Railway Practice (W. B. Potter). See index page.....	1138
Discussion, see index page.....	1138
Operating Experience with Current-Limiting Reactors (N. L. Pollard).....	546
— Performance of a Peterson Earth Coil (J. M. Oliver and W. W. Eberhardt).....	435
Oscillography, Expansion of, by the Portable Instrument (J. W. Legg).....	381
Oxide, Film Lightning Arrester Pellet Type, (N. A. Lougee).....	905

P

Pallophotophone, The (C. A. Hoxie). See index page...	1138
Pellet Type of Oxide Film Lightning Arrester (N. A. Lougee).....	905
Performance of Auto Transformers with Tertiaries Under Short-Circuit Conditions (J. Mini, Jr., L. J. Moore and R. Wilkins).....	1060
Permeability (Thomas Spooner).....	340
Peterson Earth Coil, Operating Performance of a (J. M. Oliver and W. W. Eberhardt).....	435
Physical Consideration (Charles P. Steinmetz).....	577
— Explanation (Charles P. Steinmetz).....	470

Physical Interpretation of Complex Angles and Their Functions (Aram Boyajian).....	279
Pin Insulator Design Test Specifications as Tentatively Proposed (Insulator Subcommittee of the A. I. E. E. Standards Committee).....	562
Pipes Forced Heat Convection in (Chester W. Rice).....	685
Polyphase Reaction Synchronous Motors (J. K. Kostko). See index page.....	1138
Porcelain, Production of, for Electric Insulation (Frank H. Riddle). See index page.....	1138
Power Absorbed in Making a Barrel of Portland Cement (S. H. Harrison). See index page.....	1138
— Factor Control, Economic Considerations of the of High-Voltage Lines (A. V. Joslin).....	1057
— Stations Committee, Report of the.....	780
— Systems, General Considerations in Grounding the Neutrals of (H. H. Dewey).....	405
— The Measurement of in Polyphase Circuits (Charles Fortescue).....	358
Present-Day Practices in Grounding of Transmission Systems (Subcommittee on Grounding of Protective Devices Committee A. I. E. E.).....	446
Precise Method of Calculation of Skin Effect in Isolated Tubes (Herbert Bristol Dwight). See index page....	1138
Discussion, see index page.....	1138
Problem, The Automatic Train-Control (E. J. Blake)....	117
Problems, A Simplified Method of Analyzing Short-Circuit (R. E. Doherty).....	841
— General Discussion of (O. R. Schurig).....	832
Production of Porcelain for Electric Insulation (Frank H. Riddle). See index page.....	1138
Proposed Revision of the Laws, A; Electromagnetic Forces; A Search for More Rational Fundamentals (Carl Hering).....	311
Protective Devices Committee, Report of.....	753
Proximity Effect in Wires and Thin Tubes (H. B. Dwight).....	850
Public Address System, Use of, with Telephone Lines (W. H. Martin and A. B. Clark).....	75
— — Systems (I. W. Green and J. P. Maxfield).....	64

Q

Qualitative Analysis of Transmission Lines (H. Goodwin, Jr.).....	24
Quality of Incandescent Lamps, The (John W. Howell and Henry Schroeder).....	865

INDEX OF 1923 A. I. E. E. JOURNAL PAPERS NOT INCLUDED IN THIS VOLUME

Analyzer, Another Harmonic (F. S. Dellenbaugh, Jr.)	January, 58	Measuring Units, Design Constants and (Lawrence E. Widmark)	November, 1153
Application of Electric Motors for Driving Tube Mills (Fraser Jeffery)	April, 382	Mechanical Computation of Root Mean Square Values (L. A. Umansky)	October, 1093
Cement, Power Absorbed in Making a Barrel of Portland (S. H. Harrison)	March, 254	Modification of Polyphase Induction Motor Performance by Introduction of e. m. f. in Secondary (K. L. Hansen)	December, 1321
Design Constants and Measuring Units (Lawrence E. Widmark)	November, 1153	Motors, for Driving Tube Mills, Application of Electric (Fraser Jeffery)	April, 382
Development of the Large Electric Melting Furnace (Frank Hodson)	June, 600	Performance by Introduction of e. m. f. in Secondary, Modification of Polyphase Induction (K. L. Hansen)	December, 1321
Discussion	November, 1202; December, 1356	Polyphase Reaction Synchronous (J. K. Kostko)	November, 1162
Duplication and Safeguarding in the Electrical Equipment of a Generating Station, Desirable (William F. Sims)	July, 704	Starting of Polyphase Squirrel-Cage, (Benjamin F. Bailey)	November, 1172
Discussion	December, 1356	Multiple Plant Method for the Equitable Apportionment of Fixed Charges (George H. Moore)	April, 408
Eastman Theatre and School of Music, Electrical and Illuminating Equipment of the (Frederic A. Mott and Lloyd A. Jones)	June, 569	Pallophotophone, the (C. A. Hoxie)	May, 520
Education for the Functional Divisions of Engineering (Edward Bennett)	November, 1145	Polyphase Reaction Synchronous Motors (J. K. Kostko)	November, 1162
Electrical and Illuminating Equipment of the Eastman Theatre and School of Music (Frederic A. Mott and Lloyd A. Jones)	June, 569	Porcelain, Production of, for Electric Insulation (Frank H. Riddle), April, 343; May, 540; June, 631; July, 743; August, 858; September, 988; October, 1097	
Fixed Charges, Multiple Plant Method for the Equitable Apportionment of (George H. Moore)	April, 408	Power Absorbed in Making a Barrel of Portland Cement (S. H. Harrison)	March, 254
Fuel Determinations Made on Locomotives Operated by the Southern Pacific System, Some (A. H. Babcock)	April, 335	Precise Method of Calculation of Skin Effect in Isolated Tubes (Herbert Bristol Dwight)	August, 827
Discussion	November, 1198	Discussion	August (1924), 760
Furnace, Development of the Large Electric Melting (Frank Hodson)	June, 600	Production of Porcelain for Electric Insulation (Frank H. Riddle) April, 343; May, 540; June, 631; July, 743; August, 858; September, 988; October, 1097	
Discussion	November, 1356	Railway Practise, Observations on Electric (W. B. Potter)	May, 490
Harmonic Analyzer, Another (F. S. Dellenbaugh, Jr.)	January, 58	Discussion	June, 657
Heating a Cotton Weave Shed by Electricity (C. T. Guildford)	June, 582	Root Mean Square Values, Mechanical Computation of (L. A. Umansky)	October, 1093
Illuminating Equipment of the Eastman Theatre and School of Music, Electrical and (Frederic A. Mott and Lloyd A. Jones)	June, 569	Safeguarding in the Electrical Equipment of a Generating Station, Desirable Duplication and (William F. Sims)	July, 704
Influence of Gaseous Ionization and Spark Discharge on Fibrous Insulating Materials and on Mica (J. B. Whitehead)	December, 1297	Discussion	December, 1356
Insulating Materials and on Mica, Influence of Gaseous Ionization and Spark Discharge on Fibrous (J. B. Whitehead)	December, 1297	Scalar Product of Vectors in Locus Diagrams of Electrical Machinery, Use of the (Vladimir Karapetoff)	November, 1181
Insulation, the Problem of (Report of the Committee on Electrical Insulation, Division of Engineering, National Research Council)	June, 618	Skin Effect in Isolated Tubes, Precise Method of Calculation of (Herbert Bristol Dwight)	August, 827
Ionization and Spark Discharge on Fibrous Insulating Materials and on Mica, Influence of Gaseous (J. B. Whitehead)	December, 1297	Discussion	August (1924), 760
Locus Diagrams of Electrical Machinery, Use of the Scalar Product of Vectors in (Vladimir Karapetoff)	November, 1181	Southern Pacific System, Some Fuel Determinations Made on Locomotives Operated by the (A. H. Babcock)	April, 335
Observations on Electric Railway Practise (W. B. Potter)	May, 490	Discussion	November, 1198
Discussion	June, 657	Starting of Polyphase Squirrel-Cage Motors (Benjamin F. Bailey)	November, 1172
		Superpower—A National Resource (Paul T. Brady, R. F. Schuchardt and M. H. Aylesworth)	June, 645
		Tube Mills, Application of Electric Motors for Driving (Fraser Jeffery)	April, 382
